ERRATA

Transactions Vol. 88 (1925)

Page 1194, Lines 1 and 3 from bottom, for "p_5", read "P_5".
Page 1204, Fig. 27(*b*), for "c_y", read "e_y".

Transactions Vol. 90 (1927)

Page 486, Equation (29*a*), last term in first bracket, for "$\frac{\sin 2\ \phi_1}{\phi_1}$", read "$\frac{\sin^2 \phi_1}{\phi_1}$".

Page 541, Equation (109), last term, for "$(\phi_1 + \sin 2\ \phi_2)$", read "$(\phi_1 + \sin \phi_1)$".

Transactions Vol. 91 (1927)

Page 519, "Fig. 6" should read "Fig. 7" and "Fig. 7" should read "Fig. 6".

Page 524, Line 27 from top, for "$\frac{12}{17}$-in. outlet pipe", read "12-in. outlet pipe".

Page 716, Line 27 from top, statements in second and third sentences of discussion by W. H. R. Nimmo, Assoc. M. Am. Soc. C. E., are in error owing to the fact that the effect of the value of Poisson's ratio was not taken into account.

PAPERS AND REPORTS OF SPECIAL COMMITTEES PUBLISHED IN PROCEEDINGS, AM. SOC. C. E., AUGUST, 1927, TO MAY, 1928, INCLUSIVE, NOT PUBLISHED IN TRANSACTIONS, VOL. 92.

AUTOMOBILE HAZARD IN CITIES AND ITS REDUCTION*

By William J. Cox,† Jun. Am. Soc. C. E.‡

With Discussion by Messrs. William T. Lyle, M. O. Eldridge, C. W. Stark, L. G. Holleran, S. Johannesson, W. Graham Cole, Harold M. Lewis, J. K. Finch, G. G. Kelcey, Raymond A. O'Hara, John A. Miller, Jr., T. Kennard Thomson, W. W. Crosby, Theodore T. McCrosky, R. S. Kirby, Lee S. Trainor, Sidney J. Williams, A. B. Barber, and William J. Cox.

Synopsis

This paper directs attention to the great variations in the hazard of automobile operation in the larger cities of the United States; shows what this variation is; derives a theoretical formula to account for it; shows the applicability of this formula to cities of the United States; and discusses conclusions resulting from the investigation, which show the great extent to which street hazard is controllable by proper city planning and zoning measures.

Introduction

In taking first place among the causes of accidental deaths in this country the automobile has created a serious accident problem. Its solution has been attempted almost wholly by the use of police or regulatory measures, rather than by the application of engineering principles. State highway engineers, it is true, study highway safety and, sometimes, give it an important place in their design. City engineers have given some attention to safe road surfaces, to the improvement of especially dangerous corners, and other such details; but from the broader standpoint of city planning, the problem of traffic accidents has received little attention.

* Presented at the meeting of May 4, 1927.

† Asst. Prof., Dept. of Eng. Mechanics, Sheffield Scientific School, Yale Univ., New Haven, Conn.

‡ Now Assoc. M. Am. Soc. C. E.

Yet street safety is certainly one of the problems of the city planner. It is just as important that streets be safe as that they be convenient. This is realized in an abstract way, and the principle is applied in such obvious matters as grade separation at extra hazardous intersections; but street safety has held so little place in the minds of city planners that no fundamental analysis has been made of the automobile hazard with the object of determining the extent to which it is controlled by the physical characteristics of a city, and by what characteristics.

Failure to attempt such analysis has no doubt resulted from a general impression that personal factors, such as effectiveness of police control of traffic, carefulness of pedestrians, and average driving skill, together with variations in the ratio of automobiles to population, account for such differences as may exist in the hazard of automobile operation in different cities. This erroneous idea, in turn, no doubt rests on a general lack of knowledge of the tremendous variation in that hazard between cities of the same size, a variation so great and of such nature as to be accounted for only on the basis of controlling physical differences in the cities themselves rather than by personal differences in their inhabitants.

The hazard variation being what it is, discovery of its underlying cause is important because of the light it may throw on means of hazard reduction. The primary purpose of this paper, therefore, is to find this cause.

Accident Frequencies in Various Cities

The average driver of a private passenger automobile in New York, N. Y., will probably injure (or possibly kill) some one with his automobile about once in six years. If an operator goes eight years without such an accident either he drives less than the average, or he is an unusually good driver, or is exceptionally lucky. In Indianapolis, Ind., however, on the basis of present conditions, the driver of a private passenger car who is responsible for more than one personal injury accident in his entire lifetime of driving, is below par in driving skill, or drives more than the average, or is attended with worse luck.

This is not a random assertion, but a statement based on accurate records of the casualty insurance companies. For every 100 automobile public liability insurance policies (covering personal injury accidents) written in 1922 on private passenger cars by a large group of insurance carriers in New York City, 16.6 accidents involving personal injury claims resulted. For every 100 such policies written in Indianapolis, Ind., in 1922, only 2.7 such accidents resulted. Most other large cities fall between these two extremes. In Buffalo, N. Y., there were 9.6 accidents; in Chicago, Ill., 6.6; and in Detroit, Mich., 4.0, per 100 policies.*

It will be shown subsequently that the rate charged for this insurance in any large city is so established that it may be accepted as a fair criterion of the personal injury hazard of operation of a private passenger automobile. Consequently, the variation in rates from city to city measures the variation

* 1922 policy year experience, National Bureau of Casualty and Surety Underwriters, New York City.

in driving hazard. Table 1 shows this variation in rates (and in hazard) for a few representative cities.

Throughout this paper the expressions, "automobile hazard" and "hazard of automobile operation", unless otherwise specifically noted, mean the hazard to which an individual automobile operator is subject, of inflicting injury on some one with his automobile. It does not mean the hazard of injury to which the operator himself or a pedestrian is subject. It is the hazard involved in driving an automobile.

Importance of Differences in Hazard

Few people realize that these great differences in driving hazard exist. The automobile accident situation has become so serious in practically every city as to obscure this fact. These differences, however, are of tremendous importance; the annual cost of public liability insurance for all the automobiles in New York City would be in excess of $75 000 000. This may be taken as less rather than more than the economic loss from personal injuries from automobile accidents, as the administrative cost of handling this business, which of course is included in the rates charged, is offset by the facts that, in a collision between two automobiles, this insurance covers the injuries sustained by only one of the parties to the accident, and that in a collision between an automobile and a pedestrian (if contributory negligence on the part of the pedestrian is shown) the pedestrian is likely to receive little or no indemnification for his injuries. Therefore, accepting the cost of insurance as the economic loss (from personal injuries only) the annual cost of these in New York City is at least $75 000 000. If the hazard in New York were the same as that in Chicago, the resulting injury cost would be reduced to about $28 000 000 per year, and the resulting saving would be about $47 000 000.

Investigation of this hazard variation with a view of determining why it exists and whether it must necessarily exist is, therefore, worth while. A superficial examination of rates shows no necessary reason for its existence. It can be noted that rates are generally higher in large than in small cities; higher in the East and North than in the West and South; and higher in old than in new cities.

There are so many exceptions, however, to each of these rules as to make it apparent that none of them controls the hazard. If the hazard is greater in large, old, Eastern cities, it is not because of their size, age, or geographical

location, but rather because of some other factor which usually, but far from invariably, accompanies size, age, and certain geographical locations. The problem, then, is to discover this unknown controlling factor.

Measure of Hazard Variation

Before attempting the solution, however, the validity of the standard selected for measuring hazard variation will be explained briefly. In discussions of the automobile problem the automobile death rate in terms of population is usually invoked to show the seriousness of the situation; and, properly, because this seriousness bears a relationship to the proportion of the population killed, rather than to the number of automobiles which did the killing. In discussing why the death rate is what it is, however, the ratio of automobiles to population cannot be neglected. The City of Los Angeles, Calif., for example, with one car to each three persons, would be expected to have more automobile fatalities in proportion to population than the City of New York, with one car to each fifteen persons. What is not necessarily expected is that New York, instead of having one-fifth or one-sixth as many fatalities in proportion to population as Los Angeles, should have one-half as many; in other words, that the death rate per automobile should be three times as great in New York as in Los Angeles.

This is a significant fact in the problem. Automobile use will continue and doubtless will increase. Improvement will not come about by reduction of the number of automobiles in use, but by reduction of the damage attributable to each automobile. Anything that decreases the hazard created by each automobile will decrease the total automobile hazard. Hence, the individual automobile and the hazard created by the individual automobile are the starting points, and hazard variation must be correlated with registration of automobiles rather than with population.

On this basis, the first measure of hazard which comes to mind is the ratio of automobile fatalities to automobile registrations; but the proportion of accidents that result fatally is small, and is not uniform between cities. Data from some localities indicate as many as four or five fatalities per hundred personal injury automobile accidents, whereas other localities apparently have only two or three fatalities from a hundred such accidents.* Also, for all but the very largest cities, automobile fatalities are not so numerous as to furnish fatality rates comparatively unaffected by chance, and in consequence wide variations occur from year to year. Further still, reliable figures for automobile registrations in cities are largely lacking. For these reasons, fatality rates are not available as a satisfactory measure of the hazard of automobile operation.

Insurance Rates as Measure

Automobile liability insurance rates, however, do furnish a reasonably accurate index, and practically the only index, as the larger insurance com-

* Report of Committee on Statistics, First National Conference on Street and Highway Safety, p. 11. The great deviations between the ratios given for different cities (from slightly more than one fatality per hundred injuries to six fatalities per hundred injuries) are no doubt, as noted in the report, largely due to differences as between cities in definitions of an "injury" and in methods of reporting accidents, but must also reflect considerable differences in the true ratios.

panies are the only agencies which deal with automobile accidents, both fatal and non-fatal, on a nation-wide basis. This index is not wholly satisfactory, first because not all automobiles carry insurance, and, secondly, because no one insurance policy covers the entire hazard. It is, however, the best index available. There is no reason to believe that the hazard created by an insured car is materially different from that created by an uninsured car; or at least that the difference in hazard created by the two classes of cars varies materially between cities. Although separate policies are written to cover the personal injuries and the property damage resulting from automobile accidents, if automobile public liability rates are accepted as the index, they will broaden the scope to include the hazard of all personal injuries of any moment, whether fatal or not. Such injuries constitute the bulk of the automobile problem. These rates, as applied to private passenger cars, were used in Table 1.

Rate-Making

"Public liability" insurance is an automobile owner's insurance against legal liability for personal injuries which may result from operation of his insured car. From a somewhat haphazard system in the early days of the automobile, rate-making has reached a high degree of accuracy, so that now the public liability insurance rate of a large city may be considered a satisfactory measure of the legal liability hazard which automobile operation in that city entails. Subsequently it will be shown that the total chance of inflicting personal injury (whether the injury results in legal liability or not) is proportional to the legal liability hazard. Therefore, the variation in public liability insurance rates (Table 1) also measures the variation in the chance of injuring some one while driving an automobile.

Rates for this insurance are promulgated annually by a bureau maintained for this purpose by about thirty of the leading stock casualty insurance companies. Each member company furnishes this bureau with its loss experience, and in this way a sufficient body of experience to serve as a reliable guide is accumulated. Practically all automobile liability insurance written in the United States is based on rates established by this bureau.

For establishment of these rates, the country is divided into 251 territories (consisting each of a large city and its closest suburbs) or territorial groups (consisting each of several small cities or several counties). For each of these territories or groups separate loss experience is secured. In some cases the volume of exposure of a territory or group is not sufficiently large to be fairly indicative, and further combination is necessitated. However, for each community that develops a sufficient exposure (and this includes most of the larger cities, say, of 200 000 population and more) rates are calculated from the community's individual data and are in consequence a reflection of that community's traffic hazard.

The method of establishing the rates on private cars is as follows:* The number of cars insured in the community during each of the three preceding years is ascertained, and also the losses incurred in each of these years as indem-

* For a full discussion of this subject see "Automobile Rate-Making," by H. P. Stellwagen, *Proceedings*, Casualty Actuarial Soc., Vol. XI, Pt. 2.

nities for accidents attributable to the insured cars. Dividing the losses for each year by the number of cars insured, and averaging the three resulting quotients, gives the average loss per car or "pure premium". This average "pure premium" is weighted by a fixed percentage to cover the administrative cost of the business and the average rate is thus determined for each community or group. For purposes of business administration these groups are then combined into a much smaller number of "rate territories", in each of which the rate is the average of the rates of the groups included in that "rate territory". The units comprising any given territory may be widely scattered over the country, but the average rate assessed against all localities which are placed in any one rate territory is within a very few per cent. of the rate determined individually for each group placed in that territory. Sixteen (in 1924 and 1925) average public liability rates for private passenger cars are thus established, some one of which will apply to any locality in the United States. Finally, by another set of calculations differentials are obtained which are applied to the average rate to give the actual listed rate for different makes of cars.

Thus, the variation in liability rates for private passenger cars, considering only cities large enough to be individually rated, is an accurate reflection of the public liability hazard for insured cars. There is no reason to believe that the hazard of operation of uninsured cars is materially different from that of insured cars; the variation of rates from city to city for commercial cars and public vehicles is nearly the same as for private passenger cars; and private passenger cars very largely predominate in every city. For these reasons the variation of rates for private passenger cars (Table 1) may be taken to indicate the variation in public liability hazard of all automobile operation in such cities.

What, then, is the reason for this great variation, and what is the determinant of a hazard that varies so widely from one city to another?

Theoretical Derivation of Formula for Hazard Variation

For purposes of analysis, imagine a city in which traffic, both vehicular and pedestrian, is distributed uniformly over the entire street mileage, all paved; in which no automobile accidents occur except collisions of automobiles with other automobiles and with pedestrians; in which all automobiles are of the same type, and are the only vehicles in use; and in which the percentage of automobiles in use at any given time is the same as the percentage of the population using the streets as pedestrians at that same time.

Let H = the hazard that results from the annual use in this city of the average automobile (average in respect to total annual mileage, maintenance, and driving skill).

h = the hazard that results from operation of this automobile through a unit distance.

h_a and h_p = the components of this hazard that relate to collisions with other automobiles and with pedestrians, respectively.

Then,

$$h = h_a + h_p$$

Let M = the street mileage of the city.
P = the population of the city.
R = the number of automobiles registered in the city.
a = the average number of occupants of each automobile in use.
p and r = the number of pedestrians and of automobiles, respectively, that the average automobile passes from any direction in traveling a unit distance.

As pedestrians and automobiles are uniformly distributed over the streets of the city, $p \propto \frac{P - a R}{M}$ and $r \propto \frac{R}{M}$.

As every time an automobile passes a pedestrian or another automobile, there is danger of a collision, obviously, $h_p \propto p$ and $h_a \propto r$.

Then,

$$h_p \propto \frac{P - a R}{M}, \text{ or } h_p = k_1 \frac{P - a R}{M}$$

and,

$$h_a \propto \frac{R}{M}, \text{ or } h_a = k_2 \frac{R}{M}$$

k_1 and k_2 being constants.
And,

$$h = k_1 \frac{P - a R}{M} + k_2 \frac{R}{M}$$

Let,

$$\frac{k_2}{k_1} = w$$

then,

$$h = k_1 \frac{P - a R}{M} + k_1 \frac{w R}{M}$$

or,

$$h \propto \frac{P - a R + w R}{M}$$

or,

$$h \propto \frac{P + (w - a) R}{M}$$

If $w = a$, (and it will be shown that from a public liability standpoint for cities of the United States this is approximately true), the expression becomes,

$$h \propto \frac{P}{M}$$

Also,

$$H \propto h ;$$

then,

$$H \propto \frac{P}{M}$$

giving the basic relation of automobile hazard to physical surroundings.

This variation is rationally deduced and should express accurately (assuming that $a = w$) the elements of the public liability hazard of automobile operation in the hypothetical city. It does not necessarily follow that it accurately expresses the elements determining the hazard of operation in cities of the United States, because assumptions were made in the derivation of the formula which do not hold true, and the effect of these untrue assumptions on the applicability of the formula is problematical.

Test of Validity of the Formula

There is, however, the means of testing what this effect is, to what extent it invalidates applicability of the formula to American cities. The actual variation in hazard from one city to another is known from insurance rates. It has been shown that this variation covers a very wide range and that it is independent of the size, age, or geographical location of cities. The variation is also not caused by automobile congestion or by differences in the effectiveness of traffic control.

These possible causes of the variation can be quickly eliminated. If automobile congestion determined hazard, New York City, with a hazard four and one-half times that of Los Angeles, would have to have a vehicular congestion four and one-half times as great, not only in the center of the city, but in residential districts as well. This is not true. In fact, some cities in which automobile use is most extensive are those in which the hazard is least.

As to the variation being caused by differences in efficiency of traffic control, any such idea is disproved by study of the variation itself (see Fig. 3). The cities having the most advanced traffic regulation, as, for example, those in States embraced in the Eastern Conference of Motor Vehicle Administrators, often show the highest, not the lowest, hazards. If excellence of traffic regulation determined hazard, the variation would be in many respects just the reverse of what it is now. This is true because good traffic regulation is usually the outgrowth of high hazard—of conditions so intolerable that they force improvement.

On the other hand, if this hazard variation can be accounted for on the basis of the formula, $H \propto \frac{P}{M}$, very strong evidence will be furnished that this formula does correctly set forth the determinants of public liability hazard. If comparison of the variation calculated from the formula with the actual variation as known from insurance rates, reveals discrepancies, these discrepancies may serve to define the limitations of the formula or to indicate modifications that must be made before it will be applicable to cities of the United States.

Modification for Unpaved Streets

One such modification of the formula is necessary before this comparison of the calculated and actual variations can be attempted. In deriving the formula it was assumed that all streets of the hypothetical city were paved. In actual cities this is not true—the ratio of unpaved to paved mileage varies between wide limits. In applying the formula it is not fair wholly to dis-

regard this unpaved mileage, nor should it be included at its face value. In a typical city in which the unpaved mileage makes up 25 or 30% of the total, the unpaved streets are largely on the outskirts of the city, where perhaps the majority of lots are vacant and the streets do not carry the traffic that would warrant their being paved. Hence, in including them with paved mileage, they should be weighted at much less than unity to indicate their much lower mile-for-mile value in distributing traffic and population.

Considering a city, however, in which there are several miles of unpaved streets for each mile of paved streets, a large portion of unpaved streets will be in outlying, partly developed areas, but a part will also be in built-up districts and will carry almost as much local traffic as they would carry if paved. These latter streets should be included with paved streets at not much less than their face value, or if both these classes of unpaved streets be lumped together (as must be done, practically) a higher coefficient should be used to express their average weighted value than was used for the typical city in which paved mileage exceeds the unpaved. This principle can be expressed as follows:

In determining the value of M in the expression, $H \propto \frac{P}{M}$, paved street mileage should be counted at its full face value, whereas unpaved street mileage should be multiplied by a coefficient less than one, this coefficient increasing, at a slowly decreasing rate, with the increase in the ratio of unpaved streets to total street mileage.

The values to be assigned this coefficient are wholly matters of judgment. It seems impossible to express exactly the relative importance of the two classes of streets in all cities by a single graph, but as an approximation sufficiently close for present purposes, the writer suggests Fig. 1.

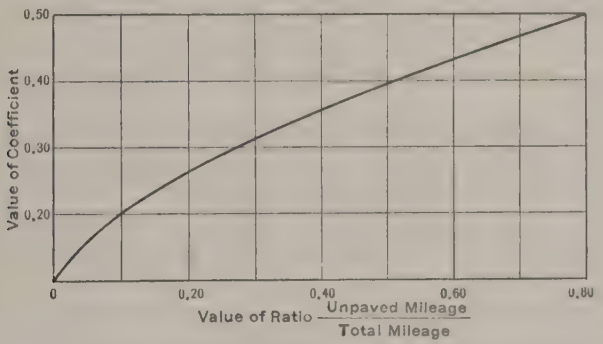

FIG. 1.—COEFFICIENTS TO BE USED IN WEIGHTING MILEAGES OF UNPAVED STREETS.

HANDLING OF WATER-BOUND MACADAM STREETS

In applying the principle of weighting unpaved mileage at less than a normal value, gravel and water-bound macadam streets present a problem. In most cities they could be classified as unpaved streets in that the surfacing is temporary, pending sufficient development to warrant improved paving.

In a few instances, however, the mileage of water-bound macadam streets is so great as to lead to a belief that it is continued in use on streets which have reached their full (usually residential) development. In this paper, therefore, the term, "paved streets", is restricted to include only types of paving better than water-bound macadam, except where the mileage of water-bound macadam exceeds that of the better types. In such cities (Providence, R. I., Denver, Colo., Worcester, Mass., and Hartford, Conn., for example) the excess of water-bound macadam over higher types of paving is considered as "paved".

Washington, D. C.	257	270	0.51	0.40	108	365	357

* The writer requested mileage figures as of January 1, 1922 (since the hazard variation discussed in this paper is based on 1924 rates, which best reflect 1922 conditions), but, in some instances, they were furnished as of later dates. Adjustment to January 1, 1922, is as follows: Make deductions from the weighted mileage at the rate of 6% of the paved or unpaved mileage per annum, whichever figure is the smaller.

† Mileages as of the following dates: May 7, 1924, New Orleans; January 1, 1924, Chicago, Rochester, Columbus, and Omaha; January 1, 1923, Baltimore and Denver; September 1, 1922, Louisville; July 1, 1922, Los Angeles and Washington; January 1, 1922, in all other cases.

‡ Includes a 10% reduction to allow for alleys.

§ Includes 56 miles of macadam streets; estimate by A. A. Krieger, M. Am. Soc. C. E., indicated that they were entitled to such classification.

‖ Includes the Cities of Brookline, Cambridge, Chelsea, Everett, Malden, and Somerville which are included in Boston insurance territory.

¶ Minneapolis and St. Paul form one insurance territory.

** Excludes Staten Island, which is not included in New York City insurance territory.

†† Includes the City of Pawtucket, R. I., which is included in Providence insurance territory.

Table 2 shows mileages weighted in accordance with these principles for all cities in the United States of 200 000 population and more (except Newark and Jersey City, N. J., which will be discussed later) for which the writer has

been able to secure the necessary data. These mileages will be used for the quantity, M, in the formula, $H \propto \frac{P}{M}$.

The data in Columns (1) and (2) of Table 2 (except for Philadelphia and Pittsburgh) were secured, if possible, from engineering departments; failing this, from municipal reference libraries, or other official sources. Paved mileages shown for Philadelphia and Pittsburgh are based on *Circular No. 9*, of the Asphalt Association, New York City, and are stated to come from official sources; figures include only paved mileage as defined in this paper, and are as of January 1, 1923; to convert these figures to weighted mileage as of January 1, 1922, they are arbitrarily increased by one-fifth their value.

Values of a and of w

It remains, however, to justify the assumption made in deriving the formula—that the quantities, a and w, are approximately equal in cities of the United States. The symbol, a, represents the average number of occupants of each automobile in use. A traffic census taken by the writer in San Diego, Calif., in 1925, showed the average number of occupants of all types of cars, Sundays and week-days, to be 2.06. A similar census taken at the same time in Washington, showed an average of 2.0. Apparently, it can be assumed with little error that in any city the average number of occupants is not far from 2, and this value will be used for a.

The symbol, w, represents the ratio, $\frac{k_2}{k_1}$, these constants being used in the equation,

$$h = k_1 \frac{P - a R}{M} + k_2 \frac{R}{M}$$

As,

$$h_a = k_2 \frac{R}{M}$$

and,

$$h_p = k_1 \frac{P - a R}{M}$$

$$\frac{h_a}{h_p} = \frac{k_2 R}{k_1 P'}$$

in which, $P' = P - a R$.

Now the relative importance, $\frac{h_a}{h_p}$, of the hazard of collisions between two automobiles as compared with the hazard of collisions of an automobile with a pedestrian depends jointly on the relative severity and the relative frequency of these two types of collision. Investigation of about 1 500 accidents shows practically the same public liability resulting from a collision between two automobiles as from a collision between an automobile and a pedestrian. This number of accidents was not sufficiently large to serve as an entirely reliable guide, but in the absence of more complete data equal severity may be assumed

for the two types of collisions. Therefore, their relative importance depends on their relative frequency, or,

$$\frac{h_a}{h_p} = \frac{f_a}{f_p}$$

in which, f_a and f_p represent the two frequencies. Equating the two values of $\frac{h_a}{h_p}$,

$$\frac{k_2}{k_1}\frac{R}{P'} = \frac{f_a}{f_p}$$

or,

$$\frac{k_2}{k_1} = \frac{f_a}{f_p} \times \frac{P'}{R} = w$$

The next step is to consider the relative frequency, $\frac{f_a}{f_p}$, of collisions between two automobiles and collisions of an automobile with a pedestrian. For a city in which all travel was by automobile, obviously all accidents would be collisions between two automobiles (assuming only the two types of collisions here dealt with) and the ratio, $\frac{f_a}{f_p}$, would be infinity. In a city with very few automobiles in proportion to the population, practically all accidents would be collisions with pedestrians, and the value of the ratio would approach zero. Hence, if the abscissas of a set of co-ordinates represent values of $\frac{P'}{R}$ and the ordinates represent values of the ratio, $\frac{f_a}{f_p}$, this ratio will be expressed by a graph tangent to the Y-axis at plus infinity, and to the X-axis at plus infinity. Reliable data for the determination of intermediate points are lacking, as such data involve not only complete reports of both fatal and non-fatal personal injury accidents over a considerable period to establish the ratio, $\frac{f_a}{f_p}$, but also accurate figures for automobile registrations to establish the ratio, $\frac{P'}{R}$*. It is difficult to obtain trustworthy figures covering all these quantities in any one city. The writer has secured what appear to be fairly reliable figures for $\frac{f_a}{f_p}$, however, for ratios of $\frac{P'}{R}$, which are probably about 3.0, 6.2, and 14.0. These points are plotted on Fig. 2, on which is drawn also a hyperbolic curve such that any ordinate multiplied by its corresponding abscissa (that is, $\frac{f_a}{f_p} \times \frac{P'}{R}$, the product being the quantity, w), gives a value of 2. This curve fits the three plotted points (both co-ordinates to which, it

* These registrations, moreover, must be accurately divided into private passenger, commercial, and public passenger vehicles, since these latter two classes carry higher average rates than the first. Since P is much greater than R and since the ratio of "equivalent private passenger cars" to "actual private passenger cars" is about the same for most cities, this refinement can be neglected in the main formula without introducing errors greater than 1 or 2 per cent. It cannot, however, be omitted in the determination of w without introducing prohibitive errors.

will be recalled, are of somewhat doubtful accuracy) with sufficient exactness to permit the acceptance of 2 as the approximate value of w. This is especially true as the quantity, R, in the expression,

$$H \propto \frac{P + (w - a)\ R}{M}$$

is so much smaller than P for most cities that a considerable error in the value of the coefficient of R has a comparatively small effect on the value of H. Within the limits of exactness attempted in this paper, then, it may be assumed that $w = 2$, and, hence, that $a = w$. The expression,

$$H \propto \frac{P + (w - a)\ R}{M}$$

thus reduces to $H \propto \frac{P}{M}$.

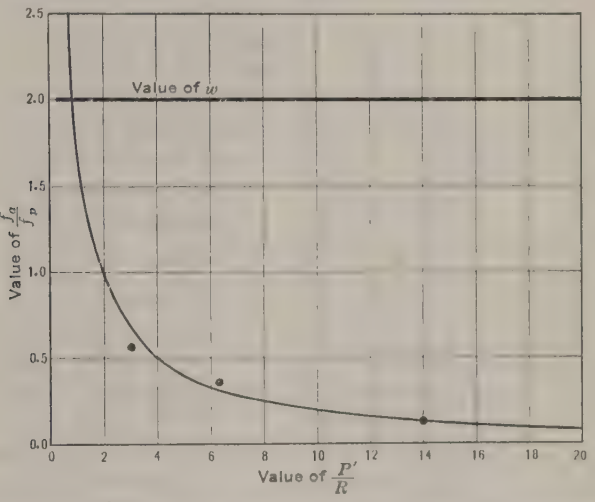

FIG. 2.—VALUES OF $\frac{f_a}{f_p}$ (RELATIVE FREQUENCIES OF ACCIDENTS TO AUTOMOBILES AND PEDESTRIANS) AND OF $\frac{f_a}{f_p} \times \frac{P'}{R}$ (OR w) FOR VARIOUS RATIOS OF $\frac{P'}{R}$ (PEDESTRIANS TO AUTOMOBILES).

"ACTUAL" AND "CALCULATED" HAZARD VARIATIONS

Proceeding with the comparison of the variation in public liability hazard as calculated from the formula with the actual variation shown by insurance rates, Table 3 shows these variations for all the cities included in Table 2. The Chicago rate is taken as the base, as percentages of which the other rates are shown. The population, P (Column (2)), is from the Census Bureau estimates of 1922.

The variation shown by insurance rates (Column (6) in Table 3) will hereafter be referred to as the "actual variation" in hazard, and the rate of any city (expressed as a percentage of the Chicago rate) will be termed its actual hazard. The hazard variation as determined from $H \propto \frac{P}{M}$ (Column (5) in

Table 3) will hereafter be referred to as the "calculated variation" and the hazard it shows for any city (expressed as a percentage of the Chicago hazard) will be termed the "calculated hazard" of that city.

Fig. 3 is a graphic comparison of the actual and calculated variations shown in Columns (5) and (6) of Table 3. To show the diversity in size of the cities entering into the comparison, the two variations are projected against a background proportional in width to the populations of the respective cities.

Agreement of Variations—Cities of Group 1

The cities included in Fig. 3 have been divided into two groups. In Group 1, consisting of twenty-one cities in nineteen rate-making units, the average discrepancy between actual and calculated hazards is 6 per cent. Considering the seventeen cities (fifteen units) of the group for which the insurance rate is based on individual experience (and for which it is certain that the insurance rate is the true, rather than the approximate, actual hazard), the

mean deviation is only 5 per cent. No one of these latter cities has a deviation of more than 10%, except New York City which shows a deviation of 13%, in the direction which would be anticipated from topographical and other peculiarities of that city and that insurance territory.

Any inaccuracies in the mileage figures used will hardly increase the mean deviation by more than 1 or 2%, if at all. As the expression, $H \propto \frac{P}{M}$, accounts for the hazard variation in three-fourths of the cities investigated, its applicability to the average city of the United States under 1922 conditions seems evident.

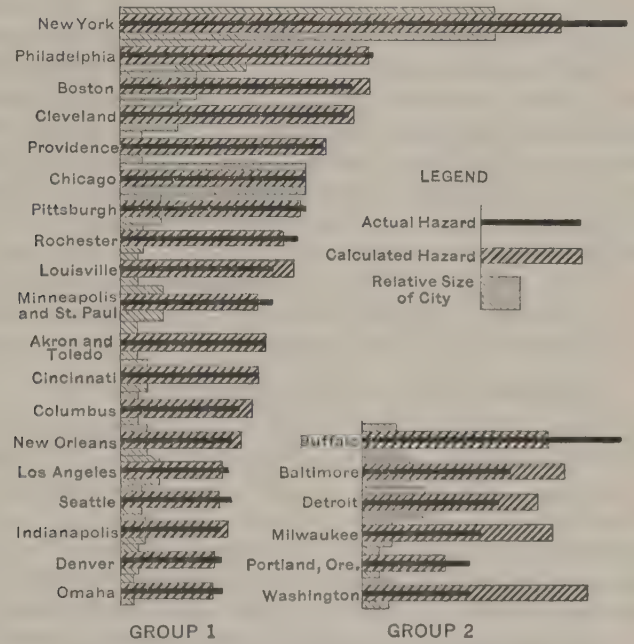

FIG. 3.—ACTUAL AND CALCULATED HAZARD VARIATIONS (FROM TABLE 3).

DISCREPANCIES IN VARIATIONS—CITIES OF GROUP 2

Referring to Group 2 of six cities, these show discrepancies between actual and calculated hazards ranging from 24% of the actual hazard for Portland, Ore., to 109% for Washington. A full discussion of the reasons underlying these discrepancies is beyond the scope of this paper. The formula, $H \propto \frac{P}{M}$, is applicable to actual cities only because the large number of factors which it fails to take into consideration seem usually to compensate for one another. Where the formula fails to apply, these factors fail to compensate, perhaps because of some one outstanding deviation from the average or of a number of minor variations all chancing to fall in the same direction. The deviations in the cases of Washington and Baltimore, however, suggest important conclusions.

Washington, D. C.—Washington shows the greatest discrepancy between actual and calculated hazards of any city of Fig. 3, the actual hazard being less than one-half the calculated. One explanation that immediately presents itself is the superior planning of the city. This includes the street layout, with its liberal widths of pavement, its set-back building lines, with consequent good sight distances at intersections, and its straight, continuous thoroughfares, almost free from "bottle-necks" and well distributed to carry the traffic of all sections of the city. In addition, it includes the satisfactory distribution of population which results from the absence of slums and crowded tenements and the satisfactory geographical distribution of the principal business of the city, the Federal Government. In short, Washington possesses a system of streets well designed to carry the traffic which should result from a good distribution of population and of business, and it possesses such a distribution. While these possessions probably do not entirely account for the favorable position of Washington from a traffic hazard standpoint, it seems certain that they play a sufficient part to make evident their great value.

Baltimore, Md.—Baltimore, the remaining city in Group 2 of Fig. 3, is an old city, which although up to the average as regards adaptability of street layout to traffic needs and as regards distribution of business and of population, is not an exceptional city from a planning standpoint; nor had it as a city prior to 1923 made outstanding efforts for traffic safety. Nevertheless, it is subject to an actual hazard less than three-fourths that calculated for it.

Possible Influence of State Motor Vehicle Laws

Maryland, however, was one of the pioneer States to recognize the responsibility of the State in safeguarding its citizens from reckless and incompetent automobile operation. For a number of years it has had a law providing that no citizen shall operate an automobile within the State without an operator's license conditioned on passage of tests in driving ability and knowledge of traffic regulations; and also that the State Commissioner of Motor Vehicles shall be empowered to exercise a general supervision over automobile accident conditions. Within recent years a number of States have enacted such laws. Such enactments, and vigorous administration under them, however, do not date back far enough to have affected 1922 conditions, except in Maryland, Connecticut, Massachusetts, and New Jersey. Hazard conditions in these States may serve to show whether there is support for the suggestion which Baltimore conditions make that such laws are effective in reducing the hazard of automobile operation below what it otherwise would be; and the extent to which the expression, $H \propto \frac{P}{M}$, which seems to hold good generally as between cities without this special type of legislation, applies between cities in States with this type of legislation.

Few cities in these States have populations of 200 000 or more for comparison with those already studied. Connecticut has no cities of this size, but has three cities with populations of 100 000, or more—Bridgeport, Hartford, and New Haven. These cities have the same insurance rate, derived from their combined loss experience (compare Akron and Toledo in Table 3). Since

their actual hazard is the same, the three cities may be combined in this paper for comparison of both their calculated and actual hazards.

Similarly, eight cities in Massachusetts with populations of less than 200 000 are combined into one or more groups for determination of their insurance rate. The writer is not advised whether this hazard is determined from one grouping or several, but as all the cities have the same rate, it will be proper to consider them in one group for comparison of their actual and calculated hazards. These cities are Fall River, Haverhill, Lawrence, Lowell, Lynn, New Bedford, Springfield, and Worcester. The City of Boston, of course, will be considered separately, as its actual hazard is different from that of the grouped cities.

Baltimore is the only city in Maryland of sufficient size to warrant investigation in this connection.

New Jersey has two cities—Newark and Jersey City—with populations of more than 200 000. These cities were not included in Tables 2 and 3, nor in Fig. 3 because they are not their own metropolitan centers, but form part of the Metropolitan Area of New York City (U. S. Census Bureau classification) and this has a disturbing influence on their street hazard, which is thus somewhat indeterminate. This effect results principally from the fact that, owing to the suburban location of these cities, the ratio of daytime population to resident population differs from that of the average city. In the average city there is an influx from surrounding suburban and rural areas every morning, which flows out again at night, so that the daytime (and hazard-producing) population is greater than the resident population. It is assumed that this influx is proportional to the population of a city, in which case it has no effect on the expression $H \propto \frac{P}{M}$. This assumption apparently holds true for cities which are their own metropolitan centers, but in suburban insurance territories like Newark and Jersey City, the flow of population is outward in the morning and back again at night, so that in them there is a smaller, instead of a larger, daytime than resident population. This causes less congestion on the streets and lower hazard than there would be if the cities were isolated.

This effect is heightened in such cities, and particularly in Newark, by the fact that all the suburban area about New York City is divided into sections, each of which constitutes one insurance territory, although it may contain several cities. Thus, Jersey City territory contains Bayonne and several smaller cities and towns of Hudson County, and Newark territory contains Montclair, Summit, the Oranges, and other commuting centers.

A contrary effect to that just described results from through traffic, bound in and out of New York City and traversing these suburban areas. This adds to street congestion in these areas, and partly compensates for the outflow of commuters. The compensation is more complete in Jersey City territory than in Newark territory, as the former is less of a commuting area, and, also, being closer to New York, is traversed by more through traffic.

The net effect of these suburban conditions is indeterminate, but that there is such an effect, and that it is greater in the Newark territory than in the Jersey City territory should be kept in mind.

Table 4 shows populations, weighted street mileages, the ratio, $\frac{P}{M}$, and calculated and actual hazard variations (based on Chicago) for the cities which have been mentioned as being in States which in 1922 had the better type of motor-vehicle legislation.

The street mileages shown are paved and unpaved mileages weighted and combined in accordance with principles set forth previously. The figures for the larger cities are from local sources, usually engineer departments; those for the smaller cities are usually from local sources, but are supplemented in some instances by data from The Asphalt Association, with estimates of the mileage of unsurfaced streets. The error in the mileage figures should in all cases be less than 10 per cent. Hoboken, in Jersey City territory, and Irvington and Bloomfield, in Newark territory, are omitted from Table 4 because of lack of mileage data. The population figures are from 1922 Census estimates.

TABLE 4.—Calculated and Actual Hazard Variations for Cities in Connecticut, Maryland, Massachusetts, and New Jersey.

Cities.	Population, P, in thousands.	Weighted street mileage, M.	$\frac{P}{M}$	Calculated variation.*	Actual variation.*

* As percentages of the value for Chicago.

† Includes Cities of Brookline, Cambridge, Chelsea, Everett, Malden, and Somerville.

‡ Includes Bayonne, West Hoboken, and West York, which are included in Jersey City insurance territory.

§ Includes Montclair, East Orange, Orange, West Orange, and Summit, which are included in Newark insurance territory.

Indicated Benefits of State Control

Table 4 shows calculated hazards considerably greater than the actual hazards in all cases. For the Connecticut cities, for Baltimore, and for the smaller Massachusetts cities, the discrepancies between the two hazards are 28, 27, and 32%, respectively, of the calculated hazards. The discrepancy for

Boston is 7% of the calculated hazard, for Jersey City, 31%, and for Newark, 34 per cent.

As already noted the suburban location of Jersey City and Newark gives them unusual advantages in regard to the hazard of automobile operation, which have the effect of making actual hazards perhaps 5% lower in Jersey City and 10% lower in Newark than they would be if these cities were isolated. Making this allowance, the remaining discrepancies between their calculated and actual hazards become 28% of the calculated hazards in both cases. Then, for all the cities or groups in Table 4, except Boston, approximately the same discrepancy—about 28% of the respective calculated hazards—can be accounted for on the basis of a beneficent influence exercised by their motor-vehicle laws. As this discrepancy is so nearly the same in all cases, the following conclusions would be justified (except for Boston):

1.—As between themselves, the variation in public liability hazard of automobile operation is given by the expression, $H \propto \frac{P}{M}$.

2.—In comparison with other municipalities, cities in States having the better laws show this hazard to be from 25 to 30% lower in proportion to population congestion.

The fact that Boston has a calculated hazard only 7% in excess of the actual hazard still must be explained. As already noted, Washington benefits tremendously from a well-planned street layout. Boston, by reason of topography, age, and random growth many decades ago, suffers from street conditions which in many of the older parts of the city are more or less the antithesis of those from which Washington benefits. It would seem logical, therefore, that Boston should have an actual hazard larger than its calculated hazard by perhaps 20 per cent. Instead it is 7% smaller. This discrepancy of 27% is attributable to the State motor-vehicle law. Hence, Boston tends to confirm rather than to upset the conclusions just stated.

The first conclusion supports what the first group of cities in Fig. 3 indicated, namely, that the great determinant of the public liability hazard resulting from automobile operation is population density. Of the two conclusions just stated, this is the more important from an engineering standpoint—perhaps from any standpoint.

The second conclusion—that a well-drawn and well-administered motor-vehicle law is capable of greatly reducing this hazard—is of great importance, to every motorist and to every citizen. It is of particular importance to city or State officials concerned with accidents on streets and highways.

It is interesting to note what this decrease in hazard means in terms of money. According to the National Automobile Chamber of Commerce, the registration of automobiles in Massachusetts in 1924 was 486 952 private passenger cars and 83 626 commercial and public automobiles, the increase in registrations from 1922 to 1924 being 48 per cent. If it is conservatively estimated that the increase in registrations from 1924 to 1926 was only 25%, the 1926 figures will be 618 000 private passenger cars and 105 000 commercial

and public vehicles. The average private passenger car public liability insurance rate in Massachusetts is about $30. The average commercial or public vehicle rate is more than twice this, or at least $65. The cost of public liability insurance in standard amounts for every automobile in the State for 1926 would thus be about $25 000 000. As has been pointed out this is less rather than more than the economic loss from automobile personal injuries, which will approximate $25 000 000 for the year. The automobile hazard level in Massachusetts cities has been shown to be only about 0.7 as high as the level which would be anticipated for them. If this difference between actual and anticipated levels prevails throughout the State, the anticipated personal injury loss for the year would be about $36 000 000, $11 000 000 more than it actually is. This $11 000 000 represents a saving from decrease in personal injuries only, and, of course, is accompanied by a saving from decrease in property damage from automobile accidents. Placing this latter saving at less than half as much, or $5 000 000, which seems conservative, the annual automobile accident loss in the State is $16 000 000 less than would be expected.

The annual cost of administration of this law is about $1 000 000 ($648 725.90 for 1922, fiscal year).

"Natural" Variation in Hazard

It may be said that $\frac{P}{M}$ is the determinant of the "natural" level of public liability hazard resulting from operation of an automobile, and that the variation as between cities given by the expression, $H \propto \frac{P}{M}$, is the "natural" variation in this hazard, that is, the variation that would obtain if all cities were on a par as regards street layout and methods of traffic regulation.

Transition from Public Liability to Total Personal Injury Basis

Up to this point discussion has been limited to public liability hazard, because of the lack of any reliable check on the applicability of a theoretical formula to actual hazard conditions except the variation from city to city of automobile public liability rates. As has been shown these rates vary closely with the public liability hazard of automobile operation, which, consequently, is accounted for by the expression. $H \propto \frac{P}{M}$. This same variation, however, holds good not only as regards public liability hazard, but also for the hazard of all personal injuries which automobile operation may entail.

The expression, $H \propto \frac{P}{M}$, was related to public liability hazard; when in determining the value of w it was stated that as regards public liability the average collision between two automobiles is of the same severity as the average collision between an automobile and a pedestrian.

Since when two automobiles collide the total personal injuries inflicted by each, the car responsible for the accident and the car not responsible, upon

occupants of the other, tend to be equal, the total personal injury from a collision between two automobiles tends to be twice the public liability. In a collision between an automobile and a pedestrian, public liability means legal liability of the motorist for injuries to the pedestrian. If the accident resulted wholly from some fault of the pedestrian, legal liability of the motorist does not exist; if it resulted from joint carelessness of both parties, the motorist's liability is at least curtailed.

It is impossible to determine the proportion of collisions between automobiles and pedestrians for which pedestrians are responsible. The smallest degree of responsibility is given by the Massachusetts Registry of Motor Vehicles, which reports pedestrian liability as from 35 to 40% of all automobile accidents involving pedestrians. Similar reports from New York State indicate about 50% responsibility; and from New York City (Police Department) and the State of Connecticut, somewhat more than 50 per cent.

Probably one-half, or a little less, of the personal injury to pedestrians by insured automobiles is indemnified. In other words, the total personal injury damage from such accidents tends, as in collisions between two automobiles, to be about twice the public liability. Assuming this, it follows that from either a public liability or a total personal injury standpoint, the two types of collision are of the same average severity, and the expression, $H \propto \frac{P}{M}$, holds good for both.

There are other automobile accidents in cities, such as collisions of automobiles with trains and electric cars, with fixed objects, etc. The total is small, however, compared with the two great classes, collisions between automobiles and of automobiles with pedestrians. Moreover, this small disturbing influence is doubtless in such direction as to be counteracted by any excess (of which there is probably a little) of liability of pedestrians for accidents involving them above what has been assumed for them.

It may be safely stated that the determinant of the total personal injury hazard which results from operation of an automobile in any city is given by the expression, $H \propto \frac{P \pm n R}{M}$, in which, n is a fraction probably varying a little as between cities, but always so small that the quantity, nR, is of negligible importance in comparison with P. In other words, from the standpoint either of public liability or of all personal injuries, the natural determinant of hazard of automobile operation is simply the density of population, it being practically immaterial to a motorist from a personal injury hazard standpoint, whether this population, or the proportion of it using the streets at any given time, is encountered as pedestrians or in automobiles.

Automobile Fatalities

As regards automobile fatality hazard, however, this is not true. Under unvarying methods and efficiency of traffic control and of public education in traffic safety, and with no change in the ratio, $\frac{P}{M}$, of a city during a period of

years, there should be no change in the personal injury hazard of automobile operation. If, however, during this period the ratio of automobiles to population is increasing, the ratio of automobile fatalities to automobile registrations should steadily decrease; that is, the fatality hazard of automobile operation normally decreases with an increase in the number of automobiles.

Death Rate per One Thousand Automobiles Registered

To demonstrate this: The expression for personal injury hazard of automobile operation, $H \propto \frac{P}{M}$, is derived from,

$$H \propto \frac{P - (a\,R - w\,R)}{M}$$

in which, $a = 2$ and $w = \frac{f_a}{f_p} \times \frac{P - a\,R}{R}$, which product is also approximately equal to 2 for all ratios of $\frac{P - a\,R}{R}$. In other words, whatever the degree of motorization of the city, the second term of the numerator cancels, leaving the population density, $\frac{P}{M}$, as the determinant of personal injury hazard.

Considering the fatality hazard, which may be termed, H_F, the expression may be derived,

$$H_F \propto \frac{P - (a\,R - w_F\,R)}{M}$$

in which,

$$w_F = \frac{F_a}{F_P} \times \frac{P - a\,R}{R}$$

F_a and F_p representing the numbers of motorists and pedestrians killed in automobile accidents, respectively. Then,

$$H_F \propto \frac{P - a\,R + \left(\frac{F_a}{F_p} \times \frac{P - a\,R}{R}\right) R}{M}$$

or,

$$H_F \propto \frac{\left(1 + \frac{F_a}{F_p}\right)(P - a\,R)}{M}$$

For the average city, a may be taken as 2, the expression thus becoming,

$$H_F \propto \frac{\left(1 + \frac{F_a}{F_p}\right)(P - 2\,R)}{M}$$

The expression for the variation of personal injury hazard could have been written in similar form, namely,

$$H \propto \frac{\left(1 + \frac{f_a}{f_p}\right)(P - 2\,R)}{M}$$

Here, however, as the importance of R relative to P increases, the increase of $\frac{f_a}{f_p}$ (Fig. 2) tends to neutralize it, giving the simpler form, $H \propto \frac{P}{M}$.

However, the ratio of fatalities of the two types, that is, $\frac{F_a}{F_p}$, for a given ratio of population to automobiles, has not the same value as has the collision ratio, $\frac{f_a}{f_p}$ (Fig. 2). Thus, in 1922, the ratio of collisions between automobiles to collisions with pedestrians, $\frac{f_a}{f_p}$, was apparently greater than 1.0 in Los Angeles, whereas the ratio of motorists killed to pedestrians killed, $\frac{F_a}{F_p}$, appears to have been as low as 0.33 or 0.25. Similarly, in New York City, the ratio, $\frac{f_a}{f_p}$, was about 0.12 in 1922, and the ratio, $\frac{F_a}{F_p}$, was 0.07. The ratio, $\frac{F_a}{F_p}$, always has lower values than $\frac{f_a}{f_p}$, and its values increase much less rapidly than those of $\frac{f_a}{f_p}$ from less highly to more highly motorized cities. The increase in the first factor of the numerator of the expression,

$$\frac{\left(1 + \frac{F_a}{F_p}\right)(P - 2R)}{M}$$

is insufficient to counterbalance the decrease in the second factor as the motorization increases; consequently, the fatality hazard decreases with increase in motorization, the population density, $\frac{P}{M}$, remaining constant.

The formula for H_F is entirely theoretical and neglects the effects of chance and other possible factors. The importance of these effects is indeterminate, as it is impossible to make a satisfactory check of the fatality hazard formula against the automobile death rate (as the personal injury hazard formula, $H \propto \frac{P}{M}$, was checked against the insurance rate). This is true because (*a*) the automobile fatality figures available through the Census Bureau are for deaths occurring in the respective cities, irrespective of the place of occurrence of accident, and a high automobile fatality rate in a city may indicate good hospital facilities (attracting persons injured outside) as much as bad traffic conditions; (*b*) there are apparently no figures for automobile registrations available for some cities, and, in other cities, the registration figures appear to be of doubtful accuracy; and (*c*) figures are almost wholly lacking for the ratios of motorists killed to pedestrians killed, in the several cities.

The great fluctuation in the automobile fatality rate from year to year in most cities indicates that chance plays a considerable part, as would be expected. This part may be even so great as to make it not permissible to speak

of a "probable" fatality hazard. As attempts have been made, however, to account for the variation in automobile fatality rates between cities by means of formulas, the writer suggests the formula for H_F as being apparently more applicable than any other that has come to his attention.

Empirical Formula

The principle that increase in motorization lowers the fatality hazard of operation of each automobile, may be clearly expressed by the empirical formula,

$$H_F \propto \frac{P}{M}\left(\frac{P}{R}\right)^{\frac{3}{8}}$$

This formula appears to give almost as satisfactory results as the more rationally deduced expression,

$$H_F \propto \frac{\left(1 + \frac{F_a}{F_p}\right)(P - 2R)}{M}$$

Such application of both these formulas as can be made in the light of present information reveals discrepancies for several cities due to some other unknown factor, probably the average speed of traffic. Cities with unusually slow average speeds seem to have fatality rates lower than would be anticipated from the formulas, and *vice versa.*

It may be noted that the average speed of traffic should have much less influence on personal injury hazard than on fatality hazard; low speeds lead to carelessness and many accidents of minor severity, whereas high speeds cause fewer accidents, but of higher individual severity, the total severity being much the same in both cases. This applies primarily to cities in which low speeds are caused by extreme congestion, especially of pedestrians, and in which high speeds are made possible through special traffic regulations, such as the "boulevard" stop plan.

Automobile Death Rate per 100 000 Population

The formulas for fatality hazard relate to the operation of the individual automobile; that is, to the hazard as expressed by the automobile death rate per thousand automobiles registered. To express the variation in the automobile death rate per 100 000 population, these formulas can be written:

$$H_{FP} \propto \frac{\left(1 + \frac{F_a}{F_p}\right)(P - 2R)}{M} \times \frac{R}{P}$$

and,

$$H_{FP} \propto \frac{P}{M}\left(\frac{P}{R}\right)^{\frac{3}{8}}\left(\frac{R}{P}\right)$$

or,

$$H_{FP} \propto \frac{P^{\frac{3}{8}} R^{\frac{5}{8}}}{M}$$

in which, H_{FP} represents the automobile death rate per 100 000 population. In these formulas, strictly speaking, R, except in the term, $(P - 2R)$, should denote "equivalent private passenger cars"; that is, the actual registration of private passenger cars plus the registrations of commercial and public vehicles weighted in such a manner as to reflect the excess of hazard which the latter create over that of the average private car. This is a refinement difficult to apply and one that may be neglected without invalidating the principle of the formulas.

Conclusions

From city planning and engineering standpoints three conclusions may be based on this study of street hazard.

Zoning to Prevent Congestion.—The variation expressing the personal injury hazard of automobile operation as proportional to population density, $\frac{P}{M}$, adds a warning against such degrees of congestion of population as prevail in almost all older large cities. This congestion will occur in newer cities and grow still worse in old cities unless the tendency is checked by zoning regulations.

Since the desirability of such zoning measures is evident from other considerations than that of street safety, it might be said that this warning is unnecessary. This is hardly a sound argument, however, because anything which may serve to show the danger of population congestion is worth while from the standpoint of its influence on public opinion, on which zoning measures must ultimately rest.

To change the population density of a city is a slow process, however. It attacks the hazard problem from a preventive standpoint, but offers little cure for existing bad conditions. The second conclusion relates to such a cure.

Traffic Segregation.—From the derivation of $H \propto \frac{P}{M}$, it is seen that this expression holds good as the determinant of hazard because the ratio, $\frac{P}{M}$, measures, for the average city, the frequency of crossings of the path of an automobile by other automobiles and by pedestrians. In other words, diffusion of population leads to a decrease in the number of possible collisions per unit distance of travel, and thereby reduces hazard. Any other measures which do the same should likewise reduce hazard. Such measures are to be found in a proper segregation of street traffic.

"Traffic segregation" is no new term, but is ordinarily used in a very limited sense to mean separation of slow-moving from fast-moving vehicular traffic. As regards safety, this is the least important of three forms of traffic segregation.

The second form is the segregation of right-angled streams of vehicular traffic from one another at intersections. This may be a space segregation, resulting from a separation of grades, or a time segregation. One of these forms is always present except when an accident occurs. Space segregation

being usually out of the question, the reduction of collisions between automobiles rests largely on a more certain time segregation. As the majority of collisions between automobiles in the average city occur at a comparatively small number of intersections, proper time-segregation measures may be quite effective in reducing the hazard of collision between automobiles. The situation in almost any city is susceptible of improvement through such means.

The third and most important form of traffic segregation, however, is given least attention. This form is the segregation of pedestrian from vehicular street use, and its importance in any community as compared with vehicular segregation at intersections is measured by the ratio of collisions with pedestrians to collisions between automobiles. Thus, in New York City, the prevention of collisions with pedestrians is, from a personal injury standpoint, at least five times as important as the prevention of collisions between automobiles, and as regards fatalities it is seven or eight times as important.

At present, about the only special effort made to reduce accidents involving pedestrians is through "jay-walking" campaigns and educational work. Such campaigns are meeting with considerable success, but the problem is sufficiently serious to merit supplementing them by careful studies to see whether a better segregation of pedestrian and vehicular street use and travel may not be accomplished. Although improved methods of handling traffic at street intersections may greatly reduce the hazard of collisions between vehicles, they will have little effect on collisions between automobiles and pedestrians, only a small proportion of which occur at street intersections.

A complete segregation of pedestrian and vehicular traffic is not possible, and would be undesirable because of the restrictions it would place on street use, or the great expense it would entail. In practically any city, however, a much safer distribution of pedestrian and vehicular travel might be realized at small expense and with facilitation rather than restriction of traffic.

To go into detailed methods of doing this is beyond the scope of this paper, but many applications of the principle may be discovered in any city. As most automobile collisions with pedestrians occur in residential districts, particular attention should be given to the segregation of pedestrian from automobile traffic in those districts, as far as possible through measures which will naturally drain the greatest possible proportion of automobile traffic into arterial ways.

A study of the high hazard areas shown on the automobile fatality map maintained by the Police Department of New York City illustrates very strikingly the great hazard from intermittent vehicular traffic through tenement streets filled with playing children. Under such conditions, even elaborate measures to bring about a better segregation of vehicles from pedestrians are justified. The roping off of "play streets" barred to vehicle use, in such areas, is the first step. The logical supplement to this is the provision of some means through which other near-by streets may be kept clear, between curb lines, of pedestrians (particularly of children at play) so that vehicles may pass through them at good rates of speed and without high hazards.

Extreme conditions may even justify the erection of fences along the curb lines of certain main traffic arteries through congested tenement districts. Such fenced streets would have to be provided with tunnels or bridges for cross traffic at intervals. These would be of great value from a safety standpoint and might prove of little inconvenience if traffic were heavy in two directions and light at right angles. They should always be the supplement of "play streets" or other adequate play areas.

In many cities where automobile hazard conditions are very bad, the regulation of traffic by police and motor-vehicle departments seems to be approaching the limits of its effectiveness. Further improvement must apparently come largely from engineering measures to insure a safer distribution of pedestrians and automobiles over the street system. Such measures imply better traffic segregation, particularly of vehicles from pedestrians, and secondarily of conflicting streams of vehicles at street intersections. These measures are apt to be expensive and so should always be based on careful determination of the benefits that may be expected. A case in point is furnished by the railroad grade crossing, which for some reason attracts excessive attention as a highway hazard, with a consequence that sums of money out of proportion to the resulting benefits have been devoted to this elimination.

It seems not to be generally realized that the sore spot in the traffic accident situation is the crowded residential or tenement district, that for every person killed or injured at a grade crossing, in the more urban States at least, ten are killed or injured in the slums and near slums.

Street Plan.—The third conclusion, of particular importance to the future growth of cities, results primarily from the deviation from anticipated hazard which the City of Washington presents. The conclusion is that a well-planned street layout with adequate provision of long, straight, broad, and well located traffic thoroughfares, particularly if supplemented by measures that will bring about a good distribution of homes and business, will reduce street hazard far below its anticipated $\frac{P}{M}$-level.

Motor Vehicle Legislation.—These three conclusions as to zoning and other engineering means of street hazard reduction are supplemented by a fourth, equally important not only to engineers, but to all citizens—that street traffic hazard is responsive to proper efforts for increase in carefulness in street use by pedestrians and motorists. The enactment and efficient administration of the type of State motor-vehicle law outlined in this paper may, and as experience has proved does, reduce street and highway hazards 25 to 30 per cent.

DISCUSSION

WILLIAM T. LYLE,* M. AM. SOC. C. E. (by letter).—This paper commands attention not only for its originality, but also for its suggestiveness. It may be classed as a contribution to the literature of city planning. The end sought is the reduction of automobile hazard. The investigations made and conclusions reached are beyond the frontiers of present knowledge.

The analysis is clear and reasonable. The author is careful to define the term, "automobile hazard", at the outset of his paper and this definition must be borne in mind throughout. The hazard resulting from the use of a single automobile varies as $\frac{P}{M}$, the population density; therefore, the variation in the automobile accident rate per unit of population no doubt would be obtained as $\frac{P}{M} \times \frac{R}{P} = \frac{R}{M}$, the automobile density. It is necessary to appreciate these two values in order to grasp the argument for zoning, traffic segregation, street plan, and motor vehicle legislation. Fig. 3 is not only interesting, but provocative also of many questions. It demonstrates conclusively the value of motor vehicle legislation and of a city plan.

Since the variation in the automobile accident rate per unit of population is expressed by the automobile density, uniform traffic distribution and traffic control have added to the carrying capacity of streets, the safety of pedestrians, and the efficiency of the police and fire departments. Without traffic control, modern street movement would be impossible. Since, however, the effectiveness of traffic control decreases with increasing congestion, there is a point beyond which it fails.

As the solution of the traffic problem, traffic control has demonstrated its inadequacy; and traffic regulation, as made possible by physical improvements, is necessary to afford permanent relief. The traffic problem, therefore, is being transferred from the domain of municipal administration to the field of municipal design and construction. In other words, it is becoming the problem of the city planner. Whereas, in the past, its solution has been sought in the control of the traffic stream, in the future, it will be secured by improving the container. Temporary makeshifts will not answer; a radical treatment is required. This is to be found in street widening and in the general improvement of the street plan; nor in these alone, because they are piecemeal methods and, therefore, will not fully satisfy. The traffic problem (including the problem of hazards) affects, and is affected by, all the elements of the city plan. Therefore, it should form a part of a comprehensive plan in which all the physical elements of the city are treated in their mutual relationships.

The conclusions drawn by the author might be enlarged in scope to include practically the whole subject of city and regional planning. The doctrines of centralization and decentralization might be discussed from this new viewpoint, from which also the merits of a well-proportioned radial and

* Prof. of Civ. Eng., Washington and Lee Univ., Lexington, Va.

circumferential street plan, of a simplified railroad plan with grade crossings eliminated, and of parks and playgrounds as substitutes for the high-hazard residential and tenement areas, might be presented in a new light.

M. O. Eldridge,* Assoc. M. Am. Soc. C. E. (by letter).—In his paper, Mr. Cox shows that the automobile public liability insurance rates are lower in some cities than in others. On the ordinary $5 000 and $10 000 policy, the rates for 1927 are, as follows:

New York, N. Y.	$107	Detroit, Mich.	$23
Buffalo, N. Y.	57	Atlanta, Ga.	26
Philadelphia, Pa.	59	Washington, D. C.	20
Providence, R. I.	45	New Orleans, La.	20
Cleveland, Ohio	40	Los Angeles, Calif.	20
Chicago, Ill.	32	Indianapolis, Ind.	18

The rate in Milwaukee, Wis., which has about the same population as Washington, D. C., is $29.

In discussing the relations between actual and calculated hazards, Mr. Cox shows that there are discrepancies between such hazards ranging from 24% of the actual hazards for Portland, Ore., to 109% for Washington. Noting that for Washington the actual hazard is less than one-half the calculated, he attributes this, to a large extent, to superior planning of the city.

While the avenues in Washington, of which there is one for each State, are wide, the paved portions of the numbered streets running north and south, and the lettered streets running east and west, are narrow when compared with other cities. The average width of the pavement on these streets is from 30 to 32 ft., leaving barely sufficient space for two lines of traffic when automobiles are parked at the curb.

Many other streets in Washington are so narrow as to leave only one traffic lane between parked automobiles. The writer, therefore, cannot agree that these streets are well designed to carry the traffic.

The wide avenues radiating from the Capitol and White House and numerous circles at an angle of 45° to the narrow lettered and numbered streets only tend to complicate this situation from a traffic standpoint. In fact, it is said that this system of street layout was designed by L'Enfant more as a means of internal defense than as a method of handling traffic. As many as ten streets and avenues converge into some of the larger circles in Washington, and this tends to increase the traffic hazards.

Since 1924 the City of Washington has made considerable progress in reducing the number of traffic fatalities and accidents. The fatality and accident records for the District of Columbia, which is co-extensive with Washington, are as follows:

Year.	Traffic Fatalities.	Year.	Traffic Accidents.
1923	91	1923	8 491
1924	91	1924	9 131
1925	84	1925	9 331
1926	76	1926	6 485

* Director of Traffic, Washington, D. C.

These reductions have been made in spite of the fact that the population has increased considerably during this period and that the registration of automobiles and the number of new drivers has practically doubled.

It cannot be said, therefore, that this improvement has been brought about by the city planners, by the favorable street layout, or by the width of streets, etc. In reality, these reductions are attributable to the following causes:

1.—The establishment of a well laid-out system of boulevard highways at which motorists are required to stop before entering or crossing, thus speeding up traffic on these highways and making the intersections with adjacent streets much safer.

2.—The elimination of parking on the flow sides of boulevard highways during the morning and afternoon rush hours. This not only facilitates the movement of traffic, but adds an additional traffic lane during the rush hours and reduces the possibility of accidents to pedestrians who may walk out into rapidly moving traffic from between parked automobiles.

3.—The establishment of traffic control on some of the main thoroughfares by means of electric traffic signal lights which operate from 7:00 A. M. until midnight, under a plan of co-ordinated control developed in Washington.

4.—The establishment of a uniform speed limit throughout the District of 22 miles per hour, except on certain sections of boulevard and other highways in the outlying districts, where a speed of 30 miles an hour is permitted as indicated by signs.

5.—The elimination of bad drivers by the cancellation of permits for first offense in leaving after colliding or in driving while intoxicated, for second offense in reckless driving, and for third offense in speeding. Permits are also suspended or canceled for other causes, such as mental and physical defects of drivers. All new drivers are examined on the regulations and are required to demonstrate their ability to operate a motor vehicle safely in congested traffic. An eyesight test is also required.

6.—The adoption of a modern traffic code based on the principles laid down by the Hoover Conference on Street and Highway Safety. This code is being enforced without "fear or favor" by the Police Department and by a Traffic Court which holds sessions every week-day, including holidays, from 9:00 A. M. until 11:00 P. M.

C. W. STARK,* ASSOC. M. AM. SOC. C. E. (by letter).—The author has made a very valuable and unusual contribution to Society publications. It is to be hoped that such discussions will not be so unusual in the future, for the best efforts of the engineer are needed to help solve the traffic problem, to reduce the annual accident toll, the tremendous economic waste due to inadequacy of street and highway facilities, and the unscientific use of existing facilities.

From the viewpoint of the insurance companies and also of the individual motorist it is reassuring to know, as Mr. Cox has demonstrated, that the hazard of the individual automobile does not increase with the number of

* Transportation and Communication Dept., Chamber of Commerce of the United States, Washington, D. C.

automobiles. From the viewpoint of the man on the street this is not so cheering, because it confirms his belief that the hazard to himself, be he afoot or in a motor car, is the sum of the hazards to himself from each motor vehicle and, therefore, increases with the number of motor vehicles. Since this number is constantly and rapidly increasing, it behooves each one to bestir himself in every way to reduce the unit hazards for self-protection.

Although Mr. Cox proves mathematically that $w = a$ and, therefore, that the hazard to the pedestrian is the same as that to the occupant of the other motor car, those who do much walking will still feel that there must be some flaw in the reasoning. Perhaps the seeming discrepancy between formula and experience can largely be explained by the author's statement that in a collision between an automobile and a pedestrian, if contributory negligence on the part of the pedestrian is shown, the pedestrian is likely to receive little or no indemnification for his injuries. Since the pedestrian is alleged to be at fault in about one-half the cases, evidently this half does not enter into the formula. Of course, many automobile collisions also do not enter.

It might be added that injuries to persons are seldom averted by such persons leaping to safety from automobiles about to suffer collision, whereas pedestrians are constantly avoiding accidents by jumping and dodging. Only by their own agility, exercised in many cases where they clearly have the right of way, do they avert many accidents, and thereby greatly reduce h_p.

Mr. Cox quotes several agencies to derive an average conclusion that pedestrians are at fault in about one-half the pedestrian accidents. Obviously, it is much easier to get testimony from a living motorist than from a dead pedestrian. Obviously, also, if a pedestrian is found injured or dead in a roadway in the middle of a block, it is reasonably certain that he was not crossing the street on a cross-walk. But there may be no witnesses or other proof of the fact that the motor vehicle was going at double the legal speed, or was on the left-hand side; that the pedestrian saw the vehicle and would have had ample time to get out of its way, but that the driver wilfully or heedlessly ran him down. On the other hand, if the pedestrian is hit on a cross-walk there is always the chance to prove that he wavered or darted forward suddenly, or did something else that the oncoming motorist could not foresee and, therefore, he was at fault. Pedestrians jumping for their lives from the paths of reckless, unidentified drivers, have darted into the paths of law-abiding drivers. Cause of accident—confusion of pedestrian.

Thinking further along these lines, those who live and walk in Washington, D. C., will not be lulled into a false sense of security by the fact that the "actual" hazard is less than one-half the calculated hazard, because there comes into the problem another element, which could not very well be calculated by Mr. Cox, namely, the indifference of the Washington police and apparently the prosecuting authorities to the welfare of the pedestrian. The great majority of Washington traffic officers operate their signals as if pedestrians were non-existent, shifting traffic without regard to persons on foot marooned in the middle of the street, giving no interval for the clearing of intersections, and permitting vehicles to crowd and obstruct the cross-walks

and make illegal right turns with little interference. Naturally, such officers are of little help in proving the responsibility of motorists when pedestrians are injured. The writer's personal experience has been that in Washington the interest of the public authorities in the welfare of the pedestrian approaches zero. For this reason the likelihood of insurance companies having to pay claims resulting from pedestrian accidents approaches zero, and, therefore, h_p approaches zero.

The wide streets of Washington certainly provide an opportunity for safety not enjoyed by many cities. They make it possible for vehicles to operate with a minimum of interference with each other; but they also make possible higher speeds and more rapid rounding of corners, more lanes of traffic, and greater distances for the pedestrian to negotiate, creating additional hazards for the pedestrian and calling for special effort on the part of the regulatory authorities to overcome those hazards. Because such special effort is not in evidence, the writer has heard more than one man, coming from the hurly burly of New York City, with its abnormally high value of H, to work with committees of the National Conference on Street and Highway Safety, express fear of walking on Washington's streets, and a desire to get back quickly to the comparative safety of the metropolis.

From the author's opinion that improved methods of handling traffic at street intersections will have little effect on collisions between automobiles and pedestrians, the writer emphatically dissents. Is there not a very positive relationship between the treatment accorded the pedestrian at intersections and his general attitude toward traffic? If he has no guaranty of protection when he proceeds on a "Go" sign—if he has to wait intolerably long periods for the signal to go, because there is little wheel traffic going his way, and when he does get the signal has to detour around cars stopped on the cross-walk and dodge other cars making all manner of turns, and then, perhaps, be left in the middle of the swirl by a sudden shifting of the signals—and if at unofficered intersections he has to weave his way through solid lines of vehicles that completely obliterate the cross-walks, and have the motorists blow their horns and crowd up to close the gaps so that he cannot get through—in short, if the whole scheme of traffic control makes him a mere incident, he is, of course, going to cast rules and regulations to the winds and cross the streets whenever, wherever, and however his judgment, faulty and inconsiderate though it be, determines. Give him a decent chance at the cross-walks. Mark them conspicuously and keep standing motor vehicles off them. Instil in motorists a wholesome respect for these intersections of sidewalk and roadway, and show pedestrians that regulation of pedestrians does not mean merely restriction for the convenience of motorists—and see whether this does not bring about changes in walking and in motoring habits that will cut pedestrian fatalities in half.

This dissertation on the pedestrian may seem a far cry from engineering, and unscientific. Surely, however, the engineering mind must see that, with pedestrian fatalities constituting about two-thirds of all fatalities in which

the motor vehicle is involved, the pedestrian problem is the most serious phase of the traffic problem; and it is about the most neglected.

Mr. Cox's figure of $15 000 000 annual saving to the State of Massachusetts (after cost of administering the laws is deducted), because of its advanced motor-vehicle laws, should be brought to the attention of all those who believe that the cost of administering such laws would be prohibitive.

Reasonable, enforceable rules of the road are one of the essentials of advanced motor-vehicle laws. Another essential on which Mr. Cox might well have laid more emphasis is the licensing of drivers. All four of the States which he cites as having advanced legislation in 1922 require and did require in 1922 that all operators and chauffeurs be licensed; and it is important to note that in none of these States is this licensing a mere perfunctory registration of drivers. The applicant for a license must prove by an examination that he has the qualifications for a safe driver. Such examinations permanently eliminate a small percentage of hopeless incompetents and compel a much larger number of applicants to familiarize themselves with the laws and regulations and really to learn to drive safely before they are turned loose on the highways. This system costs the State some money, but very little in comparison with such savings as Mr. Cox's figures show. No State having tried the licensing and examination system has discarded it.

The skeptics should not overlook the significant statement in the paper that "good traffic regulation is usually the outgrowth of high hazard—of conditions so intolerable that they force improvement." Experience is a costly school, but perhaps the only possible school for the dozen States that have suffered most and gone farthest in working out sound legislation. While these States are grappling with the problems still unsolved—and the relation of pedestrian and motorist is one of the gravest of these—the remaining three dozen States have an opportunity to profit by the experience of the dozen.

Engineers do not need to be told the advantages of intelligent zoning and traffic segregation or of well-planned street layouts. What they do need to realize is that the engineering problems are being handled to a large extent by others than engineers, and that they should hasten to take over that part of the traffic problem for which they are peculiarly fitted, so that mistakes already made, can be corrected as promptly as possible, and new and costly mistakes can be avoided.

L. G. Holleran,* M. Am. Soc. C. E.—This paper is both timely and interesting. Its only defect is that it does not go far enough. It gives an outlook on this problem from a new angle and arrives at a solution in a novel way; but it is regrettable that more ground could not be covered in the study of methods for reducing the automobile hazard.

This hazard is only one phase, although a most important one, of the large problem of taking care of automobile traffic with the inadequate street systems and facilities which exist in practically all American cities. As some one has aptly put it "we are building 40-story cities around street

* Deputy Chf. Engr., Westchester County Park Comm., Bronxville, N. Y.

systems designed for 3-story towns"; he might have added "and we are suffering the consequences".

It is enlightening to examine Mr. Cox's formula and to see what application it has to existing conditions. He found that this formula, $H \propto \frac{P}{M}$, did not hold good for a number of cities and came to the conclusion that several factors might serve to modify it. These factors will be discussed later.

On considering the formula, it is apparent that the hazard can be reduced in two ways, first, by decreasing the population, P, and, second, by increasing the street mileage, M. It is obvious that the population is decreasing in few cities of the United States, and, in fact, is increasing in most of them, so there is no hope for immediate relief in that direction. Accepting the formula, therefore, the only manner in which relief is possible is by increasing the mileage of streets and roads in such a way as better to distribute automobile traffic throughout the area under consideration.

That is the method by which the Westchester County Park Commission is attacking the problem. The County has an area of about 450 sq. miles and a population of about 500 000. It is in reality an urban district subject to the limitations inferred in the paper. It is the front dooryard of the City of New York; in addition to traffic originating in the County, its roads and streets must carry a tremendous through traffic going to or coming from the city. This through traffic has been carried almost wholly on two routes: The Albany Post Road and the Boston Post Road. Each of these routes leads through the business center of every city and village it traverses, thus greatly aggravating local traffic conditions and increasing the automobile hazard until a point was reached a few years ago where it was realized that remedies must be found or the development of the County would be seriously retarded.

The result was the appointment of the Commission which, after investigation, came to the conclusion that the only practicable way to relieve conditions was to lay out new routes, parallel to the over-taxed existing routes, to be located away from the business centers of the cities and villages, and as far as possible in undeveloped territory for reasons of economy as well as to provide for a better distribution of the population. Of such new routes 140 miles have been laid out, and the Board of Supervisors has appropriated nearly $40 000 000 for the acquisition of the real estate and the construction of these new routes, in addition to the land and construction work necessary for the development of recreational facilities throughout the County.

In order to facilitate the passage of traffic, as well as to reduce the automobile hazard, the new driveways are being constructed with a pavement width of from 40 to 80 ft. Truck traffic will be segregated on driveways other than those carrying passenger traffic. Grade crossings at all the principal street intersections are being eliminated, curves super-elevated, non-skid pavement used, modern lighting installed, and traffic regulated in accordance with approved methods.

Working along similar lines, the State of New Jersey is building a 50-ft. driveway, 13 miles long, from the westerly end of the Holland Tunnel to a point near Elizabeth, at an estimated cost of more than $30 000 000. New York City is to build an elevated roadway on its west side from the easterly end of the Holland Tunnel to connect with the southerly end of the Riverside Drive at 72d Street. The City of Chicago, Ill., has recently widened Western Avenue from 60 to 100 ft., for a distance of more than 20 miles, and is cutting through additional streets at great expense. Detroit, Mich., is building boulevards, 204 ft. or more in width, and Wayne County is carrying the boulevards from the city line for many miles out into the country. Philadelphia cut a wide diagonal street leading out from the heart of the city for a distance of about 1¼ miles a few years ago. Other cities are attempting to solve the problem by similar methods.

Such a program for Westchester County is possible largely because the County happens to be a very wealthy community. It, also, fortunately had within its borders leaders and officials possessed of those qualities of imagination and foresight which insured support of the comprehensive program proposed by the Commission. If men of vision and courage could be found to lead, most communities could discover the way to finance the program of improvements in its street system necessary to remedy unsafe, uneconomical, and unsatisfactory conditions.

If the losses due to fatal and non-fatal accidents, loss of business, loss of the time of drivers of private and commercial cars, and the general inconvenience of traffic congestion, could be evaluated and credit allowed for the increase in real estate values resulting from the improvement, it would be found, in most if not all cases, that the actual return in dollars and cents more than justified the expenditures necessary to attack the problem in the comprehensive way it deserves. It is a fact, however, that due to lack of proper leadership and other causes, a great many communities will decide that they cannot finance the large costs required to effect a relatively complete cure. It is necessary, therefore, to consider what means can be found to alleviate conditions with the funds which can usually be made available.

Mr. Cox concludes that the automobile hazard may be reduced in four general ways. These methods are of equal effect in solving the problem of automobile traffic as a whole. In addition, there are a number of others which, in the absence of funds to attack the problem in a comprehensive way, will tend to better distribute the traffic; facilitate the passage of automobiles through the streets; and, at the same time, reduce the hazard:

1.—Uniform traffic regulations throughout the United States. As it is now, even adjacent municipalities have different regulations which lead to the confusion of strangers who often constitute a relatively large proportion of the total number of drivers on through traffic routes.

2.—Widening of existing streets parallel to those for which the records show the greatest hazard, with this end in view, to attract a part of the traffic away from dangerous localities. One additional lane of traffic can often be secured by narrowing the sidewalks. Where this is insufficient or impracticable, streets can often be selected for widening where the damages to existing structures are at a minimum. It is of little avail, however, to

widen streets in the congested district, as such widening merely serves to attract traffic from adjacent parallel streets and the congestion soon becomes worse instead of better.

3.—Connecting up segments of existing streets to form new thoroughfares, where, due to improper control of real estate layouts, or other reasons, the streets in adjacent developments do not connect. Increased mileage of through streets and better distribution of traffic may often be secured in this way at comparatively small cost.

4.—Re-routing of trolley cars from congested streets to less used parallel streets. A few years ago when Chicago had a strike of street railroad employees and the surface cars ceased to operate for several days, traffic counts at a number of street intersections made during the strike and compared with counts taken afterward showed that the capacity of the streets decreased about 50% when the trolley cars were in operation.

5.—Paving through streets in the outlying districts to a width of not less than 30 ft. to provide a third lane of traffic so that one automobile may pass another in safety. Statistics show that a considerable proportion of automobile accidents occur while one car is trying to pass another.

6.—Providing sidewalks or paths along streets and roads in the outlying sections and along through traffic routes.

7.—Preventing the parking of automobiles in congested districts, leaving the streets free for the passage of traffic.

8.—Restricting the number of taxicabs and forbidding the practice of "cruising" for business.

9.—Removal of obstructions and encroachments, both public and private, from sidewalks and streets wherever possible.

10.—Preventing the practice of storing building materials and conducting building operations on parts of streets or sidewalks.

11.—Preventing the use of the sidewalk and a part of the street for considerable periods of time for the purpose of loading and unloading merchandise. This practice often forces pedestrians to make use of the streets and increases the possibility of accidents.

12.—Reducing the number of street openings for sewers, water, gas, or other public utilities, to a minimum, and making it a provision of the permit that the work of making and closing these openings shall be done in the shortest possible time. The repair of the pavement should always be done by the municipality at the expense of the person to whom the permit is granted.

13.—The use of the proper types of pavement for different traffic conditions.

14.—The prompt and efficient repair of the street surface when it begins to deteriorate.

15.—Increasing the radii of curbs at street intersections, not to invite an increase of speed in turning the corners, but to prevent cars with a long wheel base from encroaching on the wrong side of the street at turns and thus increasing the possibility of collisions with other cars as well as with pedestrians.

16.—Where it is impracticable to eliminate grade crossings at important intersecting streets, it is often possible to locate a circular island at the center of the intersection, requiring a rotary movement of traffic. This is relatively ineffective, however, unless the island has a rather large diameter, probably not less than 60 ft.

17.—Loading platforms raised about 6 in. above the street have been provided in some cities for the safety of passengers boarding or alighting from trolley cars. Safety isles for the same purposes have also been provided by marking off parts of the pavement with temporary posts connected with rope.

18.—The establishment of more playgrounds in or near the congested districts for the purpose of keeping children off the streets.

19.—Last, but not least, educating the public as to safety measures, beginning with the children in the schools.

It must be admitted that many of these suggestions are palliatives and not cures, but they will continue to be necessary until the street systems can be made over and a rational and uniform method of procedure for handling automobile traffic can be worked out and put in operation.

S. JOHANNESSON,* M. AM. SOC. C. E.—In his excellent paper the author comes to the conclusion that generally the personal injury hazard of automobile operation is proportional to the population density. It appears, however, that other factors may be involved, as may be illustrated by the following example. Traffic counts have been made by the State Highway Department of New Jersey at Rahway on July 4 every year since 1921, except 1925. The counts have been as follows:

Year.	Number of Vehicles.	Year	Number of Vehicles.
1921	12 153	1924	26 573
1922	16 610	1925	....
1923	18 314	1926	43 735

These counts indicate an increase of traffic during the 5-year period of 259 per cent. The exact population increase during the same period is not available, but it is probably not more than 20 per cent.

In this case the traffic increase is exaggerated by the traffic in transit from New York to the New Jersey coast resorts; nevertheless, it is a fact that the traveling habit is steadily on the increase. Not only does the ratio of number of cars to total population increase, but the average distance each car travels is increasing. The rate of increase of the traveling habit may decrease when the congestion of traffic on existing streets becomes excessive; but whenever new roads are built or present roads are improved the traveling habit will increase.

Consequently, it would seem as if the traffic density (which presumably is proportional to the personal injury hazard) cannot be taken to be proportional to the population density, unless the comparison is made at a definite time. It is possible to imagine, for example, a community in which the expression, $\frac{R}{M}$, might be the same in 1921 and 1926; but it seems probable that the personal injury hazard in 1926 would have increased materially over that in 1921 on account of the materially greater density of traffic.

In his "Conclusions", the author suggests traffic segregation at intersections as a means of reducing the hazard. At present, the New Jersey State Highway Commission is constructing a new highway leading from the Holland Tunnel Plaza in Jersey City through Newark and Elizabeth, where connections are made to existing traffic routes leading west and to the New Jersey coast resorts. On this highway, "space segregation" of traffic is being pro-

* Designing Engr., State Highway Comm., Jersey City, N. J.

vided by building it so that there will be no grade crossings with either railroads or existing streets. This space segregation is being provided largely on account of economic considerations. Investigations have been made which indicate that on this road, which is expected to carry about 18 000 000 vehicles per year, the cost of time segregation, or in other words, the loss in cost of operation of the vehicles on account of the delays at crossings, would exceed the additional cost of construction on account of the space segregation.

The results of these investigations indicate that, where the traffic is heavy, it may be worth while to consider the comparative economics of time segregation and space segregation.

W. Graham Cole,* Esq.—The author applies a strict mathematical formula to a problem that involves a consideration of engineering principles and human psychology. These principles are so inter-related that only an incomplete and inaccurate picture of the problem is obtainable from a purely mathematical viewpoint. Thus, if the formula, $h = \frac{P}{M}$, is carried to the nth degree of reasoning, namely, if M is sufficiently large in comparison with P, the value of h will approach zero as a limit.

It is obvious, however, that if pedestrians can be eliminated entirely from thoroughfares used by vehicular traffic no accidents between the two will be possible. Before this limit is reached a zone will be found in which the intermittent and unexpected appearance of a pedestrian on a thoroughfare, otherwise frequented by vehicles, will produce a greater hazard to the individual pedestrian than he now encounters at heavily congested intersections, where his presence is anticipated by the motorist. This is borne out by the experience of many cities, which shows that the majority of traffic accidents do not occur in congested sections, but rather in outlying sections, where lack of congestion permits of speeding and reckless practice.

The theoretical solution of the pedestrian-motor accident problem is the complete and permanent segregation of these two types of street users. Such steps, however, would not affect, to any great degree, the problem of vehicular collisions with each other or with stationary obstructions.

The segregation of vehicular traffic by direction so as to make impossible the intersection of one line of moving vehicles with another would prevent the intersection accident, but would leave unaffected many other types. Such segregations are impractical from a cost standpoint, if from no other, except at a few unusual locations in the most congested communities. As a general solution to the traffic problem, they are beyond the realm of practical consideration. The traffic problem is a serious one, dealing with the deaths of about 24 000 persons per year, a number that is increasing at an approximate rate of 1 death per 1 000 added motor vehicles. On account of this increasing toll, methods of dealing with the problem that are within the scope of practical application by the average community are not only highly desirable, but absolutely essential to the public welfare.

* Safety Engr., Metropolitan Life Insurance Co., New York, N. Y.

The Engineering Profession can render a great service to humanity by giving to this problem the same practical consideration and study that it has given to other problems. It can assist the Nation, the State, and the individual community to devise and take definite steps leading to the correction of existing conditions.

Mr. Cox has pointed out that the actual hazard, as he has developed it, is greater than the calculated hazard in many cities where traffic control has been practiced. Granting that the basis of his calculations is correct, this fact indicates that traffic control has been applied in the places most needing it; but it may also indicate that the most effective methods of traffic control have not been devised. The fact does not condemn the practice of traffic control, but rather emphasizes the need for greater and more intensive study of this important branch of engineering.

Accidents are largely the result of the inability of the human race to modify its habits of life quickly to conform with the tremendous changes of environment brought about by engineering advancement and commercial development. The average pedestrian still wishes to amble across a busy thoroughfare carrying thousands of powerful machines, in much the same way that his ancestors sauntered across a village street between a few slow-moving, horse-drawn vehicles. Engineering devices can be developed to alter certain environments so that they will conform more closely with the unchanged habits of the public. On the other hand, educational methods must be applied, in order to alter habits to satisfy changed conditions.

Accident prevention work in industry has demonstrated that only a small reduction of accidents can be effected by mechanical guards and engineering revision. This work must be supplemented by definite and organized educational activities. Likewise in the matter of public accidents only a small reduction will be made if the educational phase of the problem is overlooked. Through this educational work the individual citizen must be reached, his interest appealed to, and he, as an integral part of the community, must be taught new responsibilities.

In a number of communities, organizations have been perfected for the purpose of conducting continuous safety educational activities. The gratifying results obtained have proven beyond doubt that a community can be organized for the prevention of accidents, very much as industrial plants have been organized.

Of the list of cities given on Fig. 3, nine have been conducting organized educational work for some time. Of these nine, seven have an actual hazard below the calculated hazard.

Harold M. Lewis,* M. Am. Soc. C. E.—The author has presented a strong case for the formula he has set up—that automobile accident hazard within a city is directly proportional to the population and inversely proportional to the street mileage. Such a formula implies that the most practical way of reducing such hazards is by decreasing the density of population along a typical street within a community. This points directly to some form of decentralization

* Executive Engr., Regional Plan of New York and Its Environs, New York, N. Y.

that will bring about a better distribution of population and activities within cities. The need for such a re-arrangement has been much discussed in recent years, and it seems desirable for many reasons.

Mr. Cox assumes that motor-vehicle density is not the controlling factor, because he has developed from other factors an equation which fits his accident statistics. This is not proof. It is quite possible that by starting with motor-vehicle densities and applying necessary corrections, such as he has applied to street mileages, automobile density may also be proved to be an important controlling factor. Although fatality records vary too greatly in small areas to yield any general principles, they should indicate actual trends in large areas, such as States. They do have advantage in being more complete than accident records.

The National Conference on Street and Highway Safety presented very complete fatality statistics for 1923, 1924, and 1925. These were tabulated for total State areas and also for the total rural districts and total cities within each State of the United States. An analysis of the 1923 statistics showed that there was a larger variation in the fatality rates in the rural districts than in the cities, as might be expected because of the greater variation in conditions. The maximum rate in the groups of rural districts was 38.6 per 100 000 of population in California, and was greater than the rates for any of the various groups of cities. The average of the rural district rates, however, was only 11.1 fatalities per 100 000, and the fatalities in the total rural districts listed amounted to only 10.4 per 100 000. In contrast with these figures, the statistics for fatalities in the different groups of cities showed an average rate of about 20 fatalities per 100 000, or almost twice as great. Data for the later years showed approximately the same conditions.

One of the most striking features in the tables was the small variation for the different groups of cities, which indicated that the motor-vehicle hazard in any place was primarily a result of urban conditions and quite independent of the size of the city. Comparing the fatality rates of the different States with the automobile density in terms of cars per capita, it appeared that communities with the least number of cars per capita had the lowest fatality rates and *vice versa*. California, which had by far the greatest number of vehicles per capita, had the largest fatality rate. The States with more or less average fatality rates showed no such direct relation, and other factors apparently obtained.

It is hardly enough to know that one must have better motor-vehicle legislation, or a street system like Washington, D. C., in order to reduce motor-vehicle hazard. Other cities cannot afford to duplicate Washington in its rather extravagant provision of street areas. Proper planning must be based on analysis of the more specific causes of accidents, such as has been made by the National Conference on Street and Highway Safety, and by Connecticut, Wisconsin, and other States. The Connecticut analysis indicates that the ratio of accidents to registration increased fourfold from 1918 to 1925, while the automobile density increased only two and one-half times. These data must be discounted to a certain extent to allow for more complete returns in the later years, due to improved methods of reporting accidents.

On the other hand, the statistics of the National Conference on Street and Highway Safety show that the ratio of fatalities to registration decreased steadily from 1917 to 1924. The same trend was indicated by an analysis of fatality figures for New York City, New York State, and the entire United States, from 1917 to 1923, made by the Regional Plan of New York and Its Environs. It appeared that, in general, the number of fatalities in each of these widely different areas had been increasing as the three-quarters power of the motor-vehicle registration. During the four years ending with 1926, there was a decided change in this relationship in New York City when motor-vehicle fatalities increased as only about the one-third power of the registration.

TABLE 5.—AUTOMOBILE FATALITIES IN NEW YORK AND LONDON.

Year.	New York City.	London Metropolitan District.
1917	441	471
1918	503	440
1919	696	583
1920	780	512
1921	851	460
1922	846	560
1923	934	569
1924	936	720
1925	1 002	742
1926	1 028	895

It may be of interest to compare motor-vehicle fatality figures for New York City with those for the London Metropolitan District. New York City has less than one-half the area of the London Metropolitan District, but has an automobile density three or four times as great. Table 5 gives the information from 1917 to 1926, inclusive.

It is estimated that in the entire New York Region—defined as all the area within approximately 50 miles of the City Hall—there were about 1 870 motor-vehicle fatalities during 1925. This enormous loss of life indicates very forcibly the seriousness of present conditions. The London figures show that the problem also exists in the large metropolitan areas in other countries.

J. K. FINCH,* ASSOC. M. AM. SOC. C. E.—The author has taken up a problem of the first magnitude—think of New York City alone spending $75 000 000 annually on automobile accidents. He has pointed out clearly certain laws of automobile hazard—that these laws must be taken into account in city planning if the hazard is to be kept down to a minimum. Unfortunately, the problem is generally the reverse, namely, to reduce the hazard in cities, in the planning and growth of which no attention has been given to this Twentieth Century problem.

About ten years ago, under Police Commissioner Woods, the speaker served on a special committee of three to study the street accident problem of New York. Fairly reliable data had been secured by the Police Department which showed about 22 000 street accidents of all kinds in 1916. More than 25% of

* Prof., Civ. Eng., Columbia Univ., New York, N. Y.

these accidents were due to "collisions" between pedestrians and automobiles, and, therefore, it was clearly indicated that the problem, already alarming, would continue and grow with the rapid increase in automobile use. In 1926 there were more than 50 000 street accidents in New York.

Unfortunately, little time was available for this study, as the Committee was appointed just at the close of Mr. Woods' administration. Such studies as were made, however, established two fundamental laws of street accidents. The principal type of accident being due to a collision between a pedestrian and an automobile, these laws have to do first with the population characteristics which affect the accident rate; and, second, with the traffic characteristics, which tend to increase the number of accidents.

The first of these laws was the relation of population density to the number of accidents, which has been so clearly brought out by Mr. Cox's studies of insurance rates in cities of different population densities. He has also suggested a unit—population per mile of street—that reduces this hazard element to comparable figures. This unit applies equally well to entire cities or to parts of cities. For example, the Committee went so far as to compare a map showing the location of street accidents in New York with one showing the density of population. The coincidence was striking. The reason for this law appeared to be simple—the great bulk of the accidents was due to collisions of vehicles and pedestrians. This means, in general, the greater the number of pedestrians, the more accidents.

In continuing this line of thought, however, and arguing the more vehicles, the more accidents, the conclusion fails. Statistics showed that the maximum number of accidents did not occur, for example, on Fifth Avenue where there was a constant and almost solid stream of vehicles and where the sidewalks were crowded with people. On the contrary, they proved that the second law, which applies to vehicles, was different, that is, the number of street accidents was greatest on streets used by a variety of vehicles, such as trucks, passenger automobiles, and trolley cars, and where there was not sufficient congestion to prevent a fairly high speed with open spaces between vehicles. Eighth and Tenth Avenues below 59th Street, for example, and First Avenue throughout its length, are streets of this type with especially high accident rates.

One fundamental law in reference to city planning or to the design of new traffic lines is clear from this, namely, that new traffic routes, such as new streets, or bridge or tunnel outlets, should be kept away from centers of high population density. Thus, in attacking the street accident problem as it now exists in any city it is important to diffuse population and to concentrate traffic.

The chances of diffusing the population, or, to be more exact, of reducing the population density in heavy traffic sections, seem very small. Mr. Cox has mentioned zoning laws. It is also clear that the development of low-priced homes in suburban sections with adequate rapid transit facilities, may aid in this direction. In general, however, the population densities of great cities is increasing and is certain to continue to increase with the construction of the skyscraper apartments, offices, and hotels. It seems clear that little can be done through attempting to secure a diffusion of population.

This narrows the principal line of attack to the traffic problem. Three methods are available for securing a concentration rather than a diffusion of traffic. What is needed is to secure an orderly stream of traffic moving at as high a speed as is reasonable and possible. Fifth Avenue, with trucking eliminated and traffic controlled by semaphores, is probably, in spite of its pedestrian density, one of the safest streets in the world. Three methods have been shown to be effective in securing the desired results—the semaphore system, traffic segregation, and the one-way street. It has also been shown, however, that these plans cannot be applied to a few streets, for this simply results in deflecting traffic to other streets—often in diffusing it through areas of high population density, which has just the reverse of the desired effect.

A map of New York City shows how completely these laws have been neglected in planning traffic routes and gives ample reasons for the high automobile hazard. There have been, of course, sound reasons based on topography, economy, and transportation needs, for most of these traffic routes, but the problem of the automobile hazard introduced by them apparently has received little consideration. Indeed, the usual traffic idea is to break up the solid streams of traffic which enter the city over bridges and through streets and to distribute it among the side streets and avenues—a plan directly opposed to a fundamental principle of hazard reduction. Furthermore, the close regulation of traffic on certain avenues has the same effect—that of forcing traffic into other streets and avenues, thus increasing the hazard.

The lower East Side bridge section of the city is the section of highest hazard. Here, there is a dense population with several main traffic routes, trucks, trolley cars, and passenger automobiles, feeding toward the bridge entrances. Obviously, wide avenues with traffic segregated, is the only solution of this problem. Costly approaches and street widening are as essential as bridges and tunnels.

The automobile hazard in Manhattan cannot be reduced materially except through the adoption of a comprehensive traffic plan for the entire Island, a plan based not only on traffic requirements—capacity and speed—but also on the laws of traffic hazard. Isolated efforts here and there over the streets and avenues of New York will have comparatively little effect; indeed they may increase the hazard. A comprehensive plan of traffic segregation, one-way streets and avenues, and semaphore operation for the city, as a whole, is essential to facilitate traffic and reduce the hazard. All future street and bridge plans should be studied from the standpoint of hazard as well as of traffic facility.

G. G. Kelcey,* Assoc. M. Am. Soc. C. E.—This paper develops a formula by which traffic accident hazard may be determined. Some factors which might be expected to have an influence in determining hazard are eliminated on the assumption that their bearing is slight and that they will, under average conditions, balance each other. Therefore, the question concerns the accuracy as to the premises and in the development of the conclusions.

* Mgr., Traffic Eng. Div., Am. Gas Accumulator Co., Elizabeth, N. J.

A summary of factors which may be considered as having some bearing on the automobile accident hazard should include the following:*

Motor Vehicle Group.—

Motor vehicles per person.
Motor vehicles per square mile.
Motor vehicles per mile of surfaced road or street.
Average yearly motor vehicle mileage.
Distribution of automobiles by type, as trucks, taxicabs, etc.
Concentration of majority of vehicles over limited number of routes as distinguished from a general distribution of vehicles over many streets.

Population Group.—

Persons per motor vehicle.
Persons per square mile.
Character and intelligence of population.
Driving experience and ability of vehicle operators.

Miscellaneous Factors.—

Playground provision for children.
Simplicity of traffic regulations.
Enforcement of regulations.
Methods used for physical regulation and control of traffic through the use of other traffic aids.
Street design with respect to crown, curb radii at intersections, width of streets, etc.
Average visibility at intersections.
Sidewalks, or the lack of them, in outlying areas.
Topographical conditions.

All these factors have a bearing, and others might be added. Certain of them are fixed conditions and not subject to modification, while others, such as street design, visibility, and driving habits, are subject to treatment and control. It would seem that a formula to determine hazard should be based primarily on the mass factors of population, automobile registrations, and street mileage. The result, however, should be modified by the factors that are subject to a direct control and that vary from one community to another in direct proportion as the treatment of correctable conditions is successfully undertaken.

Although traffic accident data at present available are neither searching nor accurate, there is sufficient information at hand to indicate that 30 to 40% of persons killed and injured by traffic are children. It further indicates that about one-half of all the persons injured or killed are pedestrians "jay-walking" between blocks, and that about two-thirds of these are children. Two conclusions are obvious, if all "jay-walking" could be stopped, presumably 50% of the injuries and deaths could be prevented; if children could be kept from playing in the streets or crossing in the middle of the block, it is reasonable to suppose that a large proportion of that group of injuries and deaths would be prevented. It seems clear, therefore, that any hazard formula would be incomplete if it failed to provide for modification to suit local variables when sufficient control is established over those accident-producing factors that

* From data comp. by Hawley S. Simpson, Jun. Am. Soc. C. E.

are subject to moderation. In any event, it is believed that hazard will tend to approach, as a limit, the base values which depend on the mass factors of population, registrations, and street mileage, and which may be considered as the inevitable and unavoidable price of progress.

If, as in the paper, "hazard" refers to all classes of vehicles and if it may be measured by insurance rates, then such insurance rates must be the average charge for insurance per car for the various hazards insured. This average charge for insurance must then be the total insurance paid by cars of all classes, divided by the number of cars. If this is the case, it does not seem proper to predicate conclusions with respect to hazard in general on insurance experience and rates, for the following reasons:

(1) It is generally understood, although not definitely confirmed, that less than one-half the motor vehicles in an average community are insured and that the percentage varies.

(2) The lower the rates, the greater are the number of insured and the less is the average individual risk.

(3) As the rates are increased, the preferred class of risk drops out until, as in New York City, the rate is so high that there is an undue percentage of bad risks.

(4) The majority of cars insured in cities, such as Indianapolis, Ind., are private, and may be expected to cover less than 10 000 miles per year; whereas the majority of cars insured in a city like New York are commercial and have a mileage range from 25 000 to 100 000 miles per year in the case of many taxicabs. Hence, if the degree of hazard is to be established, all vehicles involved must be included in the calculation.

If it is true that higher rates do cause the preferred risk to drop out, leaving the costly risk, and so on in a vicious circle, and if many drivers who are greater risks cover many times the average mileage of a lesser risk, is it not reasonable to assume that insurance experience is not an exact measure of a hazard of the city as a whole, but reflects instead an unbalanced situation?

This brings in the matter of automobile club insurance competition in such cities as Chicago, Los Angeles, San Francisco, and Detroit. These clubs have the advantage of a membership fee, and sell their insurance to members at a very low sales cost and, it is assumed, without profit. In all these cities insurance rates are exceedingly low. For example, in Detroit the Automobile Club began selling insurance in March, 1922. Conference rates, to which Mr. Cox refers, continued without change through 1923, but, in 1924, public liability insurance on a Ford dropped 30%, on Buicks, 32%, and on Cadillacs, 31 per cent. The other cities referred to are understood to have had a similar experience.

It seems reasonable to conclude that the insurance companies are subject, not only to variations in risk, but that their rates are subject to the same competitive conditions which cause price variations in gasoline. If this is so, insurance rates cannot be taken as an accurate basis for measuring automobile accident hazard.

As a general conclusion, the paper suggests that: "The variation expressing the personal injury hazard * * * as population divided by street

mileage, adds a warning against such degrees of congestion of population as prevail in almost all older large cities." Again, "the diffusion of population leads to a decrease in the number of possible collisions per unit distance of travel and thereby reduces hazard". And, finally, "most automobile collisions with pedestrians occur in residential districts." These statements seem to be contradictory since, for the most part, residential districts are areas in which the population is diffused.

Recently, some one asked the head of a large insurance company to state where, in his opinion, was the safest place. His answer was, first, on a railroad train; and, second, at the crossing of 42d Street and Fifth Avenue, New York, when it is carrying a maximum load of traffic.

It seems reasonable to suggest that, under conditions either of congested movements of vehicles or pedestrians, the hazard per unit vehicle or pedestrian is reduced, although the total reported accidents may be increased. In general support of this conclusion, Fig. 4 has been prepared from 1926 figures furnished through the courtesy of W. A. Van Duzer, M. Am. Soc. C. E., Deputy Engineering Executive of the Pennsylvania State Highway Department. This diagram shows the volume of traffic and the number of accidents for each hour of the day. From this information the degree of hazard (accidents, in terms of traffic) is determined. The curve indicates a rising hazard as the density of traffic decreases. It is reasonable to suppose that the declining density of traffic is, in part, responsible for this increase in hazard.

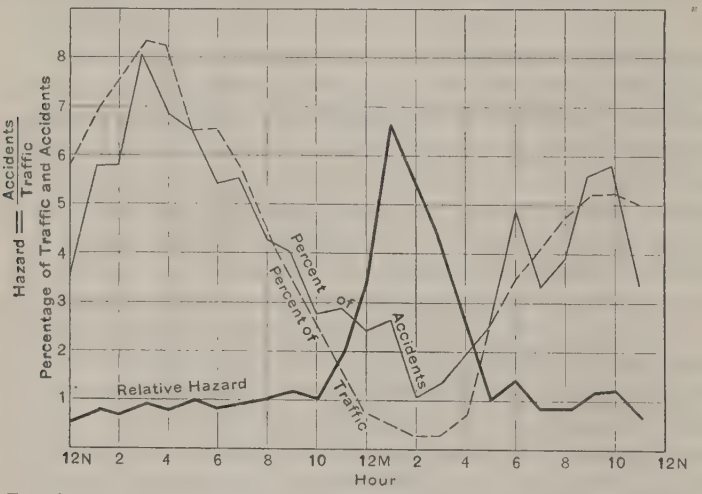

FIG. 4.—ACCIDENT HAZARD BY HOURS, PENNSYLVANIA STATE HIGHWAYS.

Mr. Cox is to be commended on his effort to clarify a subject which is shrouded in the fog of confusion, misinformation, and opinion. It is the speaker's conclusion, however, that he has not included all the factors necessary, in his formula, and that, although insurance rates and experiences are an index to the hazard experiences of selected classes and groups of cars, they are of doubtful value in measuring the hazard of a whole community.

RAYMOND A. O'HARA,* ASSOC. M. AM. SOC. C. E.—That automobile hazard may be reduced by proper planning, is recognized if not appreciated. Roads on which intersecting highway grades have been separated minimize the chance of accident. Good examples of this type of highway are the Bronx River Parkway, extending from the northerly end of Bronx Park in New York City to the Kensico Dam in Westchester County, New York, and the highway being constructed by the New Jersey State Highway Department to connect with the Holland Vehicular Tunnels. The proposed West Side Elevated Roadway in Manhattan is another example.

There is a relationship between building bulk and automobile traffic. Replacing buildings of low heights with higher buildings brings additional traffic into the district. Further congestion and increasing hazards may be expected with increasing building bulk. Traffic control signals have played a part in the reduction of accidents and fatalities.

JOHN A. MILLER, JR.,† ASSOC. M. AM. SOC. C. E.—Where comprehensive traffic regulations have been adopted, as Mr. Cox points out, the accident hazard often is worse than in other cities. This suggests that the method of regulation is not always well suited to the needs of the situation. In New York City, for example, an elaborate system of traffic signals has been installed. Unfortunately, however, they are so operated that many of the beneficial results which might easily be obtained, are lost.

Several shortcomings stand out prominently. Signals all flash simultaneously over long stretches of important thoroughfares. Thus, all traffic on these streets starts and stops at regular intervals. There is no speed at which the driver of the vehicle may go and be assured of making continuous progress. Naturally, he tries to cover as much ground as possible while the signal is clear. This leads to excessive speed and many dangerous attempts to "beat" the lights.

In other cities this difficulty has been overcome by the installation of lights operated on a progressive or wave plan. In essence this is nothing more than alternation of the lights in groups of two or more, so that a vehicle starting when the light changes to green can proceed at a regular moderate pace throughout the entire area controlled without stopping, successive groups of lights changing to green as the vehicle approaches them. Under this system traffic as a whole moves faster than under the system used in New York, but excessive speed is penalized. From the point of view of reducing the accident hazard, it has marked advantages over the synchronized signal system.

Another glaring defect of the New York traffic signal arrangement is its failure to adjust the time intervals to suit conditions at the individual intersections. Traffic is held up very frequently when there is no cross traffic on the intersecting street. This constitutes an altogether unnecessary delay and slows up vehicular movement. The detrimental effect of synchronized signals was practically admitted by the Police Commissioner when he asked for an appropriation to extend the system. He said that the installation of lights

* Prin. Asst. Engr., Regional Plan of New York and Its Environs, New York, N. Y.
† Editor, *Area*; Associate Editor, *Electric Railway Journal*, New York, N. Y.

on any street caused the drivers of vehicles to avoid that street and use a parallel thoroughfare. This he wished to discourage by equipping the parallel street with similar signals. Such lack of adjustment of the system to meet actual needs causes disgust with the whole arrangement and frequent disregard of it.

This leads directly to the third weakness of the system now in vogue in New York City—its slipshod enforcement by the police. Where traffic officers are present, they sometimes enforce immediate compliance with the signals, sometimes allow vehicles to "steal" a little on the light, and not infrequently make no attempt at all to see that the signals are obeyed. Where no traffic officers are present, a majority of the drivers of vehicles obey the lights, but a large minority ignore them. From an accident standpoint this creates a hazard at least as great as, if not greater than, that which would exist without the signals.

Thus, it appears that two things are urgently needed to improve traffic control in New York City: First, an engineering study to determine the most efficient type of signal system, and how it should be operated; and, second, more careful enforcement of traffic regulations.

T. Kennard Thomson,* M. Am. Soc. C. E.—For more than sixteen years the speaker has done some work nearly every day on a plan which, it is hoped, will not merely reduce, but almost eliminate, the automobile hazard.

It is almost needless to point out the intolerable condition of New York streets—where one can often walk a mile quicker than he can ride—to say nothing of the accidents. There is no reason why the city should not have buildings as high as it wants, as many people as can occupy the buildings without congestion of the sidewalks, streets, or transit lines, and without the enormous cost of subways, which now is about $9 000 000 per mile.

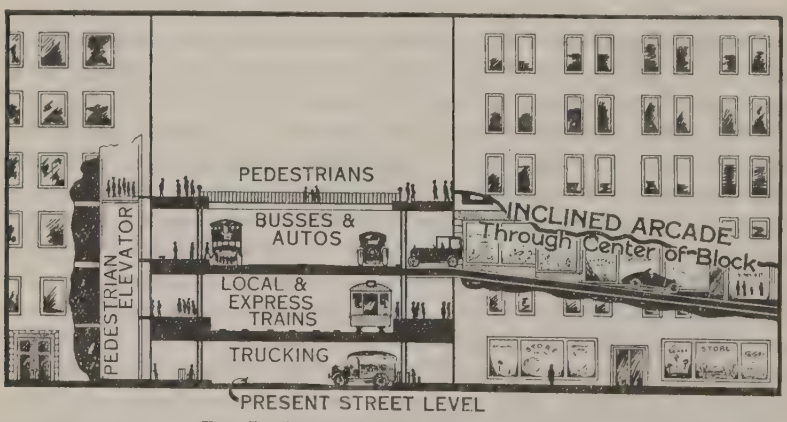

Fig. 5.—Proposed Rapid Transit Plan.

The city cannot raise money to build enough subways to eliminate the congestion. The remedy which the speaker has been advocating for many

* Cons. Engr., New York, N. Y.

years is multiple streets (one over the other) with separation of different kinds of traffic and the ultimate elimination of subways for passengers. Subways never should have been built, for five streets above ground can be built for the cost of one subway.

Fig. 5 shows a plan for three elevated streets (not viaducts) above the present grade. The ground or present street level of the avenues is to be reserved for trucking; the next level for transit lines, with the local cars running close to the sidewalks, allowing the passengers to observe well-lighted shop windows all the way. This level, as well as the one above it, will have elevated sidewalks so that one cannot step in front of automobiles or transit lines.

Access from the third or automobile level to the present ground line will be by inclined arcades through the centers of the blocks, giving four sidewalks where two now exist. At first, these inclined arcades should be placed a mile or two apart. Later, they may be installed wherever the property owners are willing to beg or pay for such accommodation, which means, eventually, every block.

The most valuable floor of a building is the ground floor—this plan gives four ground floors. By leaving the present cross streets as they are, there would be natural ventilation every 200 ft. on the two lower levels of the improved avenues. These levels would have perfect artificial lighting. The third, or automobile, level, and the fourth (sidewalks only), would have sunlight.

When first the speaker started these plans most people laughed at him. Later, there were various attempts to appropriate his plans bodily.

The speaker is always interested, although sometimes skeptical, in discussions on zoning. To advocate, as some very prominent men have done, that areas within New York City be laid out with very narrow streets, which will never permit thoroughfare traffic, would result in the value of the land being restricted to that for a two or three-story building—would be confiscation.

Even the multi-millionaires scrap their marble mansions when the value of the land becomes high enough. One man built what was then the highest building in New York, and at once tried to convince people that no one else should be allowed to put up a high building. When zoning becomes confiscation it is time to pause.

W. W. CROSBY,* M. AM. SOC. C. E. (by letter).—The proper location of highways, the writer has long contended, is fundamental to reducing or relieving many highway difficulties, including those of highway safety. Location shares with zoning in a recognition and understanding of the kinds of traffic to be provided for; it comprehends, as does planning, the automatic segregation of traffic; the avoidance of congestion when and where necessary; the question of speeds; and the widths of highways, as well as alignment of the roadway.

As to "hazards" and "safety", at this time when such a highly scientific consideration of a common public matter is being carried on, a note of warning

* Cons. Engr., Coronado, Calif.

should be sounded. People should remain unemotional in considering this matter, strongly as they may be impelled for a while to personalize "safety", in order to bring home to the Nation, through the individual, the need for action to attain a lasting public benefit.

"Safety first" does not seem to convey the meaning elsewhere that it has in the United States. In America, highway safety began with the "watch-your-step" injunction of the New York subways and surface railways. That this had as a basis the safeguarding of the financial interests of these corporations against liability for personal damages can hardly be denied. There followed the somewhat broader "safety first" with its personal and individual appeal.

The Parisian practice of arresting the pedestrian run down by a vehicle in the streets of that city, and charging the unfortunate with "disturbing traffic."* may sufficiently exemplify the basis on which European ideas of safety on the public roads seem to rest and from which foundation the present attitude has been developed in the European capitals, where most highway problems are older and, in some ways at least, better understood.

A study of the reports of the Fifth International Road Congress (Milan, September, 1926) impresses one with the recognition, apparent in the minds of the higher road authorities, of the public interest in the secure (safe) and steady (economic) flow or circulation of all traffic over the highways. The thought and effort seem to be toward "the efficient utilization of the highways with the greatest possible integrity of the most rapid circulation practicable"; first, by means of engineering expedients, and, second, when necessary, by supplementary general regulation. As long as it is consistent with the ends in view, the public is left unhampered in the choice of its means of highway use. Interruption of the personal choice of transportation, or other use of the highway by the individual, is imposed only where reliance on the individual responsibility, for his own and the general welfare, cannot longer be satisfactory to the community.

Mr. Cox has given a scientific treatment of what is so often regarded as a psychological or sociological problem. He brings out with astonishing clarity the functions of the engineer and proves his theories with intelligible mathematics. The elimination of some of the indefinite factors in these problems and the resolution of others into mathematical equivalents strike the writer as both logical and ingenious—well worth imitation and development.

Theodore T. McCrosky,† Jun. Am. Soc. C. E. (by letter).—In reducing the complex problem of automobile accident hazard to mathematical terms, the author has found a formula which gives a gratifying agreement with the "actual hazard", as determined by insurance companies for rate-making purposes.

The author deduces that, from a public liability standpoint, the hazard is proportional to $\frac{P}{M}$, for any given city, and hence is independent of the number

* Highway Code, Article 55.

† Asst. Engr., E. P. Goodrich, New York, N. Y.

of automobiles in the city. Some cities have a large concentrated population, but very few automobiles. The value of the hazard, H, would be high, as given by the formula, $H \propto \frac{P}{M}$. There are many such cities in Europe, in which, automobiles being scarce, the accident hazard is necessarily low.

Mr. Cox has proved that, for 1922, street width, good motor vehicle laws, and efficient handling of traffic are quantities which appear as mutually compensating in the majority of American cities of more than 200 000 population; and, consequently, need not be taken into consideration as variables in the problem. In the case of the other cities, he has taken up these three auxiliary factors as accounting for discrepancies between calculated and actual hazards. In the practical application of his formula, it would be hard to predict when these variables would compensate.

The writer believes that these three variables, as well as the registered number of automobiles, should appear in the formula, because all four of these considerations have changed greatly since 1922, and are becoming increasingly important.

Streets are being widened in the congested parts of cities where sidewalk widths permit. There are rigid motor vehicle laws in many more States than the four listed in 1922. The scientific regulation of traffic has increased enormously, but it is far more efficient in some cities than in others. Since 1922, the automobile registration in the United States has increased more than 80 per cent.

The writer fears that the author, in his praiseworthy attempt to reduce the problem to simple terms, has somewhat overshot his mark by omitting from his analysis these unknowns which, unfortunately, should no longer be neglected.

R. S. Kirby,* M. Am. Soc. C. E. (by letter).—The author has made a keen analysis of a pressing and intricate problem, from an actuarial standpoint, using a type of mathematical reasoning not so familiar to the average engineer, and the result comes out as a formula. Engineers delight in formulas, but are chary about using them unless they are reasonably familiar both with their antecedents and with their consequences.

Concerning the author's basic formula, $H = \frac{P}{M}$, a number of facts should be kept clearly in mind:

First.—The whole discussion has to do with fairly large centers of population, where less than one-half the automobile accidents occur. In less thickly settled localities this problem assumes quite a different aspect; there are fewer street intersections, and a much smaller proportion of pedestrians to cars.

Second.—The author centers his discussion about automobile accidents in which pedestrians and automobilists are injured or killed. An accident in which both cars were hopelessly wrecked, if providentially no one was injured,

* Associate Prof., Eng. Drawing, Yale Univ., New Haven, Conn.

would not figure in his analysis at all. Neither, apparently, would an accident in which the driver was killed, or any of the occupants of his car. This is, of course, confining the argument within narrow limits and excluding a large percentage of what are commonly thought of as automobile accidents. For example, in 1926, in the entire State of Connecticut, out of every 100 accidents reported to the Motor Vehicle Commissioner, 65 involved damage to property only and 35 resulted in injury to a person, either in a car or on the street. Of all the accidents reported, only about 15% were collisions with pedestrians. Of the persons killed in Connecticut in 4 years, 55% were pedestrians. The percentage of pedestrians among the injured was about 45. Of course, in large cities, all these percentages are quite different.

Third.—Dealing with the problem as one of insurance, the author entirely neglects the large number (about 50%) of uninsured cars, dismissing them with the statement that "there is no reason to believe that the hazard created by an insured car is materially different from that created by an uninsured car; * * *". Of course, it is yet too early to draw any certain conclusions from experience with compulsory insurance.

Fourth.—Concerning the natural deductions from the $\frac{P}{M}$ formula, it is, of course, not logical to assume that the expression holds true for all possible values of the variables. If P were zero, as in remote country districts, there might still be automobile accidents, from cars passing through. Accidents caused by out-of-town and out-of-State cars form nearly one-half the total each year in Connecticut towns. The writer understands that another implication, and a justifiable one, is that if P were doubled, the hazard per car would be doubled, but the total number of accidents would be quadrupled. If the miles of improved road could be doubled over night, the number of accidents to-morrow would not, necessarily, be altered at all. This is partly because, as the author states, "a majority of collisions between automobiles in the average city occur at a comparatively small number of intersections." What effect, then, could a sudden increase in mileage in outlying sections have on traffic hazards in crowded tenement districts?

From his own experience the writer can thoroughly appreciate the author's difficulties in securing, from different localities, accident statistics which are exactly comparable. For example, the author's discussion considers only the number of injury accidents. The number of persons injured may be considerably greater and is more usually recorded.

What is a motor vehicle accident? The various States are not uniform in their definitions. Connecticut, for example, requires the reporting of all accidents which result either in any personal injury or in property damage to an apparent extent of more than $10. Other States neglect property damage accidents entirely. This illustrates only one phase of the difficulties in securing comparable statistics from various cities. Uniformity in this matter is a long way off, and some of the statistics that the author needs in order to substantiate his reasoning are available only in a very few cities, if at all. Engineers are natural born statisticians and can help in keeping such facts before the public.

The author states emphatically that the variation in hazard between different cities is not caused by differences in automobile congestion or in the effectiveness of traffic control. However, in the case of Boston, Mass., may it not perhaps be that both these factors contribute, each in its own way, to reduce the local hazard?

The latter portion of the paper, in which certain methods of reducing accidents are most concisely outlined, should have been expanded. For example, the main motor-vehicle arteries of the future will not pass through the centers of any towns. This involves intelligent engineering, and is vastly more important than much of the minor puttering and patching which is being done. A decided reduction in accidents can be brought about by intensive local public campaigns designed to crystallize public sentiment against three practices. Of these, the first is speeding, or driving too fast for conditions. The second is unnecessary driving in congested areas, or using the public highways for trivial errands. The third is a lack of consideration for the other fellow, be he on wheels or on foot. While these three practices are not engineering matters, nevertheless, the engineer, as a private citizen, can do much in his quiet methodical way to better conditions.

All the author's suggestions concerning the use of streets as playgrounds, particularly in tenement districts, are reasonable. Autoists of the future must, perforce, give up many more of their "rights" for the common good.

Drivers are responsible for three-quarters of all automobile accidents (including collisions between cars), at least that is the conclusion of the Connecticut Motor Vehicle Department which has had long experience in determining primary causes. When drivers are trained to concentrate their attention on their driving, to have a decent regard for ordinary rules of the road, and to drive so carefully that their cars need never skid, two-thirds of the automobile accidents will have disappeared.

The State of Connecticut held pedestrians to have been at fault in 74% of the pedestrian collisions last year. The 1926 percentage in Massachusetts was estimated at 37 for non-fatal collisions and 25 for fatal, a wide divergence, due probably in large part to varying methods of analysis.

Lee S. Trainor,* Assoc. M. Am. Soc. C. E. (by letter).—This paper is most valuable and presents clearly the existing automobile hazards in cities and the major points of traffic control affecting these hazards. The writer wishes to call attention to a few factors of particular importance to municipal engineers.

In a paper before the Society of Automotive Engineers, T. R. Agg, M. Am. Soc. C. E.,† emphasized the fact that whereas vehicles were formerly designed to fit the road, to-day pavements are built to suit the vehicle. Several points in the relationship of pavements to the vehicles operating on them, should be given consideration.

The type of street pavement and its condition has an important bearing on the safety with which traffic moves. A street can hardly be considered as

* Mgr., Highways and Municipal Bureau, Portland Cement Association, Chicago, Ill.

† "The Design and Construction of Highway Systems," *Journal*, Soc. of Automotive Engrs., Vol. XXI (August, 1927), p. 200.

giving efficient transportation service unless the pavement on the street is in such a condition, from curb to curb, that vehicles are given the uninterrupted use of the entire width of the thoroughfare. A poor street pavement, the surface of which is irregular, or spotted with holes, offers a hazard to passing vehicles which is often difficult to surmount. Bad holes or rough places cause vehicles to deflect from their line of travel into another line, creating a hazard for oncoming vehicles. It is important, therefore, that heavily traveled thoroughfares be provided with pavements that retain smoothness of surface and that can be maintained with minimum expense and the least interference to the normal flow of traffic. The Keystone Automobile Club, of Philadelphia, Pa., reports that the City of Philadelphia expends $500 000 per year in damages for accidents caused by defective pavements.

Congestion of traffic in large centers of population is mounting more rapidly each year. Unfortunately, the majority of the larger cities in the United States were laid out and developed long before traffic congestion had become a problem. The unprecedented growth of the motor industry and its allied industries, which has produced the present-day volume of traffic, could not have been imagined at that time. Consequently, the street systems of the larger cities have become antiquated and do not render full transportation service.

Because of the lack of proper street width, congestion presents a traffic hazard that is most difficult to overcome. American cities have grown at such a rapid rate that street widening in densely populated areas has become an expensive operation. Congestion is truly a sufficient cause for providing main arteries of traffic with such pavements that the maximum service of the existing width can be obtained. Many American cities are spending millions of dollars annually for street widening in order to reduce the hazard of congestion.

Blind corners, short-radius street intersections, and poor visibility, especially at night, are other hazards encountered by traffic in metropolitan areas. Even the color of a pavement affects the safety of moving vehicles, especially at night. A dark pavement has a tendency to absorb the rays of headlights to such an extent that the limits of the thoroughfare are but dimly defined. It is also more difficult to see pedestrians and parked vehicles at a safe distance. The same is true concerning the amount of light perceived from vehicles approaching from the right or left at street intersections. A light-colored pavement reflects the rays of the head lamps, thus outlining the course for a greater distance ahead. A light-colored pavement also creates enough contrast to give a clear outline of parked vehicles or other hazards that may be placed at the curb. During wet weather, such a pavement is especially conducive to safety because of the contrast in color with surrounding objects.

Heavily traveled arteries should be provided with pavements that are reliable under all conditions. Skidding and sliding with locked wheels are the causes of many accidents on congested thoroughfares. Safety on the boulevard has become more than a matter of good tires and good brakes.

The characteristics of pavement surfaces must be considered. Any pavement that becomes slippery when it is wet is a source of danger often beyond the control of the driver. A rough and bumpy street often induces skidding as tires lose contact with the surface.

Starting and stopping must be accomplished rapidly, and the pavement must do its part perfectly if the hazards are to be reduced. The surface should be such that it will not be slippery and cause skidding on sudden application of the brakes. It should be sufficiently gritty to provide a grip for the tires, and bring the vehicle to a stop as quickly as possible. A pavement surface of this character is especially beneficial during wet weather. On steep grades it provides enough traction to make ascent easy and safe, and on descent provides sufficient tractive resistance to prevent skidding or side sliding. Such a surface automatically provides hazard elimination for the motorist. The construction of streets and pavements suited to present-day traffic is of material assistance in reducing automobile hazard in cities.

Sidney J. Williams,* M. Am. Soc. C. E. (by letter).—This paper by Mr. Cox is the first real attempt to develop a scientific formula for the occurrence of automobile accidents in cities. Like any other pioneer job, this method is doubtless open to refinement at the hands of the author or some one else. Further information may correct some of the assumptions that Mr. Cox was compelled to make; but he has at least given all students of the subject something to "shoot at", and his careful and intelligent analysis constitutes a real contribution to the safety movement in the United States.

It would be very desirable to check the formula against data later than 1922 and to check the application of it to the changing experience of one or more cities from year to year.

Many things have happened since 1922 to affect accident causation and accident prevention on the highways. In various cities, there has been opportunity to observe the effect, on the accident record, of various changes in the traffic control situation and in the state of public opinion. It has been found that, in fact as well as in theory, the accident record of a city can be vitally affected by factors other than those stated in the basic formula developed by Mr. Cox; for example, by better traffic regulation and by the right kind of public education. Cities are beginning to accumulate statistical evidence, covering a period of years, to show that continuous and properly organized educational campaigns can be depended on to reduce the accidents in a community just as they do in a factory.

Aside from definite safety educational campaigns, there is the element of the general public attitude toward law enforcement. As a native of the State of Wisconsin, the writer feels able to say with some assurance that the attitude toward law observance in that State and in the City of Milwaukee is very different, and much better, than in the State of Illinois and the City of Chicago, for example. This is probably one reason for the accident record in Milwaukee being better than anticipated, as shown in Mr. Cox's paper. In

* Director, Public Safety Div., National Safety Council, Chicago, Ill.

fact, the writer feels that the general public attitude toward law observance and accident prevention will be found to have an even greater effect on the accident experience of the community, than the street mileage or any other engineering factor. The statisticians and engineers of the National Safety Council, for example, are just beginning to obtain data on which to make quantitative studies of these complicated and important factors. These remarks are in extension and not in criticism of Mr. Cox's excellent paper.

A. B. BARBER,* M. AM. SOC. C. E. (by letter).—This paper is a distinctly original contribution to the study of the automobile accident and traffic problem and is of special value because of its method of approach. It establishes, in mathematical form, facts that have heretofore generally been supported only by opinion. It is teeming with suggestion, both in and between the lines.

No one who has seriously studied the traffic problem will be surprised at the deduction that, H, the hazard from the operation of the individual automobile, varies directly with population, P. Unfortunately, motor traffic is still generally so poorly organized and pedestrians still roam so freely over the street surface that the assumption of uniform distribution of both these elements is not a material departure from the fact.

The expression, $H \propto \frac{P}{M}$, suggests that H can be lowered by reducing P, or by increasing M. To reduce P signifies relieving a portion of the population (including those in cars as well as those on foot) from the hazard of individually threading their way among moving automobiles. This can be done in a variety of ways. The policeman at the corner with his stop-and-go signal; the school-boy patrol holding up traffic to let the children pass; the automatic traffic signal system; all these are means for decreasing the aggregate amount of the population subject to the hazard indicated in Mr. Cox's initial assumption. That they are successful is shown by the practical elimination of accidents on streets where traffic control is well established and enforced, by officers or by automatic signals. This, as Mr. Cox points out, is one form of traffic "segregation."

Pedestrian control also reduces the amount of the population, P, exposed to the automobile danger. Control, however, is objected to by some pedestrians as a violation of "inalienable rights", just as some motorists regard licensing of drivers as violation of their rights. Both are safety measures, the importance of which is just beginning to be realized.

Under Mr. Cox's formula, H may also be reduced by increasing M. While this holds for the purpose of this paper it may not be true as a permanent measure of accident reduction, for it is natural to suppose that any great increase of street mileage through decentralization or a general spreading out of the population would lead to such an increase of distance traveled per automobile as to require that new element to be taken into account. Proper city planning and zoning measures, however, would serve to offset this tendency. The modern conception of a city or metropolitan region contem-

* Mgr. Transportation and Communications Dept., Chamber of Commerce of the United States, and Director, National Conference on Street and Highway Safety, Washington, D. C.

plates the location of commercial, industrial, and other centers at appropriate widely distributed points, with housing and community facilites for employees in close proximity to each center. The working out of this conception should economize, not only time and expense of travel, but should also tend to reduce the accident hazard.

WILLIAM J. COX,* JUN. AM. SOC. C. E. (by letter).†—The writer's purpose in the presentation of this paper was not to create a finished document, nor to state a final word. Rather it was to open a new line of thought on the problem of automobile accidents, and to encourage thinking along more fundamental lines as to the basic factors in their occurrence. He feels gratified that the paper has aroused so much discussion.

The writer did not intend to suggest that the automobile accident problem cannot be influenced by other factors than the density of population. He did wish to show that density of population is the basic factor in determining the personal injury hazard of operating an automobile in a city. Other factors, some susceptible to statistical treatment, perhaps, and some not, may exert a modifying influence and should, of course, be given careful consideration in traffic control and accident prevention work; but, basically, the hazard level is a function of the density of population. The writer is satisfied in his own mind that this is the case, and has been pleased to note that most of the commentators on the paper agreed on this point. It was suggested by several of the discussors that more stress should have been placed on conclusions to be drawn from the principle that the paper set forth. It is the writer's feeling that to have done that would have enlarged the scope of the paper unwisely. The aim was, as stated, to call attention to the principle in the hope that it might encourage further work and thought on the part of others as to its applications and implications.

Among the many points brought to light was the particularly interesting discussion of traffic conditions in Washington, D. C., by Messrs. Stark and Eldridge. Mr. Eldridge is in a position to know the difficulties of traffic administration in Washington, but the writer is unable to agree with him that Washington streets are not well designed to carry the traffic. It is true that many of the streets in the city are narrow, but there is no reason why all the streets of a city, or even a majority of them, should be wide. Provided there is a sufficient network of arterial ways to carry through traffic, it is advantageous for several reasons that intermediate streets should not be too wide. Like all cities, designed before the invention of the automobile, Washington has an inadequate street system, but its streets are more nearly adequate for their traffic needs than those of any other large American city, and the distribution of business and population through the city is also unusually good.

Mr. Eldridge speaks of the hazard introduced by the convergence of a number of streets at certain points in Washington; as, for example, at Thomas and Scott Circles. The writer is not in possession of accident

* Asst. Prof., Dept. of Eng. Mechanics, Sheffield Scientific School, Yale Univ., New Haven, Conn.

† Now Assoc. M. Am. Soc. C. E.

statistics for these two localities, and they may be more dangerous than they appear, but he has repeatedly watched the streams of traffic converging on them and diverging, and has been impressed with the smoothness and safety with which they move. He finds it difficult to believe that such circles add to the street hazards of Washington.

Mr. Eldridge calls attention to the decrease in automobile fatalities and accidents in Washington from 1923 to 1926, and suggests certain causes, denying that the improvement was brought about by the planning of the city, etc. This is true. From 1923 to 1926 there was no marked shift in the planning of the city. The writer's paper was based on 1922 conditions; and the improvement subsequent to that time, which no doubt is due to the causes enumerated by Mr. Eldridge, is outside the scope of the paper. The planning of the city and perhaps the superior administration of traffic in Washington, even before Mr. Eldridge took charge, made it possible for the improvement to which he refers to be based on hazard conditions that were apparently already surprisingly good.

Mr. Stark, in vigorously dissenting from the views set forth by Mr. Eldridge as to the excellence of police regulation of traffic in Washington in recent times, makes a well-reasoned plea for a greater consideration of the pedestrian in traffic. He has convinced the writer of the error in stating that improved methods of handling traffic at intersections will have little effect on collisions between automobiles and pedestrians. He advances a sound argument that the effect, although indirect, is nevertheless present.

Mr. Williams also stresses the indirect connection between traffic hazards and "the general public attitude toward law observance and accident prevention". The writer recognizes the weight of Mr. Williams' judgment in this matter and the very great importance of the relationship he mentions. The writer does not believe, however, that any differences in this attitude of the public could exist sufficiently great to overbalance entirely the physical advantage of low population density. That is, he doubts if such an improvement in the attitude of citizens toward traffic rules in New York, coupled with such a retrogression in Indianapolis, could occur as to overbalance the differences in population congestion and place those cities on a par from an automobile-operation hazard standpoint.

Mr. Lewis is apparently confusing the fatality rate per unit of population and the fatality rate per automobile. All the data to which he refers are based on the automobile-fatality rate per population unit, while the writer's paper was a discussion of the hazard per car—the hazard of operating an automobile. This was found to be $\frac{P}{M}$. As Professor Lyle points out, the hazard per unit of population derived from this formula is $\frac{R}{M}$, which would seem to accord with Mr. Lewis' views.

Among those who discussed the paper, Mr. Kelcey was the only one to express marked distrust of the use of automobile liability insurance rates to measure hazards. There were probably other readers who felt about this

as Mr. Kelcey did, since there is a general disposition on the part of the public to suspect that insurance rates are established wholly competitively and are based on what the traffic will bear.

Mr. Kelcey's objections to the insurance rate as a measure were along three lines. He states that the proportion of taxicabs and commercial vehicles among the total number of cars insured in New York is much greater than in smaller cities, such as Indianapolis; that these public and commercial vehicles have much greater annual mileages than the average private passenger car, and, therefore, a greater annual hazard; and that, consequently, they distort the insurance rate of New York, making it unduly high in comparison with those of other cities where the proportion of relatively safe private passenger cars insured is greater. Mr. Kelcey's argument would be sound, granting his premises, if the insurance rate were established, as he assumes, by totaling the premiums paid by cars of all classes, and dividing it by the total number of insured cars of all classes in the city. Insurance rates are not made this way, however, but separately for cars of each type, private passenger, public passenger, and commercial. As stated by the writer, the private passenger car rate, being by far the most important and the most accurately determined, is the one selected as a means of comparison. The variation from city to city of commercial and public passenger car rates does not differ greatly from that of private passenger car rates, and no material error is introduced by selecting the latter as a standard. The fact that the ratio of insured taxicabs to insured private passenger cars is greater in New York than elsewhere, if true, is without force as regards this discussion.

A second question raised by Mr. Kelcey may be more pertinent. He suggests that, as insurance rates increase from cities of low hazard to cities of high hazard, the better class of risks drop out, leaving a higher proportion of "bad risks" in cities with high rates, thus continually raising the rates still higher. This is a view held by many people, but by no means universally; and among those who hold that there is such a tendency, opinion differs as to how marked and how important it is. Light will be shed on this question when the Massachusetts law, providing that every automobile must carry liability insurance, has been in effect longer. So far as the writer is able to learn during the few months of its existence there has been no decided indication that the addition of the large number of those formerly uninsured to those already carrying insurance, either in Boston, with its high rates, or in small cities in the State, where rates are much lower, has either raised or lowered the loss ratio; that is, the newly insured cars, taken as a whole, seem to be neither worse nor better risks, in any decided degree, than those formerly insured.

The most serious objection Mr. Kelcey raises is that insurance rates are established, in considerable part, by business competition. In substantiation of this, he instances that the Detroit Automobile Club began in 1922 to sell insurance to its members at a lower rate than that of the stock insurance companies, and that within the next two years the stock companies' rate

was reduced 30 per cent. He states that the Cities of Los Angeles, San Francisco, and Chicago "are understood" to have had a similar experience following the sale of automobile insurance by local automobile clubs to their members.

The loss experience sheets of the National Bureau of Casualty and Surety Underwriters show that on policies written in Detroit in 1922 the claim frequency was 4.0; that is, for every hundred policies written that year, 4.0 claims resulted. In 1923, this frequency dropped to 3.7, and, in 1924, to 3.0. Correspondingly, the insurance rate dropped 25% from 1922 to 1926. Thus, the rate trend followed the claim frequency trend, and no competitive influence of the automobile club is apparent.

In Los Angeles, claim frequency dropped from 4.4 in 1922 to 2.6 in 1924. The 1922 claim frequency was abnormally high, so that the improvement trend has not been so great as appears from these two figures alone. Since 1922, insurance rates have declined 20 per cent. Here, again, while a decline in rates has occurred, as Mr. Kelcey states, it is less than the decline in the frequency of claims. If the Automobile Club of Southern California has played a part in rate reduction, that part has consisted in its valuable hazard-reducing work in the traffic education field.

In San Francisco, despite the existence of the automobile club to which Mr. Kelcey refers, there has been a slight increase in automobile liability insurance rates since 1922. In 1926, they stood 5% above the 1922 level. There has been no sustained trend in the claim frequency. It was 4.0 in 1922 and, again, in 1923. In 1924, it dropped to 3.0, but, in 1925, rose to 3.7. The average severity of accidents also appears to have been abnormally high in 1924 and 1925.

In Chicago, claim frequency dropped from 6.6 in 1922 to 6.5 in 1923 and 4.8 in 1924. The insurance rate declined 22% from 1922 to 1926. In none of these instances does the competition envisioned by Mr. Kelcey appear to have played a part in affecting the insurance rate level.

It is not the writer's view that public liability insurance rates make a perfect yard-stick for measuring hazard variations, but he does believe that they are decidedly the best measure available. He emphatically does not believe (and the figures support him) that insurance rates fluctuate competitively in the sense that gasoline prices do. Rates are not an immediate reflection of hazard fluctuations because they are damped (by the use of mathematical formulas, of country-wide application) to smooth out extreme peaks and hollows and, therefore, show only established, not accidental, trends. However, there is no question but that they are determined by such trends, rather than by business competition.

Mr. Kelcey apparently takes issue with the whole conclusion of the writer's paper that diffusion of population decreases the hazard of operating an automobile. He instances the infrequency of traffic accidents in the dense vehicular and pedestrian traffic at Fifth Avenue and 42d Street, New York City. He finds a contradiction in the writer's statements that, "diffusion of population leads to a decrease in the number of possible collisions per unit

distance of travel and thereby reduces hazard" and "most automobile collisions with pedestrians occur in residential districts." Residential districts, he states, are areas in which the population is diffused; hence, the contradiction.

The fallacy in Mr. Kelcey's reasoning is that sometimes population is diffused in residential areas and sometimes it is not. Who would say that the Lower East Side of New York was not a residential area and who would say that it was an area of diffused population? The fact of the matter is that most pedestrian accidents occur in residential areas, and that, as a rule, these areas are the congested, tenement districts of the residential part of the city as a whole. The writer mentioned this in his "Conclusions". Data since collected enable him now to illustrate the point numerically.

In New Haven, the highest class (single-family) residential area, where population is most diffused, is traversed by approximately 16 miles of streets. In this region, records of the Department of Motor Vehicles of Connecticut show that not a single pedestrian accident occurred during 1926. Approximately, 100 miles of streets traverse areas outside the central business district which are unrestricted for residential use. On these 100 miles of streets there were in excess of 200 pedestrian accidents in 1926.

Mr. Kelcey presents a diagram (Fig. 4), based on data from the State Highway Department of Pennsylvania, which, to his mind, shows that the more diffused vehicular traffic becomes, the more hazardous automobile operation becomes. His data relate to rural, not urban, conditions, and it is questionable whether they do not indicate the reckless character of the traffic on the highways at 2:00 A. M., as much as anything else. He is correct, however, in thinking that decreasing the density of vehicular traffic may add to the hazard of automobile operation. The explanation is obvious. A very dense vehicular traffic must be controlled; and a controlled traffic is a safe traffic. A diffused vehicular traffic becomes an unregulated traffic, and often becomes a high-speed traffic, which is correspondingly dangerous.

The writer has not urged that vehicular traffic be diffused. He has urged that population be diffused, and that in passing through areas of diffused population, vehicular traffic be concentrated in arterial ways into streams of sufficient density that their continuity may bring safety.

Professor Finch expressed the idea much more effectively than the writer. "* * * in attacking the street accident problem as it now exists in any city," he states, "it is important to diffuse population and to concentrate [vehicular] traffic." In other words, spread out population until the smallest possible proportion is encountered in a given street, and then put the largest possible proportion of the vehicular traffic through that street, regulating it as may be necessary. As Professor Finch points out, diffusion of population is often impracticable. Concentration of traffic is much less often impracticable; it is obviously good sense, but is often not done.

As an instance of this in the neighborhood of the writer's home, traffic on a "through" route traversing the city, has intentionally been routed over

several parallel streets, although the volume of it is not so great that one street could not handle it all. As a result, sparse streams of out-of-town vehicular traffic pass through an apparently quiet residential section at fairly high speeds and, without warning, come to a cross street carrying a fairly high speed and fairly heavy, but often intermittent, city traffic. Some of the worst accident corners in the city are the result. The through traffic should be gathered into a condensed stream on one street, freeing the parallel residential streets of it; and this stream should be controlled by lights or otherwise where it crosses other traffic arteries. Almost every city can show examples of the same failure to appreciate this law of safe street use.

A number of other worth-while points were brought out in the discussion. Mr. Cole called attention to the fact that nine of the cities shown on the writer's Fig. 3 have been doing organized street safety work for some years, and that seven of these nine cities had "actual hazards" lower than their "calculated hazards." This is very significant as an indication of the possibility of modifying the "natural" hazard level.

Professor Kirby calls attention to the very great need of more adequate and better organized statistics relating to street and highway accidents. Mr. Holleran and Mr. Johannesson deal interestingly with measures developed in their sphere of highway work to make highways safer. Space is lacking to comment adequately here on other points of interest.

Colonel Barber's discussion emphasizes, in words that will bear repetition, the fundamental importance of more satisfactory planning of cities, as follows:

"The modern conception of a city or metropolitan region contemplates the location of commercial, industrial, and other centers at appropriate widely distributed points, with housing and community facilities for employees in close proximity to each center. The working out of this conception should economize not only time and expense of travel, but should also tend to reduce the accident hazard."

As suggested, the street safety problem is tied up closely with the matter of the economical use of city streets; that is, with the basic economics of city life.

The problem of automobile accidents confronts the city as an existing condition. This fact has been often pointed out, and, unfortunately, people have already suffered enormously from the too great emphasis placed on it. In the last 20 years the population of most large cities in the United States has increased from 50 to 600, or more, per cent. There is reason to believe that such increases of urban population will continue to be typical. There is, therefore, every reason to give more constructive thought than has yet been generally given to the probability of such increases and to their street-traffic implications. By all means, cities should avail themselves of the expedients that Mr. Holleran's discussion enumerates and describes as palliatives rather than cures. However, with them they must give (and progressive cities are giving) increasing consideration to a more far-sighted view of future traffic needs and to the provision of the proper facilities to meet them.

Paper No. 1657

CONSTRUCTION METHODS ON THE MOFFAT TUNNEL*

By R. H. Keays,† M. Am. Soc. C. E.

With Discussion by Messrs. T. Kennard Thomson, H. F. Dunham, and Lazarus White.

Synopsis

This paper describes in detail the interesting methods used in the excavation of the Moffat Tunnel in Colorado. This work is really two parallel headings constructed at the same time, one a single-track railroad tunnel and the other a pressure tunnel for water.

There is also included a brief statement of the location and purpose for which the tunnels are built, as well as some notes on the financing of the work by the Moffat Tunnel Commission representing the Moffat Tunnel Improvement District, the form of contract for the construction, and the workmen's bonus plan.

The Moffat Tunnel is the longest railway tunnel in America, and the methods used in its construction are believed to represent the best present-day practice.

This paper was written before the completion of the project and describes methods used only up to August 1, 1925, at which date the headings were approximately 62% completed.

Selection of Site

For many years the general location selected for the Moffat Tunnel has been considered the best place, in fact, the only practicable location in Northern Colorado for building a railroad through the Continental Divide. At this point the approaches on both east and west sides are most favorable.

* Presented at the meeting of March 2, 1927.

† Chf. Engr., Ulen & Co., Athens, Greece.

At various times tunnels have been laid out at different elevations and of different lengths, the higher ones of course being shorter and having the merit only of relative cheapness. The Moffat Tunnel is at the lowest practicable elevation. Any further lowering would require a much longer tunnel and would not improve the alignment or grades of the railroad on either side of the Divide. The work is at an elevation of approximately 9 200 ft. and is 32 250 ft. long.

Physical and General Conditions

The tunnel is to be used by the Denver and Salt Lake Railroad—usually known as the Moffat Road—which has been in operation for twenty years. The original builders always had in mind that ultimately a tunnel would be built at this location, but were induced to locate a line "over the hill" as a temporary expedient. The gradient of the railroad from the East Portal to Denver, Colo., 50 miles east, is 2%, down-hill practically all the way. On the west side the grade from the West Portal to Tabernash, Colo., 9 miles beyond, is 2% down-hill and thence 1% down-hill to State Bridge, 60 miles farther on. As shown on Fig. 1, it is intended eventually to build a connection between the Moffat Road and the Denver and Rio Grande Western Railway, the so-called Dotsero cut-off. By developing the line between Tabernash and the West Portal (Fig. 2), it is feasible to build all the way from the Denver and Rio Grande Western Railway to the West Portal on a 1% ruling grade against the traffic. There is also a project on foot to build a connection between Salt Lake City, Utah, and Craig, Colo., the western terminus of the Moffat Railroad.

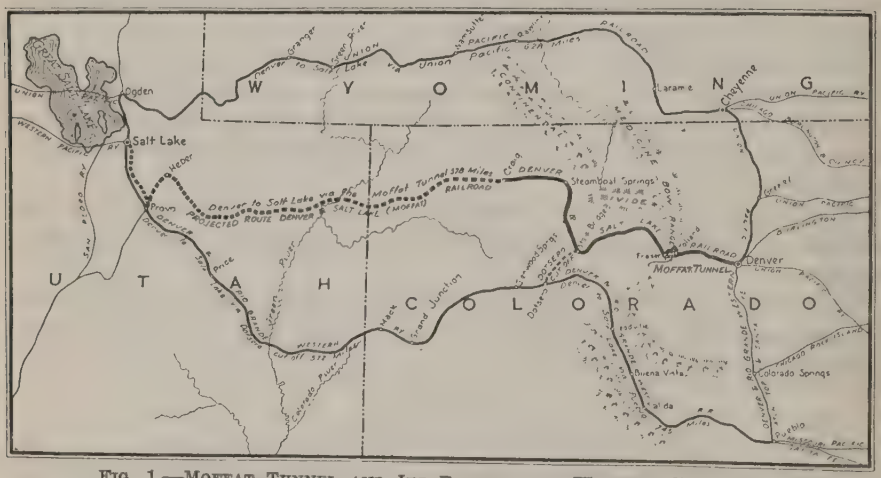

Fig. 1.—Moffat Tunnel and Its Relation to Western Railroads.

The line "over the hill", however, is built on a 4% grade from a short distance above the tunnel elevation to the summit at Corona, Colo., an elevation of 11 660 ft. Snow, ice, and wind conditions are not serious matters up as far as the elevation of the tunnel, but above this point the conditions

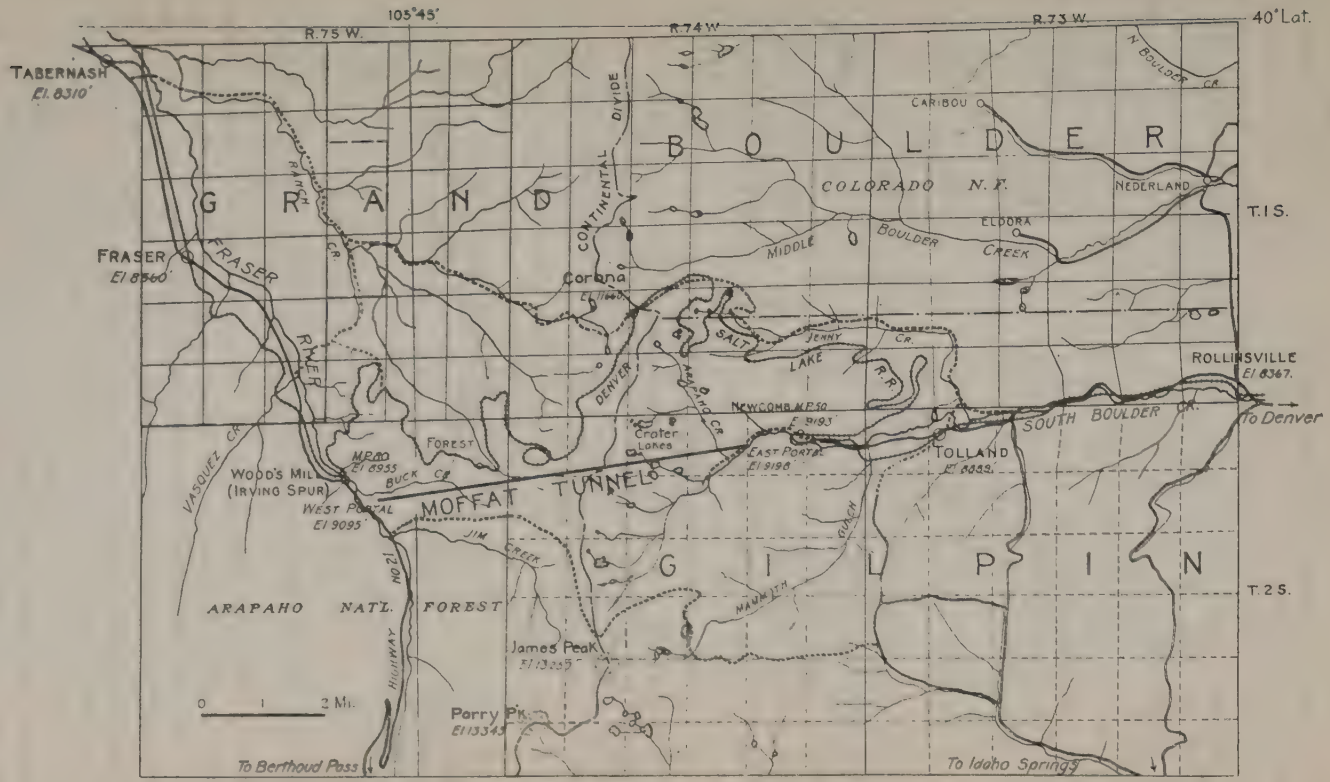

FIG. 2.—LOCALITY MAP, MOFFAT TUNNEL.

become much worse up to the top of the range. The significance of a 4% grade at such altitudes is perhaps not fully realized without taking into account the difficulties added by the weather conditions. These are perhaps at their worst in March and April, the first warm days of spring causing some melting of snow which in the form of water finds a natural channel following the rails. At nightfall, or on entering a snow-shed, this flowing water freezes, covering the rails with ice, which no snow-plow can remove; in addition to which there are snow drifts 20 ft. deep caused by winds as high as 90 miles per hour. A trip over this section in winter is truly an adventure, and as to the cost of operating "over the hill", it is stated that 41% of the entire operating expenses of the railroad are spent at this point on the line. The need of the Moffat Tunnel is thus obvious.

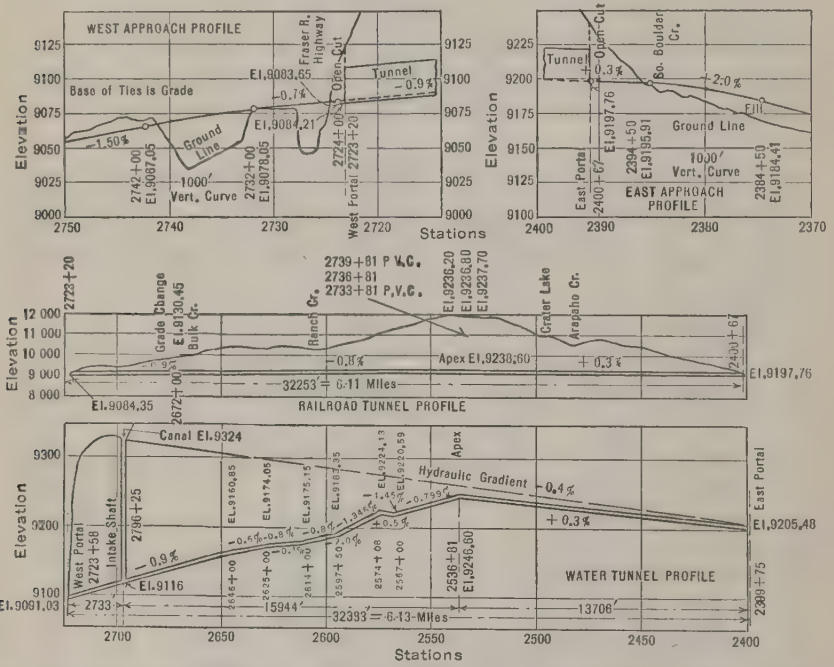

FIG. 3.—PROFILES OF RAILROAD AND WATER TUNNELS AND APPROACHES, MOFFAT TUNNEL.

Speaking now more particularly of the especial considerations governing the exact layout of the tunnel, it will be noted from Fig. 2 that the topography at the west end is somewhat lower than that at the east. The Victory Highway and Fraser River are important features at the West Portal and South Boulder Creek at the East Portal. The West Portal is located at a convenient elevation for building overhead approach bridges crossing the Victory Highway and Fraser River; and the East Portal is located so that the approach may be as low as possible without danger of flooding the track by the waters of South Boulder Creek, and so that the disposal of muck would interfere as little as possible with the outflow from the water tunnel.

The grades in the tunnel itself (Fig. 3) were fixed with the idea of running to an apex near the middle to provide drainage during construction. This worked out as a 0.3% grade on the east end (the minimum required for drainage), and a 0.9% grade on the west end. At the request of the officials of the Denver and Salt Lake Railroad, the upper part of the 0.9% grade was later changed to 0.8 per cent. This threw the apex farther east, which, together with the fact that the work at the East Portal had advanced much faster than that at the West Portal, made it necessary to drive part of the tunnel down-hill.

The Moffat Tunnel is being built out of the proceeds of the sale of bond issues by the Moffat Tunnel Improvement District, a political sub-division of the State created for the especial purpose of building the Moffat Tunnel and leasing it for railroad purposes. This District is composed of the City of Denver and the whole northwestern part of the State. It was required by the law creating the District that provision should be made in building the tunnel for the conveyance of water from the western to the eastern slope of the Divide, as a prospective domestic water supply for the City of Denver, to the amount of 100 000 acre-ft. per year. It was decided by the Board of Consulting Engineers for the Moffat Tunnel Commission that this object could be best obtained by constructing a separate parallel and smaller tunnel for the conveyance of water only. Such a plan would incidentally enable both tunnels to be advanced simultaneously by the so-called pioneer, or better, the twin-heading method, a plan similar to those used on the Simplon and Rogers Pass Tunnels. Such a plan is very desirable for purposes of ventilation, if for no other reason.

The water tunnel was located 75 ft. south of the center line of the railroad tunnel (Fig. 3). In grade the center line of the water tunnel follows approximately the center line of the railroad tunnel. This design requires the west end of the water tunnel to be under pressure. The hydraulic grade originally designed to be 0.3% was later changed to 0.4 per cent. The necessary pressure at the west end will be obtained by constructing a shaft about 265 ft. deep (Fig. 3) to connect with collection ditches on the western slope. The shaft is located about 2 500 ft. in from the end. The water tunnel will be closed by a concrete plug west of the shaft, thus abandoning the west end of the tunnel which will have served no purpose except to facilitate the construction of the remainder of the water tunnel and of the whole railroad tunnel.

Geology of the Region and Its Effect

Briefly, the whole region is part of the great uplift of the Continental Divide. Practically all the rock in the immediate neighborhood of the tunnel is biotite granite gneiss. There are some pegmatite intrusions, particularly one directly at the West Portal, which determined the exact location of the portal as it was the only rock outcrop in this vicinity. In a long stretch of tunnel from the West Portal eastward the rock has been profoundly disturbed by geologic action probably incident to the mountain-making movements.

The pegmatite which extended in about 500 ft. from the West Portal turned out to be somewhat weathered. Thence, for 1 100 ft. the material almost resembled the output of a crusher, dust and all, containing enough water to form a cohering mass. There was some semblance of bedding planes, however, and practically all the fragments showed slicken-sided faces. For a further distance of 6 400 ft. the formation is different in that the faulting is more localized. The material in some of these faults was dry and crushed so fine that when exposed by blasting it would run into the tunnel like dry sand. Several of these faults, however, carried water in addition to the crushed material which complicated matters. As to soundness, however, the rock condition averaged considerably better the farther the headings advanced. To illustrate the irregular faulting in this formation, it was observed that the conditions at opposite points in the two tunnels only 75 ft. distant were invariably quite different.

As to the limit to which this faulted zone extended, it is interesting to note that east of the point where the abrupt western slope of the range near the summit intersects the tunnel grade the rock formation is relatively sound, which would indicate that the strata forming this slope extend to the tunnel grade. The eastward extension of these strata, all biotite granite gneiss, is terminated by a vertical fault at the crest of the range forming an eastward facing escarpment several hundred feet high. The escarpment is not continuous in this vicinity, however, being broken at intervals by several narrow granite formations extending eastward for various distances from several hundred feet to ½ mile. The eastern slope of these granite formations is gradual enough to form a path for access to the top of the range, which at the tunnel line is 12 000 ft. in altitude.

The eastern slope of the range, as may be seen from Fig. 3, is much more precipitous than the western. An interesting feature of the topography of the eastern slope is the so-called Crater lakes (Fig. 2) formed by glacier action, the water being dammed up by moraines of glacial till. It was rumored that some of these Crater lakes were bottomless which would mean water all the way down to the tunnel level. In reality all these lakes appear to be shallow. In one case, however, there was doubtless a connection between one of the lakes and the tunnel by means of a faulted zone. This was demonstrated in the latter part of February, 1925, when in blasting a round in the water tunnel at the East Portal a sudden flow of water was encountered, amounting approximately to 1 800 gal. per min. This water flowed down the ditch alongside the track in the water tunnel and was diverted at one of the cross-cuts to the railroad tunnel.

Unfortunately, however, the large quantity of silt carried by this water filled up the ditches, as a result of which the track in the water tunnel was flooded. As any flows previously met were trivial in quantity, the Crater lakes were suspected as being the source of this water. One of these lakes was directly above the leak, at a level about 1 400 ft. above the tunnel. Although it was during the middle of winter, men were sent up to investigate conditions but found the lake covered by several feet of ice. Digging a hole in the ice at a convenient point near the middle of the lake, which was 10

acres in extent and about 10 ft. deep, they dumped in a package of chloride of lime on the remote chance that some might be carried into the tunnel by way of the "leak". Strange to say tests of water two hours later in the tunnel showed the presence of the chloride of lime. After a few days the flow rapidly diminished to less than 100 gal. per min. This apparently was due to the silting up of the fissure, as a subsequent inspection of the lake showed no material lowering of the water level, and a further test with chloride of lime showed that the connection still existed between the Crater lake and the tunnel, the chemical coming through in 20 min.

At the East Portal the rock was granite gneiss and schist, and the bedding nearly vertical, the strike of the beds being at an angle of about 15° with the axis of the tunnel. This rock has been faulted somewhat, the faults following the bedding approximately. It is curious that at the fault where the flow of water was encountered in the water tunnel practically none was found in the railroad tunnel heading only 75 ft. away.

No minerals have been found in the excavations. The problem of high rock temperatures as in some of the Alpine tunnels, notably the Simplon, seems to be non-existent at the Moffat Tunnel. Therefore, not much attention has been paid to temperature measurements, but it is interesting to note that near the East Portal the rock temperature as measured in drilled holes was about 60° Fahr. 1 000 ft. in from the East Portal and 68° at a point 8 000 ft. from the portal where the cover was 1 400 ft. At the West Portal there was little increase of temperature with the greater cover, which was probably due to the cooling effect of descending ground-waters.

Overlying the unsound rock section near the West Portal for about 2 500 ft. from the portal the surface of the ground averages 250 ft. above the tunnel level. Over the greater part of this area the depth to rock is not known, although attempts were made before the tunnel was started to determine it. One test pit was sunk by hand in the overlying glacial drift to a depth of 75 ft. Progress was then so slow and expensive that a well drill contractor was employed to start a hole in the bottom of the test pit with a well drill outfit of the percussion type. Curiously enough, within 1 ft. of the bottom of the test pit, rock was struck—hard red granite—and after drilling a hole for 10 ft. into the formation it was claimed that this was ledge rock. To test this theory another hole was started near-by drilling from the surface through the glacial drift. Practically no progress could be made, however, and the hole was soon abandoned. By this time the tunnel was being excavated from the portal and no further investigation by borings was made. Other test pits in the meantime had been abandoned on account of water. The uncertainty of the position of rock at the West Portal was the cause of moving the tunnel at the west end 400 ft. south from the previously accepted location. This lengthened the tunnel slightly but gave considerably more cover with the likelihood of a greater depth of rock overhead.

This change in alignment was adopted in August, 1923, at which time the final layout was approved. This fixed the grades, the location of the water tunnel 75 ft. to the south of the railroad tunnel, and the shifting of the East Portal 75 ft. north of the previously accepted location, which last

change allowed more room on the south side of the canyon to take care of the waters of South Boulder Creek and the water from the water tunnel.

Form of Contract

On account of the hazardous nature of the work it was considered doubtful whether bids could be obtained from reputable contractors for constructing the tunnel on a unit price basis. Therefore, the law creating the Moffat Tunnel Improvement District and providing for the appointment of a Commission to go on with the work permitted the Commission to construct the tunnel with its own forces, or to make a contract for the construction on some other basis than the usual unit price method.

Specifications and plans were prepared, however, on the assumption of constructing the tunnel by contract on the unit price basis. Proposals were asked from reputable contractors on this basis, the bids to be submitted September 12, 1923.

However, no bids were submitted except one to which had been added qualifying conditions making it irregular. This bid was held temporarily for investigation and it was stated informally by the Moffat Tunnel Commission that the work would have to be done in some other way than by the straight contract unit price method. On this announcement about eight more informal bids were submitted made up in eight different ways, all being variations of the straight percentage contract or "cost plus".

These proposals were not solicited by the Commission and created considerable confusion as to their relative merits so that it was decided by the Board of Consulting Engineers, in consultation with the Moffat Tunnel Commission, to prepare a proposed form of contract on the cost plus basis and to ask bids thereon from only four of those who had previously submitted informal bids.

The governing features of this form of contract were as follows: Plans and specifications as already prepared were to be closely followed with the single notable exception that the work involved in handling "free flowing mud or sand or the influx of water in such volumes or temperatures as to render the work impractical without special drainage or cooling devices", was to be considered as extra work to be paid for in addition to the regular items of the contract. Ordinarily a contractor is required to assume such risks and in transferring the entire risk to the Moffat Tunnel District it was expected that contractors would be more inclined to submit bids.

Otherwise the form of a contract devised by the Board of Consulting Engineers can be described as a "cost plus a maximum and minimum fee" contract. The maximum fee was to be paid to the contractor in the event of the cost of the work being less than a certain assumed total upset price and the minimum fee in the event of the cost of the work being more than the upset price. The form of contract also contained a profit-sharing clause, namely, in the event that the cost of the work was less than the upset price one-half the saving was to be paid to the contractor as additional compensation. There

was also provided a time bonus and penalty on a daily basis for finishing the work before or later than a certain fixed date. All the extra work and all work not susceptible of classification under the regular items of the specifications were to be paid for at cost plus a percentage.

In asking for bids under this form of contract the total upset price was fixed at $5 250 000 on the assumption that the final estimated quantities would be the same as those proposed for the comparison of bids on the unit price basis. As the final quantities would no doubt differ from those in the preliminary estimate it was considered necessary to vary the upset price as the quantities varied. The bidders therefore were requested to submit a schedule of prices, which, multiplied by the estimated quantities, would amount to the upset price. The bidder was expected to make these prices reasonable in respect to one another, so that his proposition should not be rejected as being unbalanced.

Bonus, Fees, and Penalties

The time for the completion of the work was fixed at forty-six months from September 20, 1923. This would bring the contract date for finishing the work to July 20, 1927. The time bonus and penalty at the rate of $1 000 per day were to be calculated from this date.

It was further provided that all the work done and methods used were subject to the approval of the Chief Engineer of the Moffat Tunnel Commission, and that if the work were not prosecuted satisfactorily by the contractors the contract could be annulled by the Moffat Tunnel Commission.

For extra work the contractor was to be paid 5% of the cost thereof independently of all other provisions of the contract. All funds for every purpose were to be provided by the Moffat Tunnel Commission.

On these general terms the bidder was asked to state a maximum and minimum fee for which he would agree to supervise the work. F. C. Hitchcock, M. Am. Soc. C. E., and Mr. C. C. Tinkler jointly submitted a bid naming a minimum fee of $140 000 and made their maximum fee the same. This was lower than that of any of the other contestants and as their bid was satisfactory in other respects it was decided to award them the contract.

This form of contract has some novel features. In order to make these entirely clear several examples of total payments under various assumptions of cost and time required for completion are given.

1.—Presume that the final upset price is $5 200 000; that the actual cost including fee is $4 640 000; that the percentage work is $200 000; and that the contract is completed 100 days ahead of time. The contractors will receive:

One-half of savings in cost	$280 000
Fee (maximum)	140 000
Time bonus	100 000
5% of $200 000	10 000
	$530 000

2.—Presume the same final upset price, the cost as $5 500 000, the percentage work as previously, and the contract completed 100 days ahead of time. The contractors will receive:

No savings	.....
Fee (minimum)	$140 000
Time bonus	100 000
5% on $200 000	10 000
	$250 000

3.—Presume the same conditions as in Example 1, except that the work is finished 100 days behind time. The contractors will receive:

One-half of saving	$280 000
Fee (maximum)	140 000
5% on $200 000	10 000
	$430 000
Time penalty	100 000
	$330 000

Time penalties, however, cannot operate to reduce the payment to the contractor, not including percentage work, below the minimum fee of $140 000. The large time bonus or penalty, $1 000 per day, represented at the time the contract was let approximately the cost of carrying the investment. On account of an additional bond issue sold to provide for an unlooked for increase in the cost of the work and also to defray the cost of supplementary work not included in the original contract, the value of speed of completion later became worth considerably more than $1 000 per day. Under these circumstances obviously a policy of energetic and rapid prosecution of the work was the only course. It is probably true that this policy was also the most economical in other respects.

To this end the contractors who, on being awarded the contract, organized the corporation of Hitchcock and Tinkler, Inc., to take over the work, decided to install the most modern and complete plant and equipment in all departments, to build, equip, and maintain high-class camps, and to pay wages and salaries high enough to attract the best class of workmen.

Construction Begun by Commission

On account of the urgency in getting the work under way the Moffat Tunnel Commission several months before the actual letting of the contract for the tunnel construction, had contracted with the Colorado Power Company for the erection of a transmission line from its power-house on Boulder Creek to the East Portal of the tunnel and thence over the Divide to the West Portal, and also for the furnishing by the same company at both portals of electric power at 44 000-volt, three-phase, 60-cycle, alternating current. The Commission had also authorized the beginning of camp construction and

opening up the portals of the tunnels by hand, which work had been started as early as the middle of July, 1923. Some of the heavy machinery had also been ordered to insure delivery before winter.

General Plan of Operations at the East Portal

The details of the water and railroad tunnels, both unlined, are shown in Figs. 4 and 5. A view inside the water tunnel is shown in Fig. 6. The work of preparation of the water tunnel for the actual carrying of water was not included in this contract.

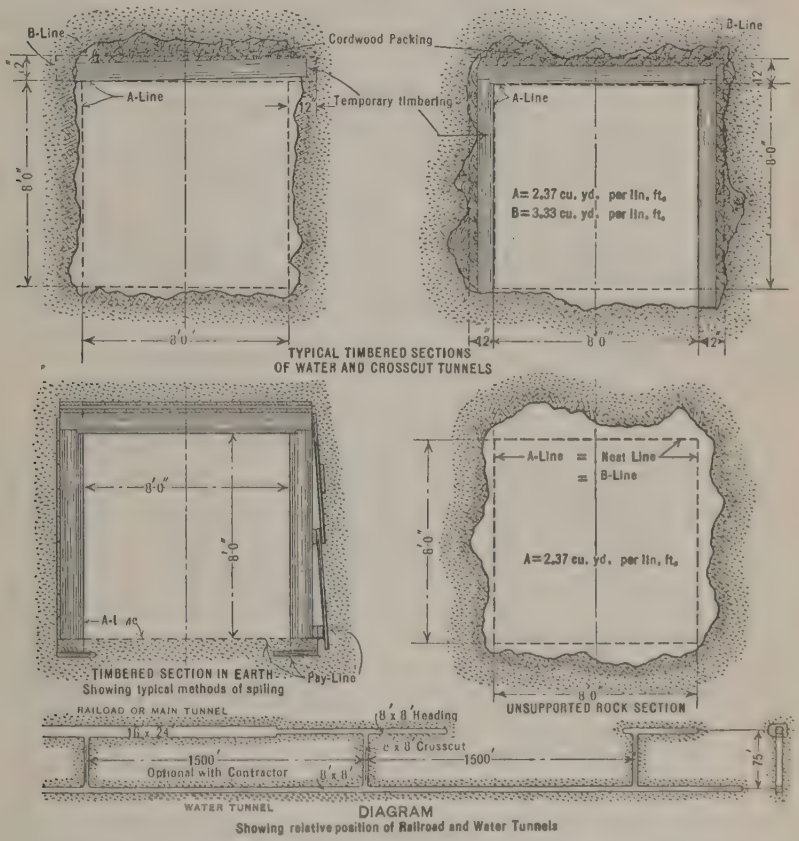

Fig. 4.—Water Tunnel Sections, Moffat Tunnel.

It had been recommended by the Board of Consulting Engineers that the grade of the water tunnel should be at mid-height of the railroad tunnel, on the assumption that the water tunnel would always be in advance of the railroad tunnel, and that cross-cuts could be driven at convenient intervals from the water tunnel to the center line of the railroad tunnel from which point another heading was to be driven, called the main heading of the railroad tunnel, and located on its center line both for line and grade (Fig. 5). This main heading of the railroad tunnel was to be of the same dimensions as

the water tunnel, was to be driven both ways from each cross-cut, and all operations in the main headings were to be carried out by obtaining access through the cross-cuts (Fig. 4). At a convenient distance back of the face of the main headings ring-drilling operations were to be carried on for the enlargement of the main heading to a full-sized railroad tunnel.

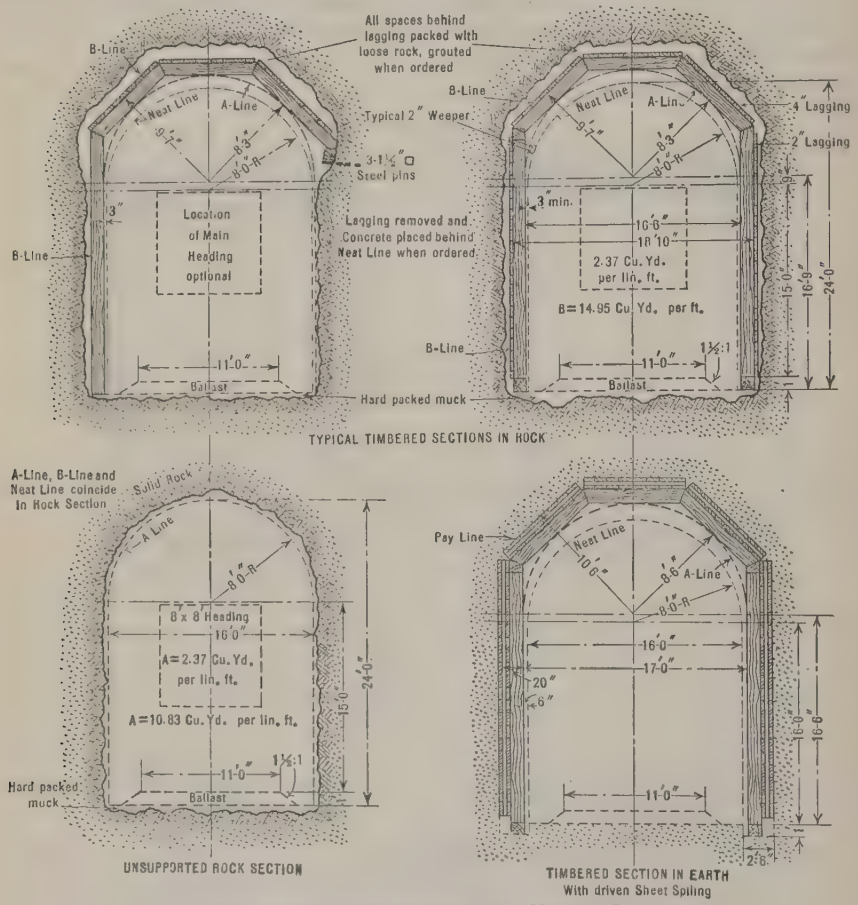

FIG. 5.—RAILROAD TUNNEL SECTIONS, MOFFAT TUNNEL.

DRIVING HEADINGS, EAST PORTAL

Some doubt was expressed that this was really the best way. It was not considered a proved fact that the small water tunnel could really be driven faster than the railroad tunnel, for at this time hand-mucking operation in the water tunnel was the only method proven to be entirely feasible. Hand-mucking, as a matter of fact, was the only method used for several months, and the writer finds in his notes a statement to the effect that an average progress of 15 ft. per day was probably all that could be expected under the circumstances. However, at this time there had been developed in the lead mines of the Flat River, Missouri, District, the so-called Conway loader.

After investigation several of these loaders were purchased and proved to be a great improvement over hand methods of mucking. By the use of these machines an average progress of 24 ft. per day could readily be obtained. This result fully determined that the water tunnel could be driven faster than the railroad tunnel. Nor was this the only good feature connected with the use of the loaders. It was soon evident that a mucking crew could load out all the broken rock from a heading in about the same time that a drill crew operating four drifter drills could set up, drill, and blast a standard round, nominally 8 ft. long. This led immediately to the adoption of the so-called "alternating method" of excavation wherein the main heading was driven only one way from a cross-cut, and the drilling and mucking crews alternated between the water tunnel and the single main heading. In this manner each crew had the field to itself for a period of approximately four hours, and great economies in labor were possible because none of the men in one crew found it necessary to wait on the other operation. Then, too, a spirit of competition was introduced between the two crews as to which could finish first.

Where each heading is driven independently both crews are in the heading at the same time and there is more or less interference. To minimize the interference the method of drilling is entirely different—only two drills are used, working from a single horizontal bar instead of four drills from two columns; and a different layout of the drill holes is necessary for the reason that to save time as few holes as possible are drilled in the lower half of the tunnel.

After shooting, the heading is full of muck about two-thirds of the way to the roof. The drill foreman assigns one of his men to scale the roof and the remainder of the drill gang level off the top of the muck pile so that a horizontal bar may be set up about 3 ft. from the roof. On this bar two drills are mounted and drilling is commenced immediately. In the meantime the mucking crew starts work and loads out the broken rock until the men get close to the bar when it is necessary to stop so as not to interfere with the drillers. The drillers continue drilling from the upper position of the bar until all the holes accessible from this position are finished. A horizontal V-cut or pyramid cut at the bottom of the heading is used.

The drill crew then removes its equipment and the mucking crew resumes work, cleaning up the heading. The drill crew then sets up its bar at what is called the lower position and drills 4 or more holes at the bottom of the heading, thus completing its work.

In the alternating method, with four drills working from columns in a heading free from muck, about 26 holes are drilled, making a regular vertical V-cut. The adoption of this method, giving each drill crew a clean heading in which to start work immediately, provided an ideal condition for using a drill carriage on which all the equipment could be mounted. With the older method all the equipment was moved by hand. Fig. 7 shows how the drill carriage operates. The horizontal bar, when in operating position, is jacked against the walls of the tunnel. The bar carries four arms, on

each of which a drill is mounted. These arms are long enough for the drills to be placed in any position in the heading. When drilling is finished, the bar is turned on a vertical axis mounted on the end of a long cantilever extending forward from a small truck. In this turned position the drill equipment will clear the walls of the tunnel. For transportation to and from the heading, the drill equipment is drawn back by a sprocket chain and sheaves to a position immediately over the truck.

With such a mounting the bar and column arms are made much heavier than in the case of equipment intended to be worked by hand. This arrangement diminishes vibration and increases drilling speed. An automatic oiler and drill manifold are mounted on this same truck.

By the use of this carriage the average elapsed time from the arrival of the drill crew in the heading until the air was turned on the drills was 15 min. as against 40 min. in the case of hand-operated equipment.

The Conway loader (Fig. 8) is probably better adapted on the whole to the particular problem of loading muck in these headings than any other machine. In considering the choice of a shoveling machine the speed with which a car can be loaded is perhaps the least important qualification. The method of placing empty cars in position to be loaded is perhaps the most important. In the operation at the Moffat Tunnel a muck car with a capacity of 50 cu. ft. could be loaded under favorable circumstances in less than 1½ min., while it took about twice as long to remove the full car and place an empty one in position. This situation could be improved somewhat by using cars of larger capacity, which, in turn, since the car is attached to the loader while being loaded, would probably require that the back and forth motion of the Conway loader on the track be geared lower to diminish the strains incident to the rapid reversal of direction. All the cars were equipped with spring couplings.

The Conway loader is particularly good at loading scattered or so-called "fly" rock, which is really quite important. It is a rugged simple machine. Among its disadvantages are its limited range of operation on either side of the track and its ability to load only on a practically straight track.

Transportation to Headings

The transportation equipment used in the headings included storage battery locomotives, having a 3-ton chassis with Edison batteries, and 4-ton General Electric trolley locomotives. The muck cars were of 50 ft. capacity, having steel bodies dumping to one side only with an angle of dump of 37° and roller-bearing wheels. The track was of 2-ft. gauge and the rail 40 lb. to the yard. Special flat cars were used for other purposes, particularly for transporting drill steel and men. These locomotives also served the ring drilling and other operations in the main heading but were used mainly only as gathering locomotives. All the long-haul work was done by 4-ton trolley locomotives operating in the water tunnel from the portal to the last cross-cut, at which point switching arrangements were such that transfers were readily made. All the trolley locomotives operated on 250-volt direct current.

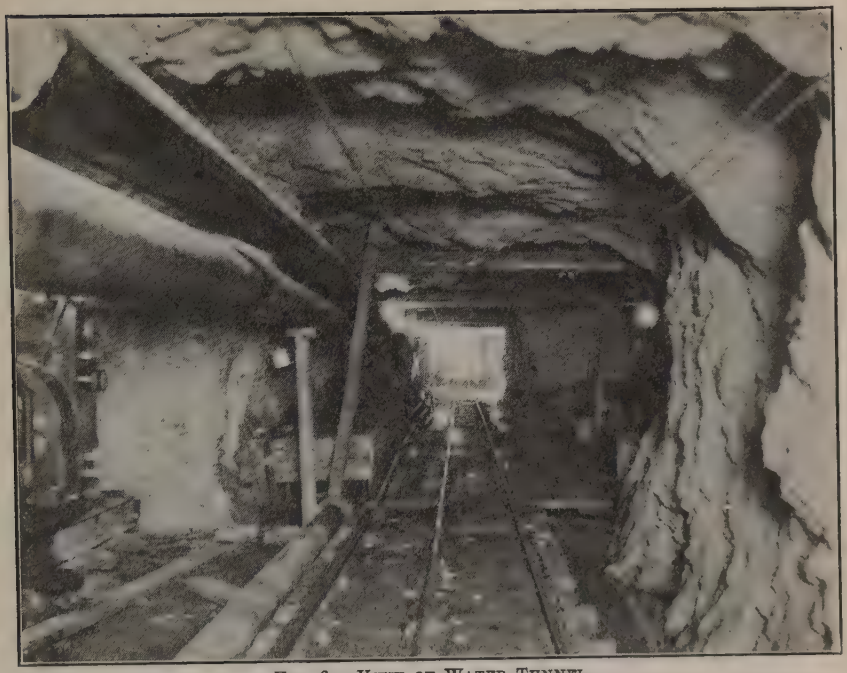

FIG. 6.—VIEW OF WATER TUNNEL.

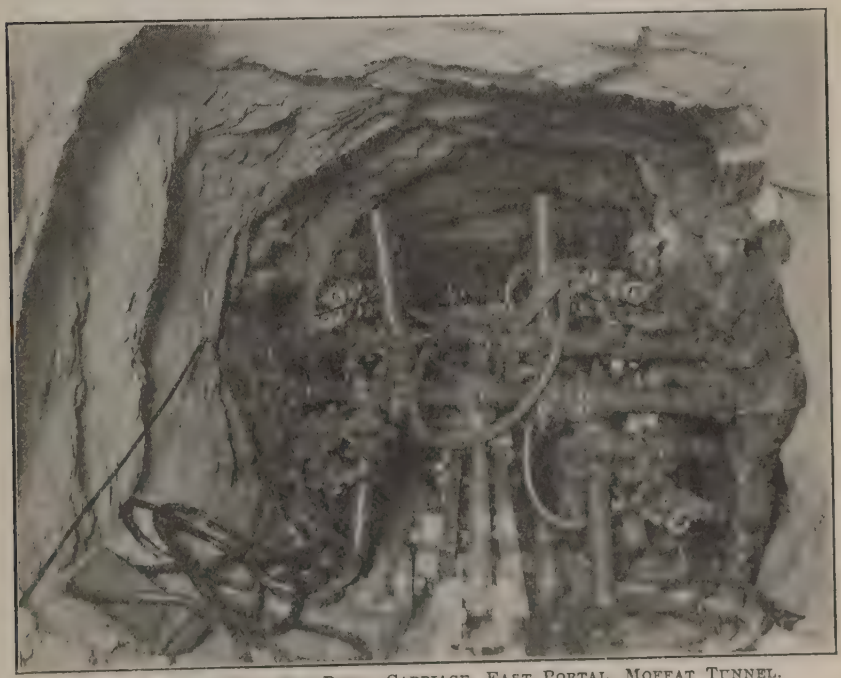

FIG. 7.—VIEW SHOWING DRILL CARRIAGE, EAST PORTAL, MOFFAT TUNNEL.

FIG. 8.—MOFFAT TUNNEL, EAST PORTAL, SHOWING CONWAY MUCKER IN WATER TUNNEL DURING FLOOD.

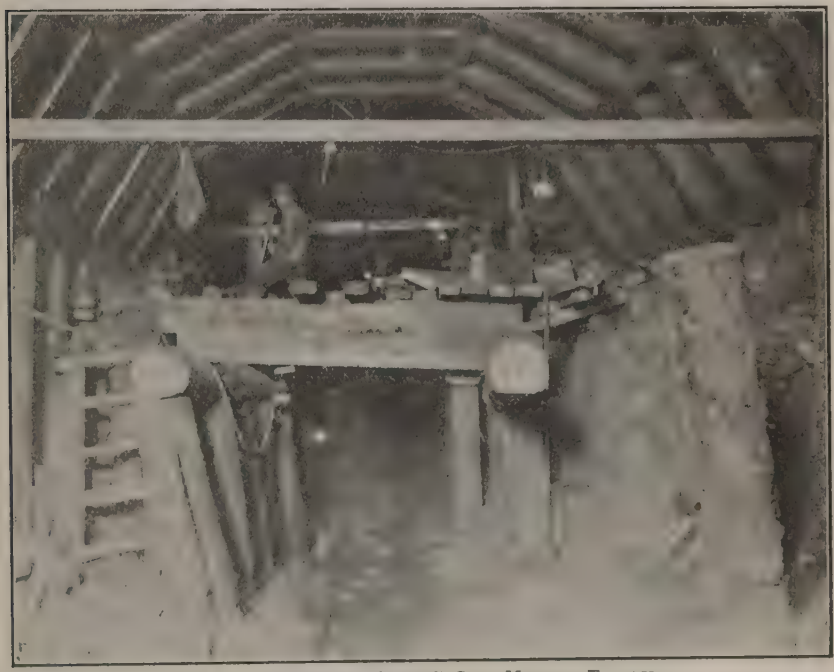

FIG. 9.—VIEW OF "JUMBO" SET, MOFFAT TUNNEL.

Power for all operations in the tunnel was brought in on a 2 300-volt, three-wire, lead-covered cable. This voltage was used directly to operate 65-kw. motor generator sets generating 250-volt direct current for the trolley service and also for the Conway loaders and for low-pressure fans forming part of the ventilating system. It was also used directly to operate 100-h.p. motors direct-connected to pressure blowers forming part of the ventilating system. For lighting purposes the 2 300-volt current was transformed to low-voltage alternating current. The use of high-voltage current in this way in the West is very general and quite successful.

Auxiliary Heading Method

An auxiliary tunnel to facilitate excavation has been used on a larger scale on two other tunnels—the Simplon Tunnel and Rogers Pass Tunnel—while in an incidental way it has been used no doubt in many other cases.

In the Simplon Tunnel the auxiliary heading, which was later to be enlarged to a single-track railroad tunnel, was at the grade of the bottom of the main tunnel, which was driven by the bottom-heading method, and the functions of the auxiliary heading were entirely devoted to ventilation and transportation. In view of the tremendous difficulties encountered, due to excessive heat and hot water, its use as such was indispensable. No attempt was made to keep the face of the auxiliary heading at a point opposite the main heading.

In the Rogers Pass Tunnel the purposes of the pioneer tunnel were the same as in the Moffat Tunnel—to facilitate transportation and ventilation and at the same time to afford a means of access to the ring-drilling operations (which were first used on the Rogers Pass Tunnel). No mucking machines were used, however, all mucking being by hand, and the headings were driven independently of each other.

In driving the Moffat Tunnel the auxiliary heading proved particularly useful in avoiding inevitable delays, due to encountering areas of unsound rock usually crossing the tunnel at a small angle. If the railroad tunnel had been excavated without the aid of the water tunnel, these unsound areas would have caused great delay and expense due to the time necessary to place the timber. These areas were found in no less than fifteen different places, requiring timbering in lengths varying from a few feet to 500 ft.

Handling Unsound Rock

All this unsound rock was readily excavated and timbered far in advance of the regular enlargement operations. Access to the work was obtained through one of the cross-cuts, thus interfering in no way with the ring-drilling or steam shovel work of the regular enlargement operations.

The method of excavating and timbering these areas was to build in the main heading throughout the unsound area a so-called "jumbo" (Figs. 9 and 10), which was merely a succession of heavy timber square-sets covered on top with heavy lagging. Under the protection of these timbers, transportation could be carried on without interference. The rock overhead was then stoped down and loaded by trapping methods into muck cars standing under the

protection of the "jumbo". Timbering closely followed the excavation. Five-piece segmental sets of 12 by 12-in. timber supported on 12 by 12-in. wall-plates were used here. The wall-plates were set 19 ft. apart on a rock bench. This distance is 1 ft. more than standard—to facilitate setting the posts under the wall-plates in the subsequent operations. Wall-plates were set about level with the top of the main center heading. After all the over-head timber was placed and all broken rock taken out, down to the level of the top of the main heading, the "jumbo" was removed and the material at the sides then excavated and loaded into cars by hand. This excavation was carried down only to the level of the bottom of the main heading, leaving an 8-ft. bench of rock which was excavated as part of the ring-drilling and excavation operations.

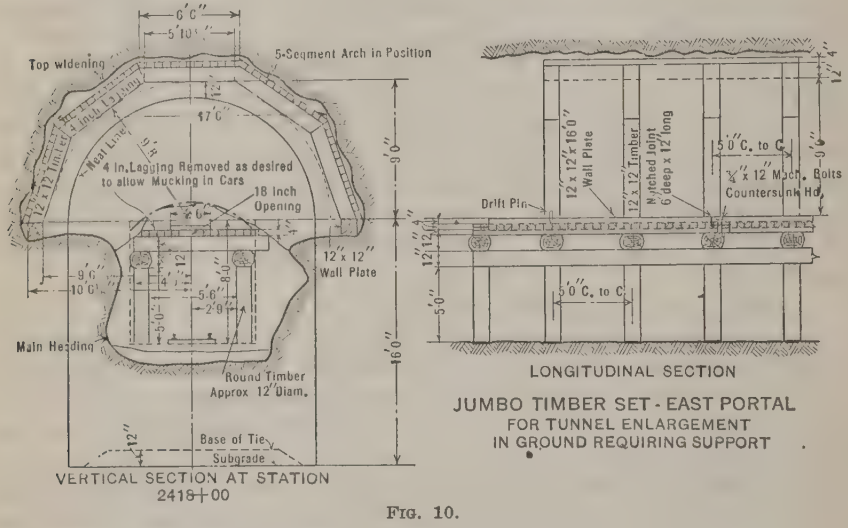

Fig. 10.

Enlargement Operations, East Portal

The standard method of enlarging the tunnel to full size at the East Portal was by the ring-drilling and shooting method. The broken rock was loaded into side-dump cars of nominal 4-yd. capacity, by a special railroad-type, Osgood, compressed-air shovel with a ¾-yd. dipper. Both cars and shovel ran on tracks of 3-ft. gauge. The dimensions of the shovel and cars were such that in a tunnel 16 ft. wide there was just clearance enough for the shovel to load a car alongside on a parallel track.

In the railroad tunnel 8-ton trolley locomotives were used. As in the water tunnel the trolley voltage was 250-volt direct current. The trolley wire was about 17 ft. above the top of rail, clearing the shovel, which was 16 ft. 7 in. high. For service close to the bench beyond the end of the trolley wire a reel was provided on the locomotive carrying several hundred feet of cable. Later, it was found more satisfactory to erect a temporary trolley wire along the sides of the tunnel on brackets at a low elevation, using an auxiliary trolley pole.

The Osgood shovel was operated by compressed air and was equipped with a compressed-air receiver. Otherwise, it was similar in design to a steam shovel of the railroad type, the dimensions being made as small as possible, particularly as to the boom and dipper arm. The shovel ran on a track made up in 5-ft. sections, a section being added as soon as enough broken rock had been removed. A small derrick was mounted on the rear end of the shovel for lifting empty cars spotted directly behind the shovel, to the loading track.

One locomotive ordinarily kept empty cars under the derrick while another hauled out the full cars and pushed the empty ones into the loading position. This second locomotive also hauled the loaded trains to the portal and returned with empty ones. Meanwhile, the switching locomotive took its place in serving the steam shovel, but before doing so it assembled a long train of empty cars behind the steam shovel, which were hauled under the derrick, as needed, by a small air hoist mounted on the back end of the steam shovel.

Ring Drilling and Shooting

One of the advantages of using an auxiliary tunnel in conjunction with a main heading is that it facilitates drilling and shooting for the enlargement of the railroad tunnel in parallel transverse rings (ring drilling). In the Moffat Tunnel, drills were set up in the main heading and holes were drilled in a radial direction perpendicular (or with a slight lift) to the axis of the tunnel. The depth of these holes was such that their bottoms were 6 to 12 in. outside the periphery of the completed tunnel. The holes were shot one ring (or rather two half rings) at a time, furnishing muck for the Osgood shovel to load.

In this method all drilling is done without interfering in any way with the shovel operations. Drilling may be carried on hundreds of feet in advance of the other work without interruptions. Access is obtained to the main heading through one of the cross-cuts, serving for piping, wiring and transportation of workmen, equipment, and supplies. The ring-drilling method contemplates the use of a main heading of minimum size (this being expensive work) and the enlargement to full size in only one more operation, giving a maximum amount of excavation to be handled by the economical air-shovel method. These advantages are important and outweigh the many disadvantages, to be mentioned later.

As a modification of this method it has been proposed to drive the heading at one side of the railroad tunnel instead of on the center line. This would facilitate drilling, in that there would be less holes, and blasting, in that the holes would be of more uniform depth.

It was also proposed to introduce another operation—widening out the heading to full width before the ring-drilling operation was carried on. The object of this was to minimize over-breakage on the sides of the railroad tunnel; to facilitate the drilling of the lower holes in the ring-drilling operation; to diminish the amount of rock to be blasted by the ring method (there being a tendency to have operations blocked by the large quantity of muck to be handled); to separate the bench from the roof, making it easy to shoot the

bench and roof separately; to enable a more rational distribution of holes to be drilled in the ring drilling; and to save in the use of dynamite.

However, the only change actually carried out was to drive the main heading 1 ft. lower than previously planned. This made the nominal bottom line of the heading 7 instead of 8 ft. above the sub-grade of the railroad tunnel, which had the effect of reducing the drilling of "down" holes mainly by making them shorter (there was little trouble drilling the upper ones) and of facilitating the breakage of the rock in the bench in the blasting operations. There was enough over-break in driving the main heading to furnish the necessary clearance for handling drill steels. The blasting of the roof was always comparatively easy, everything being in plain view with no muck in the way.

A great deal of experimenting was done by the contractors' organization in bringing this method to its final state of satisfactory operation. At the outset it was apparent that the shooting could not be done in complete rings. If there were no muck pile in the way, "fly" rock would be thrown far down the tunnel, making an endless task for the shovel in picking it up. On the other hand if a muck pile were allowed to accumulate high enough to stop the fly rock, which was absolutely necessary, then muck would fall down into the heading and cover several rows of holes not yet blasted.

Thus it was necessary to shoot the bottom part of the ring in advance of the top a distance of 16 ft., or four rings. This, in turn, introduced a bad condition at the sides of the main heading where the holes were short and did not have a good face against which to break, so that there was a tendency for rock from these holes to fly across the tunnel to the opposite side. There was also a tendency for muck to fall down in front of the lower bench in excessive quantities, leaving no place to which the rock from the lower bench could be thrown as the result of the blasting. This was especially true where the rock was relatively soft; frequently it became necessary to shovel away by hand a quantity of muck lying on the bench in order to load and blast the bottom holes.

It was customary to blast two rings at a time, that is, two upper half rings and two lower half rings. All the holes in the upper half rings were blasted in succession by the use of delay exploders. In the lower rings or bench the first row was shot with instantaneous or "no-delay" exploders and the second row with delay exploders. In order to throw the muck away from the bench as much as possible it was important to use instantaneous exploders for the first row, so that the explosion of all the holes would be simultaneous. Under these circumstances it was the usual program to have such an accumulation of muck in front of the bench at the end of a week or ten days that it was necessary to stop blasting additional rock and allow the shovel to clean up as closely as possible to the bench and then start all over again. Instances of missed holes and consequent "high bottom" of course would necessitate an immediate cleaning up. The bottom holes were loaded heavily, while the top holes were loaded with little dynamite.

FIG. 11.—RING DRILLING, MOFFAT TUNNEL, EAST PORTAL.

FIG. 12.—RING DRILLING, MOFFAT TUNNEL, EAST PORTAL.

The successful drilling of the rings was quite a problem particularly the drilling of "down" holes. It is absolutely necessary in drilling to have all the holes in the adjacent rings parallel and to have the holes in any one ring uniformly spaced and drilled to a depth at least 6 in. outside the periphery of the tunnel. The bottom holes are drilled at least 1 ft. outside.

In drilling "down" holes, heavy two-man drills of the jack-hammer type were first tried. These drills were so heavy to handle that it was impracticable to drill a hole in any other direction than approximately straight down, and although a mounting for them was considered, it was never tried. Standard drifter drills mounted on an arm on a column were then tried, but were not at all successful at first because the steel became jammed in the holes. This was remedied by arranging the water needle so that a large amount of air was forced through the drill steel in addition to the water, thus by the use of a home-made air siphon removing the water and rock cuttings from around the hole.

To remedy the difficulty in pointing the holes it was decided that the drills should be mounted on a column arm carried on a transverse horizontal bar (Fig. 11). Mounted on the column arm with the drill was an apparatus consisting essentially of two round disks about 4 in. apart, concentric about the column arm and at right angles to the axis of the tunnel. In these disks were pairs of holes drilled in such a way that a steel pin could be inserted in the two holes of a pair until the pin came in contact with the shell of the drill. The proper spacing of these holes gave the drill runner a ready means of pointing the drill. Spacing of rings about 4 ft. apart seemed to give the best results. For this spacing, the horizontal bars were set up 8 ft. apart and, by drilling on a column arm of such a length that the drill could be set up 2 ft. from the bar on either side, all the bottom holes could be drilled.

As shown on Fig. 13, two settings for the column arm were used to drill a complete set of bottom holes. This spacing was necessary in order to obtain clearance for handling the drill steels, and convenient in that it minimized the work of shifting the drills from one hole to the next and also the amount of mucking necessary to get a clear surface of rock in which to start the drill. This latter requirement was quite a problem, for, although the heading had been previously mucked carefully by hand, there was always further accumulation of rock débris, rock cuttings, and rubbish, and necessarily all depressions were always filled with water. In fact, this is one of the great disadvantages of the ring-drilling system, as the cost of this hand-mucking per foot of tunnel is more than one-half the cost of the air-shovel work. After the holes were drilled, they were plugged with a big wooden plug until ready for use.

The upper holes of the rings were always drilled with stoper drills. Air-feed stopers proved very satisfactory. As shown on Figs. 12 and 13, all these holes were drilled from one setting of the stoper on the center line. The stoper was mounted on a bar as in the case of the drifter drills. At first, the drills were mounted directly on a bar, which was of lighter weight than that

used for the drifter drills. This required a bar to be set for each ring. Later, however, the same bar was used as for the drifter drills, and the stoper was mounted on a column arm on the center line of the tunnel. In this way a bar set every 8 ft. sufficed. The pointing of the holes drilled by the stopers was facilitated by placing another bar several feet above the drill bar and parallel to it, on which were marks to show the alignment for each hole. Even with all these aids for the drill runners in the matter of pointing holes it was soon found necessary to have an inspector on each drill shift to check up and supervise the setting of the drills and drilling of the holes.

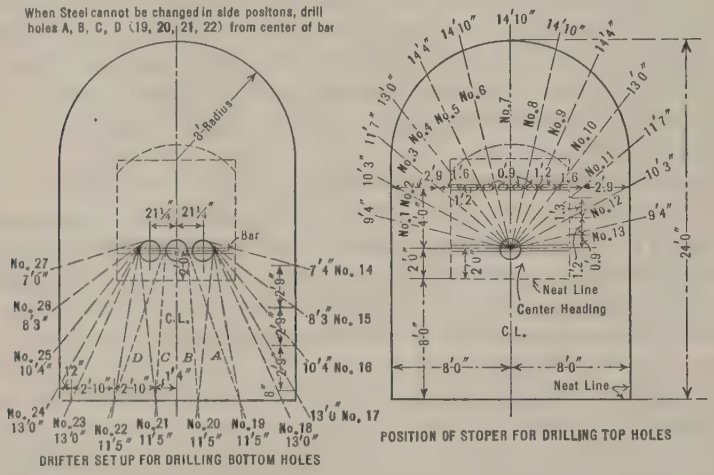

FIG. 13.—RING-DRILLING DIAGRAMS, RAILROAD TUNNEL, MOFFAT TUNNEL.

After all the experimenting the final methods for the enlargement work were very satisfactory. After lowering the heading 1 ft., and probably also due to the harder and better breaking rock, the blasting operations became quite successful in that it was no longer necessary to stop blasting operations at intervals of a week or more to clean up. Unless there were missed holes the blasting was continuous. The muck-pile was maintained just high enough so that there was no "fly" rock. The drilling and blasting were done so accurately that there was a minimum of over-break and trimming.

BLASTING OPERATIONS IN GENERAL

The headings were drilled as shown on Fig. 14. In blasting, 60% low freezing gelatin dynamite was used exclusively. "No-delay" and about four periods of electric-delay exploders were used. The "no-delay" exploders were used in the V-cut. The holes were connected in multiple, attachment being made directly from the lead wires to two copper bus wires, stretched across the face of the heading and supported on wooden pins. All the primers were prepared at the portal in the primer house and brought in with the dynamite. The drill gangs loaded and fired their own headings, although if the required time extended beyond the end of any shift the work ordinarily was completed by the succeeding shift. In the alternating system of driving these headings

the 8-hour period for each shift was rigidly maintained. Uncompleted tasks were immediately taken up by the succeeding shift. The air pressure was not even taken off the drills for a moment, operators remaining at their posts until relieved by the incoming shift.

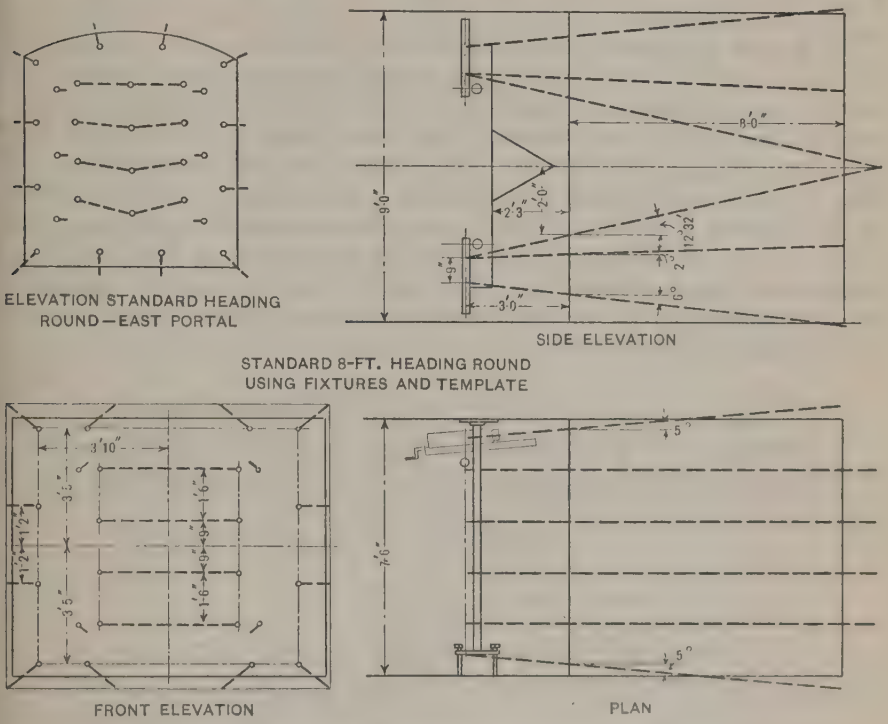

FIG. 14.—METHOD OF DRILLING HEADINGS, MOFFAT TUNNEL.

In the enlargement operations a special blasting crew was on duty most of the time. While two shifts were working on the shovel operation, this crew loaded and blasted as opportunity offered during meal hours and between shifts. Seldom was it necessary to interfere with the shovel. This crew also drilled and blasted any "tight" rock or "high bottom", and "scaled" the roof. It was necessary, however, to have a special trimming crew follow up at a convenient distance behind the shovel. In enlarging, 60% gelatin dynamite was used ordinarily in the bottom holes and 60% and 40% in the roof holes. These holes were connected in series. Two rings were usually shot at the same time by using no-delay exploders on the first ring and delay exploders on the second. It would be desirable to devise a system of shooting wherein the second ring or a third and fourth also could be shot simultaneously, so that the advantage of the greater effect of such shooting could be obtained.

VENTILATION OF EAST PORTAL

Perhaps the greatest advantage derived from the use of the auxiliary tunnel was its solution of the ventilation problem. Without it the products of com-

bustion of so much dynamite and the heat and bad air caused by the presence of so many workmen could hardly be disposed of satisfactorily. At this altitude the oxygen in 1 cu. ft. of air is only about two-thirds of that at sea level, and men seem to be much more easily overcome by dynamite fumes than at lower elevations.

In Fig. 15 is illustrated diagrammatically the layout of the ventilation system. Near the portal side of the nearest cross-cut to the headings a chamber was excavated at one side of the water tunnel, and between this chamber and the cross-cut an automatic door was installed, opening only for the passage of trains or workmen. Two low-pressure fans (No. 1 and No. 2, Fig. 15), each having a capacity of 12 000 cu. ft. per min., installed in the chamber, forced air from the water tunnel through a duct which opened on the other side of the bulkhead surrounding the door, and thus caused a strong draft inward through the water tunnel, thence through the cross-cut and outward through the railroad tunnel. The pressure against which these fans operated was never measured, but obviously it was small.

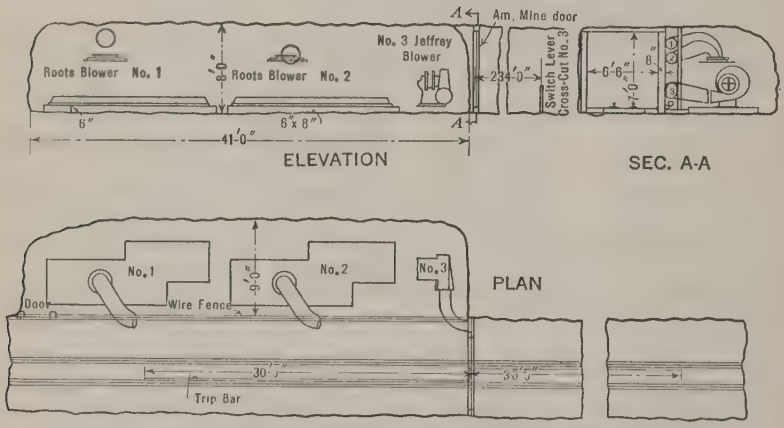

FIG. 15.—VENTILATION LAYOUT, MOFFAT TUNNEL.

Also in the same chamber was installed a blower (No. 3) with a capacity of 4 000 cu. ft. per min., designed for a pressure of 4 lb. This blower, working on the plenum system, took air from the water tunnel at this point and delivered it through a 12-in. pipe to a point near the headings of the water and railroad tunnels. By means of valves at the cross-cut the full capacity of the blower could be directed to either heading at will. This blower was operated usually only after blasting in the headings, to force the foul air back only as far as the first cross-cut from the heading, at which point it could be caught up by the strong current of air from the fans and forced out through the railroad tunnel.

The headings advanced so rapidly and the pipe was so liable to injury by flying rock that the end of the pipe was usually kept several hundred feet back from the heading. Under these circumstances, after blasting, high-pressure air was blown in from the drill line directly at the heading, which

expedient forced the foul air back far enough so that the 12-in. ventilator line could effectively dispose of it.

The bank of smoke emitted from the heading was so rapidly diluted as it came within the influence of the jet of air from the 12-in. ventilator line, vanishing into thin air as it were, that it was the firm conviction of all the workmen that the jet held the smoke in the heading. They, therefore, considered it bad practice to operate the blower until the smoke had passed the end of the 12-in. pipe. This is only one of the numerous superstitions prevalent among tunnel men particularly in regard to ventilation systems.

All other cross-cuts except the one next the heading, as long as they were in use, were provided with doors, after which they were sealed up tight. This insured against "short circuits" in the ventilation. In some instances the headings were allowed to advance a distance of two cross-cuts before it was necessary to move the ventilation system. In this the controlling factor was the capacity of the blower to force the requisite amount of air through the pipe. This blower was supposed to be able to supply 4 000 cu. ft. of air through about 1 mile of pipe, but leakage made it advisable to move oftener. The pipe was 12 in. in diameter, 20-gauge, with slip-joints. Extreme care was taken to make the joints tight, even by going so far as to put reinforcing rings on the inside in order that a joint of the Dresser type could be used. These connections were effective, but on the other hand it was found that even at the light pressure (4 lb.) all the riveted joints leaked also. In addition, the pipe was noisy, apparently because of the pulsating discharge of the blowers.

Even with this large amount of air for ventilation the condition was not entirely satisfactory in that the completed railroad tunnel between the bench and the portal remained so smoky as to interfere seriously with trimming operations and transportation.

Workmen's Bonus

The principal requirement in all this work was speed. To this end a bonus program for the workmen was early considered. In tunnel work it is very hard to devise a plan that will obtain results and at the same time be fair. On the adoption of the alternating system of working the two headings it was apparent that operations would become so systematized and methods so standardized that a bonus plan could safely be tried. After considerable discussion the following plan was adopted applicable only to the heading crews at the East Portal.* Quoting from the statement announcing the bonus plan, which was started on May 1, 1924:

"The number of crews employed and their organization are to remain as they are at present. No changes are to be made in the distances required due to changes in the character of the rock or for other reasons. The base rate above which the bonus is to be paid is for an average of 17 ft. per day in both the water tunnel and main headings or 34 ft. total. Should the above crews, as they will at times, do work in the cross-cuts, credit will be allowed for work done there but for no other reason such as enlargements for plant.

* Later this was used at the West Portal when ground permitted the alternating method.

"The bonus will be paid at semi-monthly periods corresponding to the pay roll periods on the total footage accomplished in these periods, which means that in a 15-day period at 17 ft. per day per heading, the total footage above which a bonus will be paid is 510 ft. and in a 16-day period 544 ft. Furthermore the bonus will be paid only to men who work every shift during the period except when excused by the superintendent on account of injury in which case a bonus will be paid proportional to the number of shifts worked.*

"In case a man is promoted from a lower to a higher group or *vice versa*, as shown below, his bonus will be based on the number of shifts worked in each group.

"The bonus will be a fixed amount to be paid to each man in proportion to the number of feet excavated in excess of the minimum as stated above. The fixed amount, however, is not the same for all men in the crews but varies according to the importance of their duties. For this purpose the men are divided into three groups.

"Group No. 1 will consist of: Assistant Superintendents, Shifters (Foremen), Scalers, Miners (Drill Runners), Helpers (Drill Helpers or Chuck Tenders), and Nippers.

"Group No. 2 will consist of: Mucking Machine Operators and the Muckers in the crew of the Mucking Machine.

"Group No. 3 will consist of: Tunnel Motormen and Brakemen, engaged in hauling from headings only.

"There will be no others than those stated above to be entitled to a bonus.

"The bonus to be paid to members of the different groups for each additional foot of advance will also vary in that it increases with the distance gained as stated below, it being understood that for a 16-day period all distances given below are increased by 34 ft.

"For members of Group No. 1 there will be paid:

"For every foot advance above 510 ft. up to and including 600 ft. the amount of 15 cents per ft., which we will call rate 'A'.

"For every foot advance above 600 ft. up to and including 675 ft. the amount of 20 cents per ft., which we will call rate 'B'.

"For every foot advance above 675 ft., the amount of 30 cents per ft. which we will call rate 'C'.

"For the members of Group No. 2, the distances are the same but the bonus paid is 10 cents, 12 cents, and 18 cents, respectively.

"For Group No. 3, the bonus paid is 5 cents, 7 cents, and 10 cents, respectively."

Judged by the high rates of progress later attained, these rates appear too high.

No attempt was made to apply a bonus to the other operations at the East Portal. The enlargement operation could easily progress faster than the headings by working two shifts per day, and as for the other work, extra progress required only the addition of more men or equipment.

Disposal of Spoil

The matter of disposal of the material excavated from the tunnel was not very serious. The muck cars from the water tunnel were dumped into chutes leading to 4-yd. cars standing in the approach cut to the railroad tunnel. A whole train was dumped without shifting the cars. These cars were hauled out on the spoil bank by an 8-ton trolley locomotive which also served the

* Soon afterward the superintendent also was authorized to issue excuses on account of illness.

railroad tunnel. The spoil bank was located as to line and grade to form a convenient permanent railroad approach to the tunnel.

Mechanical Equipment

The compressor equipment at the East Portal consisted of one compressor with a capacity of 450 cu. ft. of free air per min., two of 1 150 ft., one of 1 245 ft., and one of 1 300 ft. At times, all these machines were in use. It is to be remembered that at this altitude a large allowance in extra capacity had to be provided. The main high-pressure air line was 7⅝-in. well-casing, with Dayton joints for about 1½ miles and 6¼-in. for the remainder. Three of the large compressors were driven by 200-h.p. synchronous motors which served to maintain the power factor. The monthly maximum demand average of three 3-min. peaks up to August 1, 1925, was about 1 100 h.p. This, however, did not include one of the large compressors, which was put in operation later.

All drill steels were used only once, requiring the sharpening of about 1 500 bits per day. Two sharpening machines were used. The steels were heated in oil furnaces, and another furnace was used for tempering. All the furnaces were served by special low-pressure blowers to avoid the waste of high-pressure air.

Four-point bits were used, with extra wing thickness to avoid rifling of the holes. Later, the so-called McClellan bit, a modification of the standard four-point bit, was adopted with satisfactory results.

Storage battery locomotives were provided with extra batteries so that they might always be ready for service. A motor generator set supplying 250-volt direct current and located in the power house was used for charging the batteries and also for trolley service, supplemented as heretofore described by motor generator sets under ground.

Three 400-kv-a., single-phase, 44 000-2 300-volt transformers occupied the East Portal Sub-Station.

Plan of Operations at the West Portal

On account of the great amount of "heavy ground" at the West Portal the operations there were much different from those at the East Portal. On beginning the work little was known of the amount of this unsound rock and it was assumed to extend less than 1 800 ft., so that the plant and equipment provided was practically the same as at the East Portal.

The portal cuts were entirely in earth at the West Portal, likewise the water and railroad tunnels for a short distance. The water tunnel was given the same relative location with respect to the railroad tunnel as at the East Portal. It was started first and was a long way underground before the portal of the railroad tunnel was turned. Work on the portal cut of the railroad tunnel was slow on account of difficulties with the shovel, with frozen ground, and with disposal of the excavated material. Realizing this situation, the first cross-cut from the water tunnel to the railroad tunnel was excavated as near the portal as possible. Although every one continued optimistic as to the kind of material about to be encountered, no really sound rock was found for many thousand feet. Under these circumstances the use of the water

tunnel as an auxiliary heading was a tremendous advantage in expediting the work by providing access to the railroad tunnel through several cross-cuts at the same time. In this way it was possible to carry on excavation work in the railroad tunnel in as many as eight different places at one time.

Water Tunnel in Heavy Ground, West Portal

While the idea of "bad ground" immediately conjures up ideas of high cost and small progress in tunnel work, this is not strictly true in the case of a tunnel as small as the water tunnel and in rock of the particular character encountered at the West Portal. These troubles are primarily due to the necessity of timbering close to the working face and of taking precautions to avoid knocking down the timber in blasting operations. In the water tunnel at the West Portal, however, where timbering had to be carried close to the working face, the rock was uniformly so soft as to need little drilling, thus saving labor, and little dynamite in blasting, thus saving this large expense. The cost of timbering, however, was a large item. Much of this tunnel was excavated without the necessity of timbering close to the heading. Heavy ground pressures ordinarily did not become evident until some time after the face was exposed.

Where necessary, the water tunnel was timbered with square sets. Usually the caps and posts were of native lodgepole pine about 10 to 12 in. in diameter. In much of this tunnel it was necessary to drive ahead for a new set by driving spiling or poling-boards of 4-in. native timber. After the poling-boards had been driven, a cap was set under the front ends to support them, the cap in turn being supported by two cantilever beams extending from the under sides of the last caps in position. Under the protection thus afforded mucking operations were carried on so that posts could be set in position under the ends of the advanced caps.

A swinging false set for this operation was suggested but never used. No doubt it would have been an improvement for the worst of this work as it would have facilitated greatly the driving of the poling-boards. In part of this tunnel it was also necessary to drive poling-boards on the sides. In some favorable places the timber could be erected at a distance back from the heading so as not to interfere with the excavation. Then, again, much of the water tunnel did not require timbering at all. The uncertain nature of this rock is illustrated by the fact that from Cross-Cut No. 3 for 3 433 ft. eastward there were twenty places needing timber, aggregating only 1 167 ft. in all. The peculiar feature of the heavy ground at this end of the water tunnel was the relatively high pressure developed on the sides of the tunnel. Because of this pressure there was always a tendency for the posts to be forced into the tunnel. Many of them were broken and it became necessary to place reinforcing sets, frequently of 12 by 12-in. Oregon pine.

At first the posts were set vertically, a spreader of 3 by 8-in. native timber being used at the bottom between opposite posts. Settlement of the posts frequently broke these spreaders. Afterward it was decided to set the posts battering outward so that their bottoms were 12 in. farther apart than their

tops. After this, no more trouble was experienced from posts "kicking in"; but by this time the worst of the "heavy ground" was past. Many caps also were broken and were replaced with Oregon fir sets. In addition, many of the posts settled, bringing the caps down with them and thus decreasing the clearance overhead to a point requiring the replacement of the timber at a higher elevation. These serious troubles only extended about to Cross-Cut No. 3 and beyond that point, generally speaking, the timber stood very well. Cross-Cut No. 2 itself was so bad that it was necessary finally to reinforce the timber by using steel I-beams for caps. Even then the clearances were cut down to such an extent by these I-beams and other reinforcing timbers as to interfere seriously with its use.

Although much of the first 8 000 ft. of the water tunnel did not require any timbering, the adjacent railroad tunnel required it all the way. Beyond Cross-Cut No. 3 the average character of the rock in the water tunnel improved greatly, containing considerable stretches of fairly good material, but, at intervals, decidedly crushed zones that were the occasion for very serious cave-ins.

The use of native timber in the water tunnel was unsatisfactory in another important respect in that it was peculiarly subject to fungus attack and rapid decay. With the improved ventilation resulting from the use of the water tunnel as an intake, as at the East Portal, this condition was greatly relieved.

At first the water tunnel at the West Portal was driven independently of any other headings. The shifts of men assigned to this heading were selected by promotion from other work, the object being to expedite this part so that the ground could be quickly explored and more cross-cuts opened up for access to the railroad tunnel and thus the work "holed through" as soon as possible. In most of this work hand-mucking methods were used and the drill shift not only did its regular work of drilling and blasting but also all the timber work with the help of the muckers. Later, a Conway loader was used in this heading but it was of doubtful advantage in passing through bad ground as there was much lost time anyway.

The drilling and blasting followed the method as used in independent headings already described, namely, with two drills only, mounted on a horizontal bar. After July 1, 1925, however, the rock then being of much better quality, the heading was driven by the alternating method as at the East Portal, in turn with the main heading, then being driven from Cross-Cut No. 6. Thereafter progress in these headings became almost as good as at the East Portal.

Timbering Railroad Tunnel in Heavy Ground, West Portal

By far the most interesting of the operations on the Moffat Tunnel was the excavation and timbering of the railroad tunnel. The decision to try to hold this heavy ground permanently with timber only was a bold one. There is no record in engineering literature of any one having ever seriously considered such a thing as practicable, nor is it likely that it will ever be attempted again.

The ideas in regard to the weights and pressures that a timber or masonry tunnel lining will have to sustain as evolved by various theorists, seem to be in no way in accord with any reasonable assumptions and quite impractical in their applications. There is also the question of so-called "swelling ground" *versus* just ordinary "heavy ground". What, if anything, is there in the theory current in mining districts that the weight on the timbering can be relieved by "bleeding" the timber, that is, raking out some of the loose rock behind it? Or what in the theory that as time goes on weight on timber grows less instead of greater, due to the fact that the loose ground outside the tunnel tends to adjust itself into the form of an arch? Are vertical posts less likely to be pushed in at the bottom if set straight, or battered out, or battered in; and will setting the posts on foot-blocks or wedges inclined outward prevent them from "kicking" in? Is it better practice to pack the spaces outside the timber with cordwood or with rock fragments? Which is the better method in a single-track railroad tunnel, to use 3-piece, 4-piece, or 5-piece segmental arches; and what should be the particular design of these arches? How about wall-plates? Is it feasible to build a tunnel in heavy ground without them? Should lagging be made thick enough to resist decay as long as the heavy timbers or should it be made so thin that it will be the first thing to break under load? Is there anything in the old theory that the first requirement in tunneling in bad ground is to hold everything absolutely in place?

The contract for the construction of the Moffat Tunnel showed as a typical section of timbered tunnel a 3-piece set of 12 by 12-in. timber, a 12 by 12-in. wall-plate, and 12 by 12-in. posts. Timbering was not considered at that time as a serious difficulty and there were elastic provisions in the specifications for a change in design if that became necessary. All timbering operations described in the specifications contemplated the use of side-drifts in which the wall-plates were to be set in place ahead of the face of the heading. This method involves the use of a top heading and the removal of the remaining bench in one or more lifts. To work in well with this plan, the location of the water tunnel at an elevation 8 ft. below the top heading, is rather awkward. As it turned out the best method was to drive the cross-cut on a level grade and then ascend in the railroad tunnel as rapidly as possible.

However, for other reasons it turned out that practically none of the wall-plate drifts was driven. This method was tried in the earth part of the upper heading at the portal but was soon abandoned on account of its slowness. At about the same time, Cross-Cut No. 1 having been finished, a so-called timbered main heading on a rapidly ascending grade was started each way from this cross-cut, and after two or three wall-plates had been set at the portal and the heading permanently timbered to the end of them, a similar main heading was started to meet that coming from Cross-Cut No. 1. This was only a short distance, as Cross-Cut No. 1 was close to the portal.

This timbered main heading was similar to the timbered heading driven in the water tunnel except that the posts were much longer. The dimensions of the heading as to height were governed by the fact that the under side of

the cap of the square-set as it was to be left in place must clear the cap of the permanent timber, a nominal clearance of 1 ft. being allowed. The bottom of the heading was low enough to facilitate the placing of wall-plates. The operations of widening the heading and setting permanent segmental timbering followed the driving of the main heading at a convenient distance behind, sometimes not for months afterward.

The first experiment in the way of setting wall-plates from this main heading was to drive them, as it were, laterally rather than longitudinally. To this end cantilevered poling-boards were driven out laterally from the main heading to clear the tops of the wall-plates. This was not successful and was soon abandoned in favor of a method, the so-called "winging out" method (Fig. 16), wherein, working longitudinally of the tunnel, complete 5-piece sets of temporary timber (false sets) were placed outside the prospective position of the permanent timber, ample clearance being left for the placing of the permanent timber. When 3-piece permanent sets were used, these false sets were practically 3-piece sets themselves, the lower segment being quite short and vertical. When the permanent timber was changed to 5-piece sets, the lower leg of the false sets was lengthened but was still left vertical. These false sets were largely used throughout the timbered portion of the railroad tunnel. Sometimes the ground was so stable that the wing sets could be left out if the permanent timber were placed immediately after the excavation of the rock; and sometimes the rock was so bad that only by the most careful work and the extensive use of poling-boards on the top and sides could the widening be accomplished.

At the cross-cuts the main headings were driven at a steep up-grade until they were high enough for the caps to clear the permanent timber. In widening out there remained a considerable length of tunnel in the vicinity of the cross-cuts that could not be enlarged, and it was the custom to leave this part to the last and work toward the cross-cuts from the completed top headings, driving practically a new main heading on top of the old. This was ticklish work on account of the amount of ground that had to be opened up at one time and was the cause of two bad cave-ins.

The false sets (Fig. 16) were not very well framed but were good enough for the purpose. The upper inclined segment was merely beveled on the end and rested against the end of the cap of the square-set and the short vertical leg was supported by a small foot block.

The setting of the permanent arch timber—wall-plates and segmental sets—immediately followed the widening-out process. The wall-plates were first placed, carefully blocked up in position, and checked for alignment and grade; then the segments were erected, the lagging was placed, the weight of the false sets transferred to the permanent sets by blocking, the original posts of the temporary square-sets were removed, and cordwood or rock packing was carefully placed between the permanent timber and the false sets.

This system was pretty consistently followed throughout. Its disadvantages lay in the large amount of extra excavation and timber and cordwood required and the extra weight that will be applied later when the temporary timber

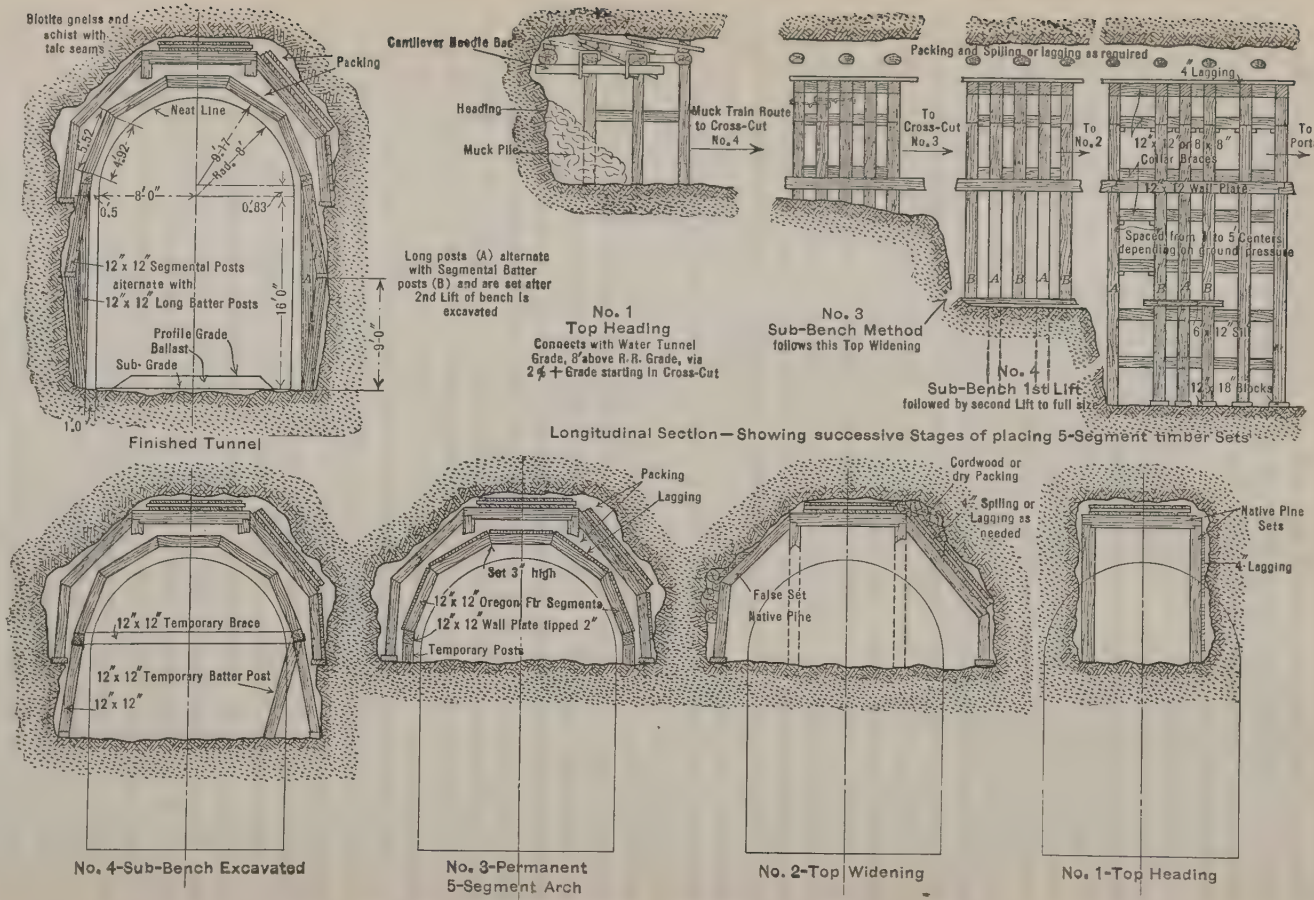

FIG. 16.—TIMBERING METHOD, WEST PORTAL, MOFFAT TUNNEL.

and cordwood compress and decay. Its advantage was its speed and the excellent appearance of the permanent timber (Fig. 19).

Many plans were proposed for placing the permanent timber directly against the rock, but none of them was tried. The permanent timber as first placed followed closely the design shown in the contract drawings, a 3-piece set with wall-plate and posts (Fig. 5). Modifications adopted shortly afterward to facilitate excavation, when it was realized that the weights to be held would be considerable, were the omission of the notch cut in the wall-plate for a bearing for the segments. This was to strengthen the wall-plate as a beam. A steel plate bent in the form of a Z-bar was used as a bearing instead. This was not successful in holding the segments in place, and it was also soon apparent that no reliance could be placed on blocking the timber away from the rock as a means of holding it in place. Instead, the wall-plate was tilted to obtain a better bearing for the segments and at the same time a five-segment arch in place of the three-segment design was adopted.

The main elements governing the design of the five-segment arch were that space should be left for 12 in. of concrete overhead, for 9 in. on the haunches, and for 6 in. at the wall-plates. This was the same as for the three-segment arches. The lower segment of the 5-piece set was inclined at an angle of 25½° from the vertical the segments were identical, and the wall-plate was about 2½ ft. lower than in the 3-piece design.

Later, in better ground, the 5-piece arch design was modified in that all the angles between the segments were made 30°, and a steel wall-plate was used instead of 12 by 12-in. timber. The steel wall-plate was an I-beam laid on its side. Its advantage is that it does not compress, holds the posts and segments in position, and practically puts the segments and posts in contact.

Details of Operations, West Portal

The excavation of the main headings advanced much more slowly than that of the water tunnel. This was due largely to their greater height. At times several of these headings were being excavated simultaneously, access being obtained from the various cross-cuts. Usually only the most advanced heading was equipped with a Conway loader. Access for the heading-widening operations was also obtained from the various cross-cuts. The headings were always driven through from one cross-cut to the other before widening was started in order that circulation of air could be established as soon as possible.

The transportation system in the water tunnel operated in the same way as at the East Portal. The trolley, however, served only the water-tunnel heading and the work in the railroad tunnel, which was carried on from the next cross-cut to the heading. Necessary haulage from other cross-cuts was handled all the way to the spoil bank by storage battery locomotives. The trolley was always given the right of way.

Water from the headings drained out through the water tunnel all the way to Cross-Cut No. 1, where it was discharged into the railroad tunnel. The quantity of water handled probably never exceeded 200 gal. per min.

On the assumption that there was to be but little unsound rock at the West Portal, the same equipment for the enlargement operation to full size was ordered as at the East Portal, an Osgood air shovel, dump cars of nominal 4-yd. capacity, 3-ft. gauge track, 40-lb. rail, and 8-ton trolley locomotives.

In order to have enough head-room for the shovel it was necessary to take out the full bench, nominally 16 ft. high, in one operation and also to keep a clear space 16 ft. wide at all times. In a timbered tunnel this introduced quite a problem as to the temporary support of the overhead timber while excavating. All kinds of travelers were proposed for this work, all supported on tracks at invert grade. The excavation, however, was started at the portal by removing only a small part of the bench at a time, batter posts close to the bench being set to support the wall-plates until permanent posts could be placed.

The rock at this point was comparatively good, a partly disintegrated pegmatite extending in for about 500 ft. from the portal. In attempting to use the shovel it was found to be a very poor piece of apparatus for mucking out short rounds. On account of the small radius of the dipper arm anything in the nature of a corner could not be reached at all. This necessitated much mucking by hand—and into high cars at that. The bench being so high and there being so little head-room above, most of the holes drilled were "lifters".

Needle-Bar Method for Bench Excavation

In any kind of industrial work the first concern is so to organize the work that all men are fully employed for the entire shift, that they do not interfere with one another, and that, if there is a regular cycle of operations each step of which has to be done in regular rotation, the cycle may be completed at regular intervals of 24 hours each so that the various shifts can go to work at the same time each day. The use of a "call" shift should be avoided on account of the ensuing extra expense, irregular sleep and meals for the workmen, and the consequent demoralization. Particularly should this be avoided where highly trained workmen, such as steam-shovel operatives, are employed.

Under the conditions at the West Portal it will readily be seen that the bench excavation by this method was very unsatisfactory as, among other things, the shovel crew could clean up all the muck from one round in about two hours. This constituted a day's work for them and, furthermore, this work had to be arranged to come during the day shift.

To remedy this situation it was imperative that some better method for supporting the wall-plates be found so that a longer round could be taken out. The solution of this difficulty for the time being was found in the use of two 24-in. by 25-ft. I-beams as so-called needle-beams.

As shown in Figs. 17 and 18, these beams were disposed longitudinally of the tunnel, one on either side. They were supported on transverse cross-beams one of which was in turn supported on the wall-plates at a point to the rear of the permanent posts, and the other on the wall-plates at a point where these plates in turn were supported by the bench not yet excavated. Another set of three or four cross-beams was hung by heavy bolts from the needle-beams. Being placed under the opposite wall-plates, this set served as their

only support for 10 or 15 ft., or more. Later, 40-ft. instead of 25-ft. beams were used.

With this system a much longer round could be excavated, although even then it was not possible to employ the shovel crew for its full time. It was also apparent that the needle-beam apparatus should be improved, especially as to the arrangements for moving ahead. Of course it would not be possible to use such a system if heading work was going on at the same time, as the heading would be blocked. In the Moffat Tunnel, however, as all the heading work was done from the water tunnel and cross-cuts, this objection did not hold.

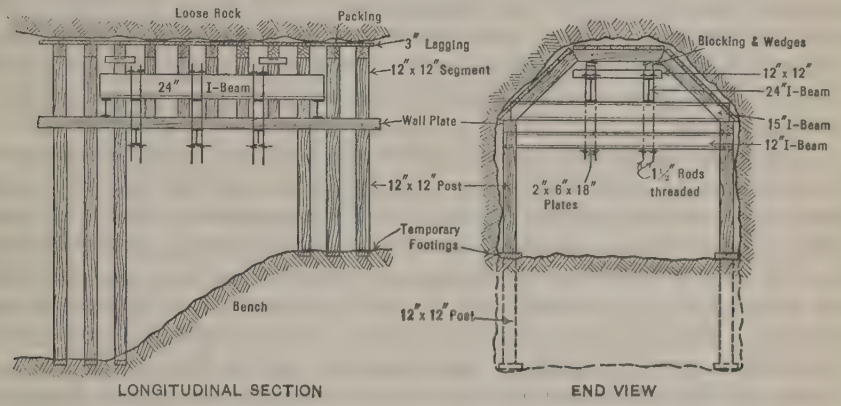

FIG. 17.—NEEDLE BARS FOR SUPPORT OF ARCHES, MOFFAT TUNNEL.

SUB-BENCH METHOD FOR EXTRA HEAVY GROUND

The excavation of the bench went on as described to the end of the pegmatite formation. This point was also the beginning of the worst section of tunnel. In entering this formation the same system was continued but on blasting the first round there was a bad cave-in from behind the wall-plate on one side. The wall-plate settled also and there were indications of careless work in supporting these plates.

It was decided that it was unsafe to attempt to take out such a high bench in such unstable material. The next decision was to take out the bench in two lifts, the so-called sub-bench method. It was also apparent at this time that a concrete lining should be placed in such stretches of unsound rock and that any attempt to depend on timber as a permanent lining would be a mistake.

The method adopted for prosecuting the work as far as it was necessary to use the sub-bench method was first to take out the top lift or upper sub-bench as far as Cross-Cut No. 2, the work being handled from the railroad tunnel portal. After passing Cross-Cut No. 2 the upper sub-bench would be handled from that cross-cut and the lower sub-bench started and handled in turn from the portal. On account of the lack of room in camp for more men and the desire to push the heading work there was no attempt to work both sub-benches at the same time, although this could have been done.

The method of excavation was to be by hand, although to cheapen the mucking operation a plan was contemplated of excavating first through the upper sub-bench a trench about 10 ft. wide and 8 ft. deep, the mucking to be done with a Conway loader. There being no loader available, however, this method was not tried.

In timbering the upper sub-bench it was necessary then to design a system of timbering that would enable the lower sub-bench to be excavated readily, and at the same time to provide for a stronger concrete lining than had heretofore been contemplated, one adapted to resist side pressure on the tunnel. At first the idea was to set vertical round posts under the wall-plate at every alternate segmental arch. The temporary posts were set on foot-blocks. At the other segmental arches a permanent post of 12 by 12-in. Oregon pine* was set battering outward. These posts were supported on a 6 by 12-in. continuous sill of Oregon pine. The inside face of this sill cleared the line of temporary posts.

Soon after the excavation had been made, however, heavy side pressure began to develop, and this was provided for by setting the temporary posts battering inward and putting heavy 12 by 12-in. spreaders between the wall-plates at their ends, or about 16 ft. apart. These spreaders soon indicated that the side pressure was increasing, as some of them were indented into the wall-plates ½ in., or more, and the wall-plates were bent in between the spreaders. Later, additional spreaders of 6 by 12-in. Oregon pine were placed intermediate to the first ones. The segmental timbers that theretofore had shown very little indication of being stressed before the bench was excavated, also began to take weight, not so much however as the posts under the wall-plates. The sudden increase in vertical weight is easily explained by noting that the weight previously had been taken by the false sets but that now, the foundation having been taken away from under the false sets, all the weight was transferred to the permanent timber. The peculiar design of the false sets is probably responsible for the development of excessive side pressure. With evidence of such tremendous lateral pressure it was quite evident that no ordinary system of segmental timber arches could withstand the strain and that the problem required a heavy concrete lining as its solution.

Meanwhile the completed timber work near the portal began to show evidence of much strain. This was in the pegmatite formation. All the timber here was of 3-piece, segmental arch design. Some of the posts were broken and all of them were bent quite visibly; in two places the wall-plate was broken, rotated over backward, the lower legs of the arches were pushed outward on top of the wall-plates, and the wall-plates forced into the tunnel. To meet this condition reinforcing timber was placed inside the regular sets. This was intended to be removed and a concrete lining placed later.

In November, 1924, the upper bench having passed Cross-Cut No. 2, preparations were made to start work taking out the lower sub-bench. The ground beyond Cross-Cut No. 2 having become more stable as the work advanced, it was decided to drop down to the bottom grade and take out the

* This timber has been replaced by separate sets of 12 by 18-in. Oregon fir (p. 104).

full bench, using hand-mucking methods. At Cross-Cut No. 4 also, work was started taking out the full bench, working west from the cross-cut and using hand methods. At both Cross-Cut No. 2 and Cross-Cut No. 4 the method was changed somewhat, as soon as a sufficient height of bench was reached, in that the bench was taken out in two lifts, the upper one being 20 ft. or more ahead of the lower. This was because more men thus could be put to work advantageously.

By means of wheel-barrows on a runway the muck was carried out and dumped into cars standing on the lower level exactly as is done in mucking out by hand a tunnel driven by the top-heading and bench method. Wall-plates were held successfully in place by the use of 10-ton single-screw pipe-jacks extending transversely of the tunnel and tightly jacked against opposite wall-plates. It is only necessary to use a sufficient number of such jacks, placed with judgment, to hold any overhead weight.

On the lower sub-bench no progress had been made since the previous July (1924). Slow progress was anticipated here and to expedite the mucking operation a so-called St. Joe loader was obtained on trial. It was operated entirely by electricity and would load into the high 4-yd. muck cars. After a trial extending over a week or more it was decided that this machine offered little advantage over hand-mucking methods mainly on account of the lack of clearance for its quick operation. As great hopes had been held out for the successful operation of this machine no other adequate method of mucking was available and it was necessary to return to hand-mucking methods.

The first timbering in the excavation of the lower sub-bench consisted in removing the temporary round posts placed at the time the upper sub-bench was removed, and replacing them by full length 12 by 12-in. posts extending to sub-grade and set on foot-blocks. Also, under the 6 by 12-in. sill was placed a short post battering in so that at the bottom it was in line with the long posts. This short post was set under the permanent batter posts placed with the upper bench and in connection with them was intended to form an arch that would help to resist side pressure. However, mainly on account of the compressibility of the 6 by 12-in. sill in resisting compression across the grain, they were of little value in this respect.

Immediately on excavating the lower sub-bench, the side pressures increased greatly. It was necessary to place spreaders lower down than the wall-plates and directly against the posts, which showed signs of breaking. A trussed design for the long posts adapted to take side strain was adopted and it was decided to replace the segmental posts by trussed posts also.

Traveling Cantilever Needle Bar

At this time a policy was adopted of attempting to hold all the tunnel by permanent timber, there being little realization of the tremendous pressures to be withstood and the inadequacy of timber for such a purpose. It was also determined to try out the Osgood shovel again. For this purpose it was necessary to return to the needle-beam method. A modification of the original needle-beam method for supporting the wall-plates was adopted (Fig. 19), using the cantilever principle. Two heavy 42-in. girders, 60 ft. long, canti-

levered out from the high bench on which they were supported, were the main feature of the design. These girders were framed together in one unit and were pulled ahead on a track by a small air hoist. Improved cross-beams and a wedge arrangement for raising them to a bearing on the under side of the wall-plates were also features of the method. These cantilevers were designed for use on the full bench, which being at this time east of Cross-Cut No. 2 could not be reached by the Osgood shovel because the lower sub-bench was not yet excavated.

It was then determined to use the cantilevers and the Osgood shovel on the lower sub-bench. This necessitated the erection of the girders on cribbing about 8 ft. high above the sub-bench (Fig. 20) and the removal of the spreaders between the wall-plates. It was hoped that it would be safe to take out the spreaders and use instead 3-piece arches placed alternately between the 5-piece arches already in place. These 3-piece sets were intended to maintain the wall-plates against lateral pressure as did the spreaders and it was necessary to make the substitution in advance of the progress of the girders. The clearance under these 3-piece sets was less than under the 5-piece sets, and it became necessary to lower the girders which, in turn, made it necessary to lower the sub-grade of the tunnel 9 in. to provide clearance for the shovel in loading cars.

Original Timber Lining Replaced by Separate Sets

Through the worst of this heavy ground section trussed posts were placed on close centers and for part of the way they were placed practically "skin tight". All this work turned out to be inadequate for shortly after the timber was finished tremendous pressures began to develop. Again the wall-plates were the main source of trouble. Even with the thorough bracing against side pressure provided by the 3-piece reinforcing sets the wall-plates were gradually forced into the tunnel. In so doing they were crushed and sheared in places almost to shreds (Fig. 21). The trussed posts were also inadequate to withstand the pressures and spreaders were again placed in part of the tunnel. An attempt was made after Cross-Cut No. 2 was reached to turn the drainage of the water tunnel into the main tunnel. Immediately some of the posts on the south side of the tunnel "kicked" in at the bottom, owing to the softening of material around the foot-blocks by the water.

It was now realized that the timber already placed was inadequate and would have to be replaced by something much stronger and particularly that the wall-plates must be eliminated.

The design adopted which is about the last word in timbering consists of a 3-piece arch set of 12 by 12-in. timber, the inclined legs being placed somewhat more vertical than usual. These sets rest directly on 12 by 18-in. posts. To erect this timber it was necessary to remove all the old timber and much of the cordwood packing behind it, just enough ground being exposed at any one time to enable one new set to be erected. This reconstruction work will probably extend over at least 2 000 ft. of tunnel much of the timber being set "skin tight". Later, it was decided to make the inclined legs of the arches of 12 by 18-in. instead of 12 by 12-in. timber, the 18-in.

dimension, as with the posts, being transverse of the tunnel. Meanwhile the bench excavation had been making progress and east of Cross-Cut No. 2 the full height of bench was attacked. This stretch of tunnel, although consisting of rock much better than that where the sub-bench method was used, had to be excavated with great care to avoid cave-ins due to the great height of the unsupported bench. As further progress was made, however, the rock became more self-supporting.

Ventilation of West Portal

The ventilation system installed at the West Portal was the same as that at the East Portal. It did not work so satisfactorily, however, due to the main headings being late in "holing through" and to smoke sifting through from the railroad tunnel to the water tunnel through some of the cross-cuts which could not be made air-tight on account of being timbered. The other apparatus used at the West Portal was much like that already described for the East Portal. There was not, however, as much air-compressor capacity required as at the East Portal because less drilling was required.

Disposal

At the West Portal all muck trains from the water tunnel went directly to the dump, descending on a 2% grade to the lower level.

Timber Framing and Treating

The large amount of timbering to be done at the West Portal led to the installation of a plant for framing and notching these timbers. The dapping machine designed on the job for this purpose was a great success.

It was also considered advisable to creosote the foot-blocks. This was done by the open-tank process. Because of indications of attack by fungus growths, the advisability of treating with preservatives all the timber was seriously considered, but after a thorough study of creosoting and other processes ordinarily used, it did not appear that any of them was adapted to the particular requirements of timbering for the Moffat Tunnel.

Papers on the same subject and treating various phases of the subject are listed as follows:

Mining Congress Journal, March, 1926.

DISCUSSION

T. Kennard Thomson,* M. Am. Soc. C. E.—The two things that make engineering really worth while are the contacts with fine men and interesting problems. This paper brings up recollections of forty-four years ago, and it would be a pleasure to tell about many of the then young men who have since made international reputations. However, only one who has passed on will be mentioned, the late Albert Brainerd Rogers, M. Am. Soc. C. E., the only engineer to discover two passes through the Rocky Mountains, one of which was mentioned by the author. Hundreds of interesting stories are told about this engineer, who discovered "Rogers Pass" (now called "Connaught"), which gave a short cut of 67 miles instead of 163 miles around the Columbia River. The discovery resulted in the Canadian Pacific Railroad awarding to Major Rogers a bonus of $5 000. Later, Mr. William C. Van Horne asked him why the check had not been cashed and was told that never before, in nearly sixty years, had any one paid him a cent more than obliged to—so he had framed the check. Mr. Van Horne again sent for Major Rogers and showed him a gold watch which was to be given him when the check was cashed. This overcame his reluctance.

On the Canadian Pacific Railroad through the Rockies some of the tunnel problems were similar to those at the Moffat Tunnel, but with very different working conditions. The timber lining and sections were similar. One of the earlier tunnels was distorted several times and finally collapsed, due to shifting clay, although the timber lining before the final collapse was a solid 12 by 14-in. wall. It was then abandoned and a temporary line (requiring a 23° curve) was used, until years afterward, a longer tunnel was built in a much safer location.

The earlier tunnel work suffered from the lack of high-grade tools, electric current, and even coal, all supplies except wood and water coming through Winnipeg, a thousand miles away, much of it from Chicago and Ontario. Nor were there any blueprints, ready made India ink, or typewriters. The labor problems likewise were radically different as all labor had to come from the East, and the men could not quit, although the payrolls were sometimes very late in arriving. Even bathing was difficult.

Only those who know the Rockies can realize how fortunate it was that, in crossing the Continental Divide, the Canadian Pacific Railroad did not have to reach any such elevations as the 11 660 ft. of the Denver and Rio Grande Western Railroad in Colorado, nor even the 9 200 ft. of the Moffat Tunnel. The highest point of the Canadian Pacific base of rail is 5 300 ft. at the summit, in British Columbia, not very far west of Banff. Elevations such as those in Colorado would probably have been prohibitive in British Columbia. The Canadian National Railway, much farther north, is still more fortunate with a maximum elevation of 3 717 ft.—a kind dispensation of Nature.

The author mentions exploders. In the East River (New York City) it was necessary to do some submarine blasting by drilling a number of holes

* Cons. Engr., New York, N. Y.

under the bed of the river from a coffer-dam, and exploding all the charges at one operation. The makers of the exploders sent an expert to supervise the loading and wiring, but, unfortunately, only a few of the charges were detonated. On connecting about twenty-five similar exploders in the same manner, but without the dynamite, and sending the current through them, only four or five went off. Several efforts were necessary to get all the exploders detonated, which illustrates the improvements that have been made in explosives.

It is interesting to note that the same kind of gneiss rock as extends under New York City was encountered in the Moffat Tunnel and that it was decomposed 100 ft. or more below the surface. In New York, so far, this "rotten" rock has been found only near the surface, although as much as 50 ft. (in depth) of this soft rock has been removed.

H. F. DUNHAM,* M. AM. SOC. C. E. (by letter).—In the Ohio Valley District there is a tradition—possibly unwarranted—that oak timbers as large as 12 by 12 in. decay far more rapidly than timbers 6 by 12 in., spaced ½ in. apart for air circulation, where "heavy ground" requires a continuous 12-in. oak lining.

Every tunnel engineer knows that the integrity of his work depends largely on maintaining the exact position of the wall-plates. Years ago when in charge of such heavy ground construction for double-track steam railway in West Virginia, the writer found that carefully placed wall-plates were continually being disturbed in removing the bench. The contractor was ordered to secure and use 60-ton jacks in the re-alignment of the wall-plates. After the first few days the hydraulic jacks acted by catalysis only.

The instrument work for alignment and grade in long tunnels offers a chance for improvement over earlier conditions by using electricity. If one "bright spot" of known position could be shown when desired, on the face of a heading, or maintained all the time, the use of a light template would ensure a correct outline for the whole heading, tending to save needless rock removal and replacement.

The line of probable least disturbance in the average tunnel would presumably be near the wall-plate line, say, 1 ft. inside and 1 ft. above that line. In most rock tunnels there is firm rock along the side walls within distances of 500 or 1 000 ft. At such points a vertical piece of timber could be anchor-bolted to the wall holding a bracket strong enough to support a wye-level on a base similar to that used by an instrument maker in adjustments between artificial, infinite-distant points. The level supported on such a bracket and brought into line by means of proper back-sights should then be reversed in its wyes, thus carrying both grade and alignment with great accuracy to the heading. A small platform for the operator would be required and a fender guard might possibly be needed, but there should be several hundred feet between the last bracket and the heading.

The next step should be to require of the instrument maker a light cylinder of the exact size of the level barrel, to be equipped with a light bulb and with

* Civ. and Hydr. Engr., New York, N. Y.

suitable lenses to converge the rays and take the place of the level barrel in projecting the desired bright spot. A simple correction of 2 in. for every ½ mile would provide for earth curvature.

LAZARUS WHITE,* M. AM. SOC. C. E.—A project such as the Moffat Tunnel has three aspects: (1) Economic; (2) engineering; and (3) contract relationship. It is difficult to understand its economic aspects, particularly as it is being built previous to an agreement with the only railroad that can operate it. Although this is quite the usual practice, it often leads to a poor bargain on the part of the community that originally finances such a project. Of course, the building of this tunnel is a fine thing for the railroad, which secures a great bulk of valuable freight during its construction and, later, will be in a position to drive a good bargain. Perhaps the community takes its profit in the opening of a new district west of the Rocky Mountains.

For building the Moffat Tunnel a new method of contracting was devised; the contractor is compensated at a small fixed fee set by himself, the main incentive of profit coming from completion ahead of time, thereby securing a bonus. Because of the difficulty in driving the tunnel, it appears that the bonus will be hard to realize and that the contractors, despite their very excellent work, experience, and abilities, will not receive much compensation, unless it is through sources not apparent in the original contract. This form of contract is, in fact, a method of hiring superintendence. In the long run, it would practically eliminate contractors, as ordinarily understood, and would substitute for them professional men in a sort of dual capacity of engineers and superintendents, operating on a salary with an incentive of a bonus, but lacking the element of profit, which is the principal attraction for the type of man who usually makes a successful contractor.

The engineering problems are those which have repeatedly arisen in connection with the driving of other long mountain tunnels of Alpine character, such as that at Rogers Pass. The difference between these two tunnels, however, is due to the presence of, or freedom from, heavy ground. The methods of overcoming heavy pressures are interesting and ingenious. Apparently, the construction was hampered by the difficulty of securing steel, cement, and concrete materials so that resource was had largely to heavy timbering. In the writer's opinion such problems could better be met by steel and concrete.

In such cases timber is not a reliable material and cannot be trusted to hold heavy pressures permanently. The failures noted in this paper are similar to those historic examples in Drinker's "Tunneling". Nowadays, because steel is readily available and methods of placing concrete by compressed air have been developed to a high degree, bad ground can be more readily supported by steel and permanent concrete lining in the writer's opinion.

This paper is valuable inasmuch as Mr. Keays very frankly states his problems and expresses doubts that the solutions reached were the best. Such an attitude leads to progress. In describing a completed construction, there is a tendency to give the impression that the methods used were the best, thus leading others to copy examples that are questionable.

Paper No. 1658

CIVIL ENGINEERING FEATURES OF THE HELL GATE STATION*

By Ernest M. Van Norden,† and George A. Hughes,‡
Members, Am. Soc. C. E.

With Discussion by Messrs. George A. Orrok, A. Streiff, and Ernest M. Van Norden.

The Hell Gate Station of The United Electric Light and Power Company, located on the East River between 132d and 134th Streets, New York, N. Y., has been well described in the technical press and also in publications issued from time to time by its owners. It is very natural in such publicity for the author to confine himself to a description of the mechanical and electrical equipment and to neglect much of the detail pertaining to the structure. The problems involving civil engineering, within the commonly accepted meaning of this term, are usually lightly touched upon, although these problems may be difficult of solution, intricate in design, and expensive in execution.

The Hell Gate Station involved many problems in this class, some of which are not found in other power station designs; and for their successful solution much credit is due the designers and contractors. It is the purpose of this paper to describe the more important civil engineering features of this station, introducing only such mechanical and electrical details as may be required to make a complete picture.

Three factors controlled the selection of the site:

First.—Proximity to the center of gravity of the load.

Second.—Real estate values.

Third.—Water-front facilities for receiving coal and supplying circulating water for the condensers.

* Presented at the meeting of the Power Division, New York, N. Y., January 21, 1926.
† Civ. Engr., New York Edison Co., New York, N. Y.
‡ Civ. Engr., Thomas E. Murray, Inc., New York, N. Y.

The station was designed to supply electric energy to Queens Borough and Westchester County, as well as to the Boroughs of Manhattan and The Bronx, and from the standpoint of center of gravity of the load the site was well chosen. Even with considerable increase in the load the center of gravity would still remain about the same.

From the standpoint of real estate values the Company was fortunate in being able to secure this property at a reasonable price. The number of water-front properties available in the City of New York that could be used for power-station development are few, and the question of cost might be regarded as unimportant, although in this particular case the relatively low cost tended to make a quicker decision as to location.

The Company succeeded in securing from the city the exclusive privilege of mooring at the foot of 134th Street. The entire length of water-front, therefore, ran from the north side of 132d Street to the north side of 134th Street, a distance of about 500 ft. It was planned to receive coal at this station in ocean-going ships capable of carrying 10 000 tons with a draft of 28 ft., but the capacity of the boats which so far have entered this service rarely exceeds 6 000 tons, with a draft of 24 ft. To accommodate the large ships safely it was necessary to obtain 35 ft. of water alongside the wharf.

An aeroplane photograph looking toward the northeast (Fig. 1) illustrates the excellent water-front advantages enjoyed by this station. The area immediately south of 132d Street, shown in the foreground, is to be developed as a freight yard for the New York, New Haven and Hartford Railroad Company which plans to build a bulkhead at the easterly end for transferring water and railroad freight. At the time this photograph was taken the station was not entirely completed, the view showing only three stacks of a total of four.

The survey to determine the elevations of the surface and the bed-rock had to be carried beyond the low-water mark. The wash borings that were made, partly on land and partly from floats, proved to be very accurate, making it possible to contract on a lump-sum basis for the removal of the over-burden and the rock down to the levels required.

As shown in the topographical survey of the rock surface (Fig. 3), the contour lines, assuming the over-burden to be removed, indicate that the rock slopes rapidly down offshore. On this map is indicated the main outline of the station structure.

The turbo-generator room was located parallel with the water-front so that the water for the condensers could be pumped directly from the river, thereby avoiding the construction of a long intake tunnel. The discharge tunnel for the condensing water was also located parallel with the water-front and as close to the river wall of the station as possible. The absence of an intake tunnel for the condensing water renders this station unique among power stations in the City of New York.

The entire rock excavation, therefore, was confined to an area very close to the water-front and was done by under-water blasting. It was necessary to go to certain depths for the discharge tunnel and for the suction pipes and screens. It was also necessary to provide sufficient depth of water for ocean-going ships along the entire length of the wharf.

FIG. 1.—AEROPLANE VIEW, SHOWING WATER-FRONT ADVANTAGES OF THE HELL GATE STATION.

FIG. 2.—VIEW OF DRILL BOAT IN POSITION AND DREDGE IN OPERATION, HELL GATE STATION.

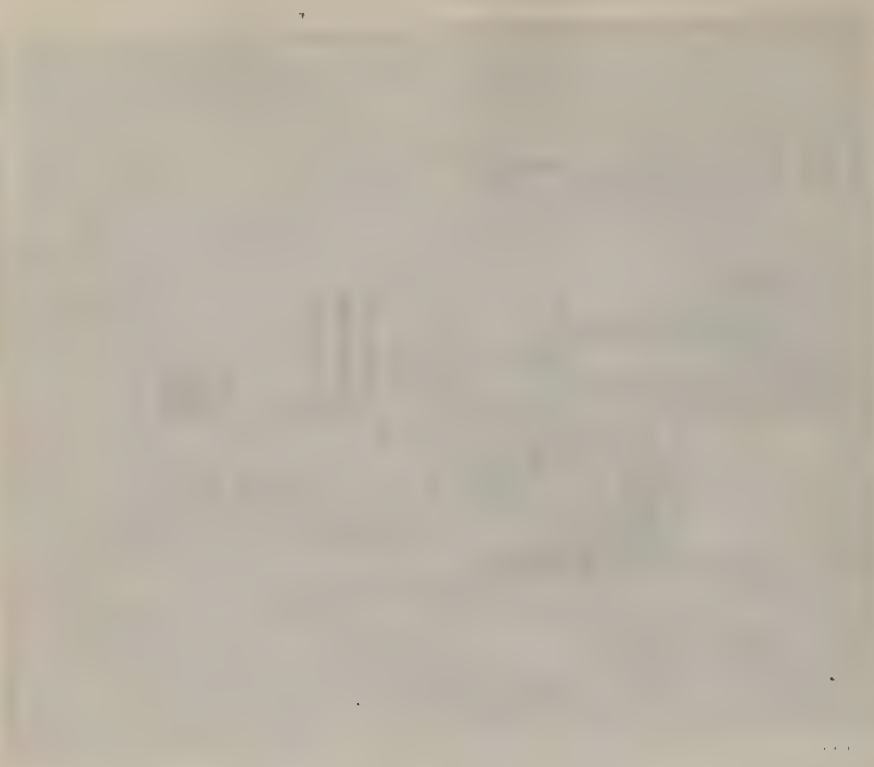

Fig. 4 is a cross-section of the station showing the cut required in the rock and also the relative position of the sea-wall supporting the easterly wall of the station and the discharge tunnel and wharf.

The contractor first dredged the site to remove the over-burden and then used two drill boats especially constructed for submarine drilling. The size of the drill bits was 4¾ in., making holes approximately 5 in. in diameter. These holes were drilled on 5-ft. centers in both directions over the entire area and were carried down to 5 or 6 ft. below the finished rock grade.

The operation of drilling was as follows: The drill boat was located by shore rangers and held in position by lines run out to anchors, by lines to the shore, and also by spuds on the boat resting on the river bed. A drill pipe was dropped down until it rested on the bottom, and the drill rod was dropped through the pipe. The drill was operated by steam and was fed down as the rock was drilled. After the hole was finished it was loaded with dynamite through the drill pipe and the wire brought up and attached to the boat. Every day all the wires were connected, the boat pulled out into the stream beyond danger, and these holes were fired. The boat then took up a new position and commenced drilling again. After the area had been drilled over it was dredged off and if soundings indicated high spots, these were re-drilled and the same procedure was repeated.

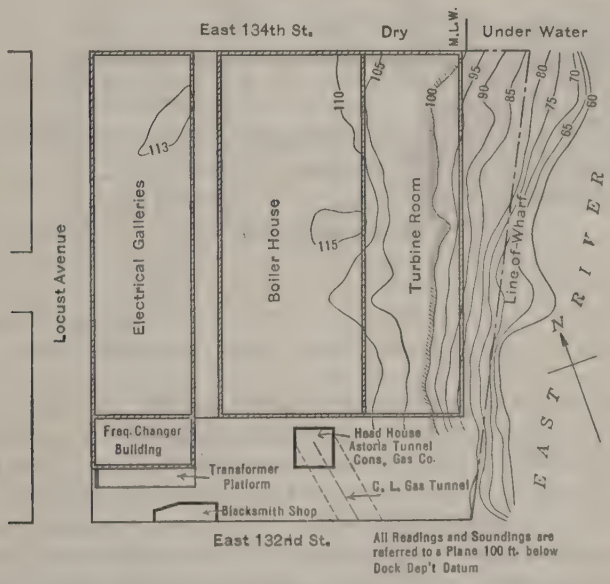

FIG. 3.—MAP SHOWING TOPOGRAPHIC SURVEY OF ROCK SURFACE AND MAIN OUTLINE OF THE HELL GATE STATION STRUCTURE.

The length of the holes ranged from 6 to 20 ft., with an average of 11 ft. A total of 1 776 holes were drilled. The average rate of drilling was about 60 ft. per day. This under-water work was started in March, 1920, and was completed in September, 1921.

Before drilling of rock was started, 2 000 cu. yd. of over-burden were dredged. In all, 23 600 cu. yd. of rock were removed by the dredge and 13 400 cu. yd. in the dry, both place measurement. An attempt was made to have the work in shallow water done by a shot drill. This was started about opposite 133d Street. A total of ten holes about 20 ft. deep were drilled when this method was abandoned because the soft strata of rock would cause the core to break and wedge the drills and also caused them to lose their shot. These holes were 6 in. in diameter. The contractor then tried a wagon drill near 134th Street in shallow water, but progress was so slow that it was abandoned. It was the custom to bring the drill boat in at high tide and work offshore at low tide. Fig. 2 looking south shows the drill boat in position at the south end of the site and also the dredge in operation. The temporary pier shown in the center of the photograph was constructed to accommodate the shot drilling.

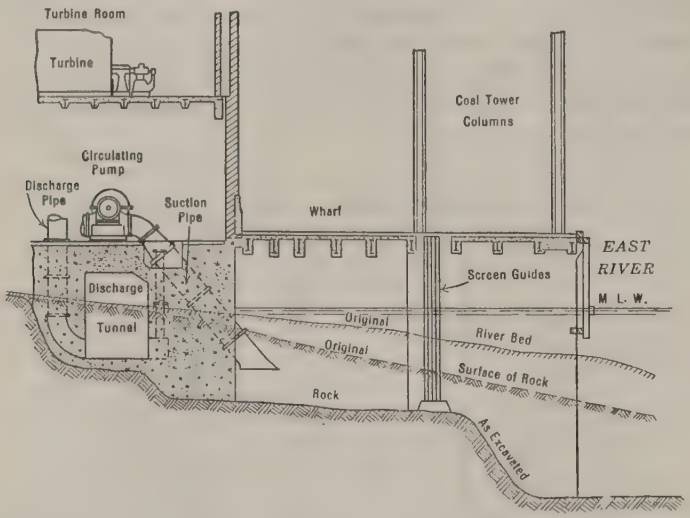

FIG. 4.—VERTICAL SECTION, WHARF SIDE OF HELL GATE STATION.

Some fear was expressed concerning the possible damage by reason of the blasting to the tunnel from Astoria which terminates in a shaft immediately north of 132d Street, between Locust Avenue and the East River (Fig. 3). This shaft is 231 ft. deep and the tunnel slopes slightly downward toward Astoria to a shaft 275 ft. deep. This tunnel, which is oval in cross-section, with an inside vertical dimension of 18 ft., a horizontal dimension of 16 ft. 9 in., and a length of 5 168 ft., carries two 6-ft. gas mains and some smaller pipes and conduits. During the blasting an inspector was stationed in the tunnel for purposes of observation and as a precaution the charges were made lighter at the south end of the excavation near the tunnel. The blasts were barely perceptible in the tunnel and no damage occurred.

To save the cost and delay of a coffer-dam the construction of the river-wall footing down to bed-rock at a depth of approximately 16 ft. below mean

low water was started immediately on the completion of the rock excavation. This footing was designed with returns inshore so as to take the part of a coffer-dam and permit the construction of a discharge tunnel in the open. The foundation of the river wall was made of concrete deposited by tremie. For convenience in construction it was divided into sections about 14 ft. long, alternate sections being constructed in the first operation. The second operation filled in between the alternate sections thus completing the continuous wall with its return.

The concrete sea-wall is trapezoidal in cross-section with an average depth of 28.5 ft. and a base 12 ft. wide. Alternate sections about 14 ft. long were first poured, with keys formed in the ends. The forms, built on the ground in advance, in the shape of an open box, were of 2 by 10-in. planks laid in a horizontal direction on all four sides. On the ends these were reinforced with 6 by 6-in. timbers and tie-rods 1 in. in diameter and on the sides the reinforcement consisted of 12 and 15-in. steel channels with similar tie-rods. The rods were run through pipe sleeves so that they could be easily removed after the concrete had set. After the forms were lowered into place by weighting them with reinforcing bars, the voids between the bottom of the box and the rock were filled in with sand bags placed by divers. Then the bottom was sealed with concrete poured by the tremie method, the sea water pumped out, and the remainder of the wall poured in the dry.

Fig. 5 shows one section of the concrete wall in place with the forms stripped and an adjacent form being lowered into place. This view is taken looking north along the line of the sea-wall, showing the movable plant of the contractor at the left. After the forms were placed in position divers sealed the spaces between the bottom of the form and irregular rock surfaces.

The view, Fig. 6, was taken from the south end of the rock showing the opening for the discharge tunnel through the sea-wall in the foreground and also the operation of shooting concrete into the tremie funnel.

Provision was made in the wall to receive the cast-iron suction pipes which run from the condenser pumps in the basement of the turbo-generator room at a slope of 45° through the concrete wall to a point 5 ft. below mean low water.

After the completion of the concrete footing of the river wall of the station the water back of the wall was pumped out and work was started on the discharge tunnel and the basement floor of the turbo-generator room, the finished elevation of which is 11 ft. above mean low water. The sea-wall proved to be exceptionally water-tight and the bed-rock was free from any open veins. To keep the excavation back of the sea-wall free from water a single 8-in. centrifugal pump was found to be adequate. Fig. 7 shows the rear of the sea-wall after it had been unwatered. The 52-in. cast-iron suction pipes are shown concreted in place and the concrete bottom of the discharge tunnel is also shown resting directly on the bed-rock. In the foreground the strike of the rock is seen to run parallel with the sea-wall.

Owing to experience at other stations in the disintegration of concrete in discharge tunnels special care was taken to make the inside surfaces of the Hell Gate discharge tunnel of a smooth, hard, and impervious concrete. To

use a similar high-grade concrete for back-filling under the entire basement would have been unnecessary waste and, therefore, a method was devised to place high-grade concrete at least 12 in. thick next to the discharge tunnel form and at the same time, lean concrete for the large mass. Fig. 8 shows the tunnel in an advanced state of construction. In addition to the suction pipes shown in the other photographs it also shows on the left-hand side the 42-in. cast-iron discharge pipes which were embedded in the concrete fill in the basement of the turbo-generator room terminating in an elbow at the bottom of the discharge tunnel. This tunnel is 11½ ft. wide by 15½ ft. high, running the full length of the turbo-generator room, the bottom elevation being 10 ft. below mean low water.

The "mixed aggregate" of sand and gravel used on this work was delivered in barge load lots and unloaded with a clam-shell bucket. In depositing this material in the storage piles the separation of the sand and gravel, particularly when the piling was done in cones, was so marked that re-apportioning of the ingredients was necessary to insure uniformity of the mixture for the special high-grade concrete used in the lining of the discharge tunnel and the reinforced concrete work.

The wharf is constructed of reinforced concrete slabs spanning between deep Bethlehem I-beams protected with a 4½-in. covering of concrete. The steel framing is supported by rectangular concrete piers, 6 ft. wide and 31 ft. long, reinforced with vertical rods and spaced 30 ft. 3 in. on centers. In several places cylindrical piers were used, 6 ft. in diameter and 46 ft. deep, and reinforced with thirty-two vertical rods, 1⅛ in. in diameter, and hoops, 12 in. on centers. The bottom of the pier is bonded into the rock with three dowels, 3½ in. in diameter. The deck of the wharf is finished with 4½-in. paving brick laid in a 1½-in. sand cushion.

The river water passes through steel screens before entering the intake basins. Each basin has an opening 24 ft. wide and 20 ft. high and is protected by four removable screens set in vertical bars spaced about 1 in. on centers and mounted in 4-in. channel frames. All the concrete below the water line was deposited through tremie pipes in forms sealed at the bottom as in the case of the sea-wall. Fig. 9 shows the wharf construction with the forms for the girder covering and deck slabs started. Fig. 10 is a "close-up" of the screen construction, showing the opening in the deck of the wharf to give access to the screens and also the base of the steel work for the coal trestle.

To provide for the ashes, which are discharged hydraulically through pipes to the water-front, a concrete bin was constructed within the lines of the wharf into which the ashes are deposited and from which they are removed by a clam-shell bucket. The hoisting apparatus (Fig. 11) is arranged so that the ashes may be deposited in barges alongside or in trucks.

The steel trestle on the wharf, which is 107 ft. high and supports two traveling coal towers also appears in Fig. 11. In this trestle construction is shown the crane beams for removing the ashes from the ash-pit so arranged as to permit ashes to be deposited in barges or in motor trucks.

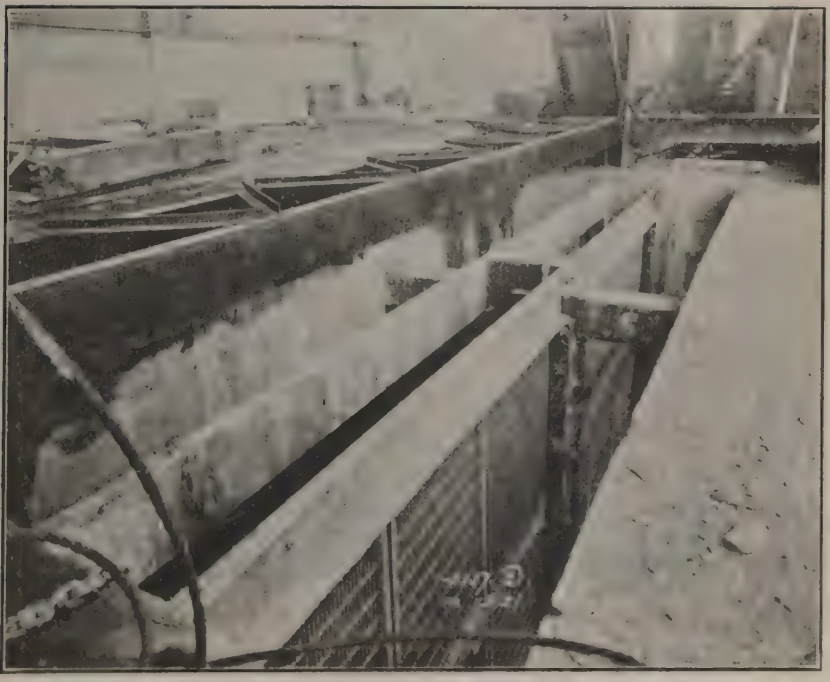

FIG. 10.—"CLOSE-UP" OF SCREEN CONSTRUCTION, HELL GATE STATION.

Fig. 11.—View of Hoisting Apparatus, Hell Gate Station.

On top of this trestle is carried a system of double tracks which parallel the bulkhead about at the level of the roof of the station. The tracks continue across bridges connecting the trestle with the turbine room, and another bridge spans the court between the boiler-house and control galleries. Where the cars cross the turbine room, the tracks are supported on the bottom chord of the roof trusses which have a span of 98 ft. West of the control galleries, the tracks are again carried on a steel trestle spanning Locust Avenue and extending 175 ft. to the center of the two city blocks used for coal storage (Figs. 12 and 13). This structure has an expansion joint at the control galleries and another at the rigid tower construction, and the three intermediate truss spans are supported by two flexible towers. The wind pressure on this trestle was assumed at 24 lb. per sq. ft., and the customary fiber stresses for static loads were used in designing the steel work. The cars deliver the coal to receiving hoppers suspended from the track floor and from there it is carried through steel chutes, 65 ft. long, and piled 35 ft. high in the storage yard for distribution by a drag scraper.

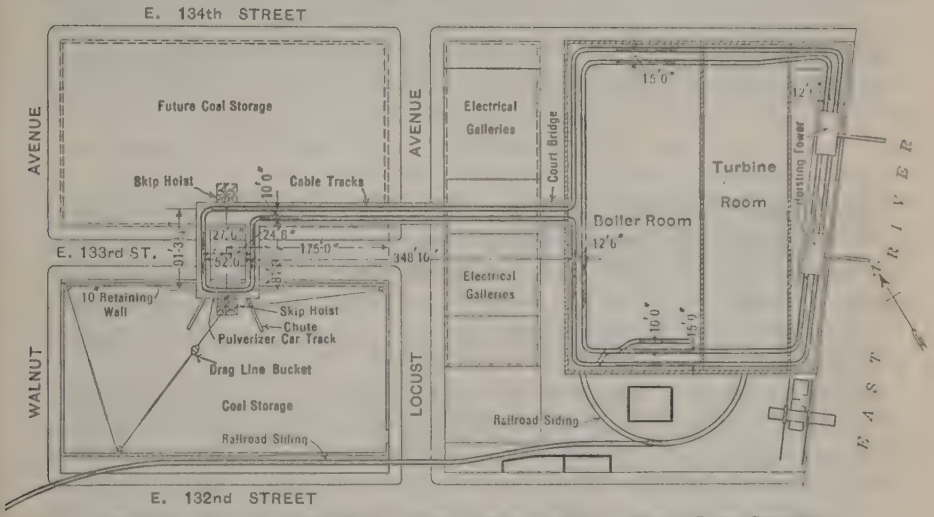

FIG. 12.—PLAN OF STATION AND COAL STORAGE YARD. HELL GATE STATION.

In Fig. 12 are shown the coal tracks from the bulkhead trestle into the storage yard in the rear, crossing Locust Avenue and also East 133d Street; also the track siding from the New York, New Haven and Hartford Railroad, which serves as an auxiliary means of supplying coal.

Four self-supporting steel stacks are carried on the roof framing of the boiler-house. Each stack has a diameter of 22 ft. and a top elevation of 258 ft. above the boiler-room floor, with provision for a possible future extension of 50 ft. A wind pressure of 25 lb. per sq. ft. of projected area was assumed on the stack and a maximum compression of 10 000 lb. per sq. in. was used in designing the steel plates. The base of the stack is anchored to the sup-

porting girders by thirty-two bolts 2¼ in. in diameter. The wind shear on the stack is carried down to the foundation through a system of wind bracing between the boiler-house columns.

The turbine room is served by two electric traveling cranes having a span of 96 ft., one with a capacity of 110 tons and the other of 90 tons. Each bridge girder of the heavy crane has two ⅞-in. web-plates, 8 ft. 8 in. deep at the center and 3 ft. 8 in. deep at the trucks. The weight of one bridge girder is 75 000 lb.

The end walls of the turbine room are braced by horizontal wind trusses 6 ft. deep, spanning 98 ft. These trusses are located about midway between the basement floor and the bottom chord of the roof trusses, a distance of 108 ft. Between the basement and the wind truss and again between the wind truss and the bottom chord bracing, three vertical columns are framed which are covered with brick pilasters to stiffen the wall.

The main turbo-generators in the turbine room have a capacity ranging from 35 000 to 50 000 kw. The machines are supported on steel foundations in order to provide sufficient space in the basement for the condensers and auxiliaries. Low unit stresses were used in designing the foundations to prevent excessive deflection and to minimize vibration. The box columns as well as the pairs of girders supporting the bed-plate of the machine are filled with concrete. Fig. 14 is a view taken from the basement floor of the turbo-room showing the heavy steel construction supporting the turbo-generators.

An interesting feature in connection with the design of the structural steel of the boiler-house, in addition to supporting the brick-lined steel stacks, is the hanging of the boilers from the structural steel. The water tubes and the steam drums are hung from the girders above and the steel and frame casing enclosing the boilers and stokers is supported on the floor below. Fig. 15 shows the boiler hung in position before the enclosing walls and stokers were erected.

Since the design of the electrical switching apparatus required the separation of the phases it became necessary to give some consideration to the heating caused by induced currents in the structural steel. To minimize this effect it was decided to build this part of the structure in reinforced concrete. In this design the steel is reduced to a minimum and the contact of the various parts of the reinforcement forming loops around the single-phase conductors is too poor to permit any appreciable rise in temperature. The electrical switching apparatus is housed in concrete compartments producing very heavy floor loads and requiring a reinforced concrete construction of rather an exceptional weight.

The first section of the switching galleries which take care of approximately one-half the total capacity of the station is 120 by 105 ft. and seven stories high. The concrete mixing plant used for this part of the work was located on the west side of Locust Avenue. The concrete was shot from a lifting tower, 220 ft. high, to a distributing tower across the street, 200 ft. high. The mixer was of ¾-cu. yd. capacity. The work on this first section of the electrical galleries, involving 6 600 cu. yd. of concrete and 574 tons of

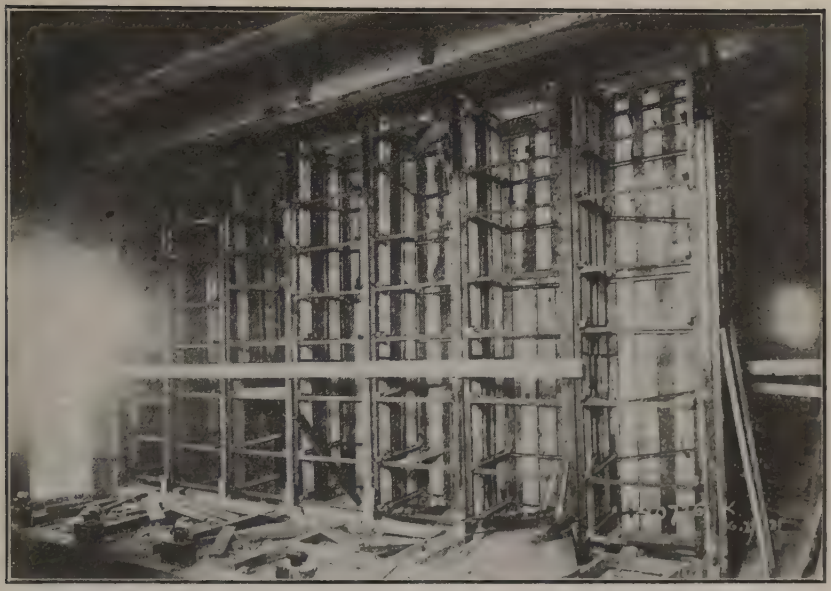

FIG. 17.—FORMS USED IN CONCRETING IN CONSTRUCTION OF HIGH-TENSION SWITCH COMPARTMENTS, HELL GATE STATION.

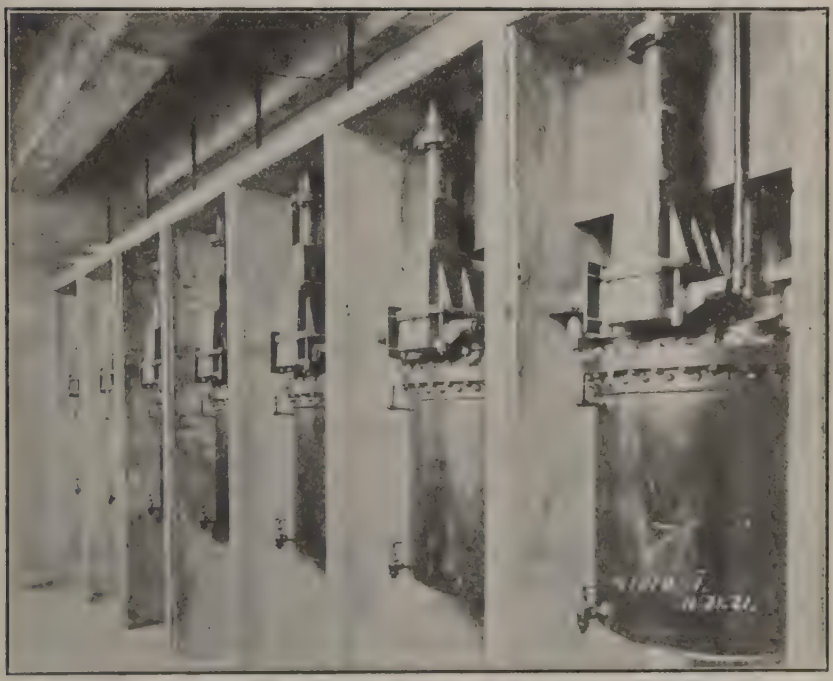

FIG. 18.—VIEW SHOWING HIGH-TENSION SWITCH COMPARTMENTS, HELL GATE STATION.

reinforcing bars, was started on February 2, and completed on March 29, 1921. Fig. 16 shows the first section of the reinforced concrete switching galleries under construction. This work is independent of the boiler-house, the structural steel framework of which is also shown.

The separation of the phases is effected by continuous walls running through all the floors designed so that it was possible to introduce ventilating shafts communicating with the various floors and arranged so that in addition to the continuous ventilation required it would be possible to remove the smoke quickly from burning oil or insulation should any short circuit to ground take place within any one of the sections.

While the high-tension switch compartments might be considered a part of the electrical switching equipment it is equally true that they are part of the structure of the building and the problems involved in their design and construction belong to the structural engineer's field. The switching equipment is probably the most interesting part of this station and to describe it properly would require a volume in itself. Those who are interested will find many excellent descriptions in the technical press.* In view of the duplication of detail in the construction of the compartments, of which there are about 3 000, a special effort was made to produce a form for concreting which could be used many times and which was readily demountable. Estimates were prepared comparing wooden with metal forms and economy seemed to point to the metal forms. These forms (Fig. 17) were constructed and assembled in the shop of the manufacturer and bolt holes and blocking were introduced where necessary to hold the inserts, which formed a part of the electrical construction, within the concrete of the compartment. The forms proved satisfactory except that in special places the sheet metal used was too light and it became necessary to introduce wooden struts. This, however, was inexpensive and successful.

The actual experience in construction again opened the question of the relative cost of metal *versus* wooden forms and in the second section of the electrical galleries, built about two years after the first ones, wooden forms were used throughout. One of the advantages of wooden forms as compared with metal forms is the flexibility of introducing and changing the inserts which could be very readily attached to wooden forms in any desired position. The inserts, numbering more than 30 000, form an important part of the detail of construction.

The compartments in general are about 4½ ft. wide by the full height of the floor, with 4-in. concrete side-walls and 6-in. rear wall (Fig. 18). The side-walls are rabbeted to receive doors which are hung in position and made readily removable.

A detail which proved most satisfactory was designed in connection with the acid-proofing of the storage-battery floors. It was absolutely essential that the sulfuric acid from the storage batteries be prevented from coming into contact with the reinforcing rods and structural steel members of the building, and the double acid-proofing method was introduced. Between the first

* Particularly in the *Electrical World* and the publications of the United Electric Light & Power Co.

layer of acid-proofing and the surface layer there was a layer of concrete about 3 in. thick. The effect of the acid on the concrete is to increase appreciably the volume and if the acid penetrates the top layer it would be evident by the swelling of the acid-proof surface, permitting a repair to be made and the defective concrete to be removed before the acid could penetrate the second layer.

The drain from this floor is a lead pipe terminating in a non-corrosive metal drain box. Fig. 19 is a cross-section of the acid-proof floor construction through the drain box.

The quantity of water pumped through the condensers has often been referred to on account of the very large volume required. When the station is completed there will be eight condensers (Fig. 20) ranging in size from 50 000 to 65 000 sq. ft. The quantity of water varies from 70 000 to 90 000 gal. per min. On the assumption that all pumps are operating, the quantity of water pumped through the condensers would be 640 000 gal. per min., or 940 000 000 gal. per day. On a 40% load factor the quantity pumped would be 376 000 000 gal. per day. A better idea of what these figures mean is obtained by comparing this quantity of water with that delivered each day to the entire City of New York, which is about 850 000 000 gal.

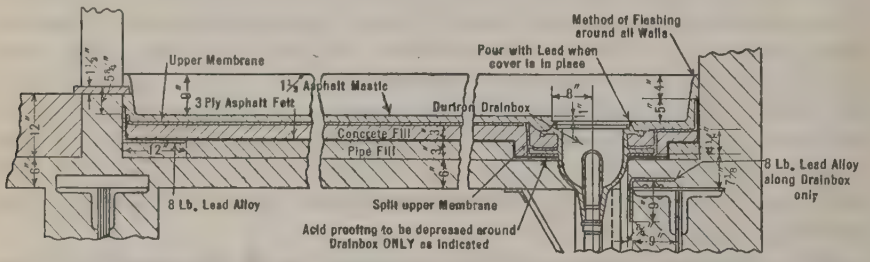

FIG. 19.—CROSS-SECTION OF THE ACID-PROOF FLOOR CONSTRUCTION, THROUGH DRAIN BOX, HELL GATE STATION.

The energy for pumping this enormous quantity of water is relatively small, since the only work required is to overcome the friction in the pipes and condensers. The whole system is operated as a siphon and the height to which the water is raised (approximately 30 ft.) does not materially affect the amount of energy required to produce circulation. Fig. 21 shows the two 54-in. suction pipes and the two 35 000-gal., motor-driven centrifugal pumps.

To insure against the possibility of the fresh-water supply (feed water) being cut off from this station arrangements were made with the city to receive water from three independent sources. The first taps the water supply at 138th Street and Southern Boulevard; the second, on a different main, from 133d Street and Southern Boulevard; and the third from the local water main immediately adjacent to the station.

The proximity of the New York, New Haven and Hartford Yard, immediately south of 132d Street, made it possible to install at this station a railroad siding (Fig. 12) which is frequently used for receiving equipment. The possibility of receiving coal on this siding was considered but it is not

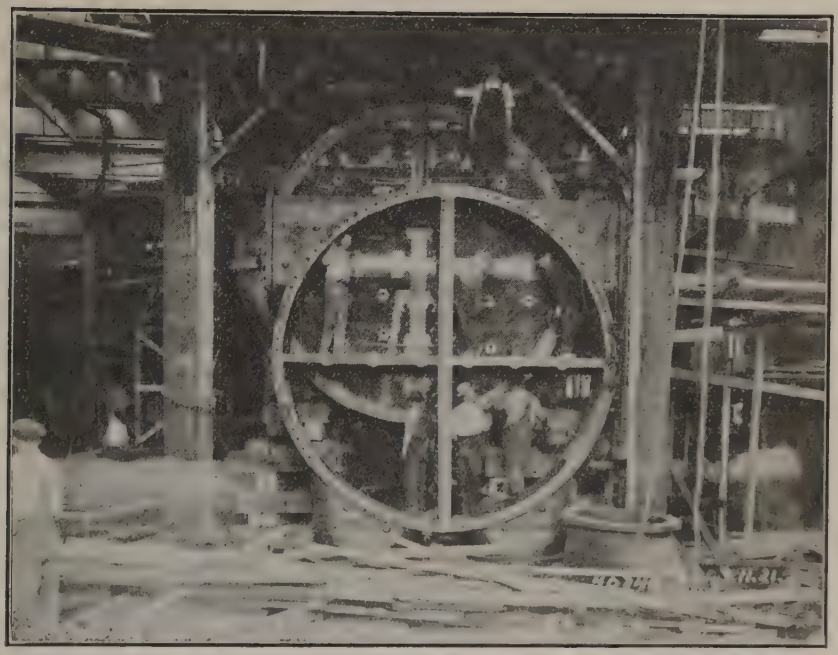

FIG. 20.—SECTION OF TYPE OF WATER CONDENSERS USED AT HELL GATE STATION.

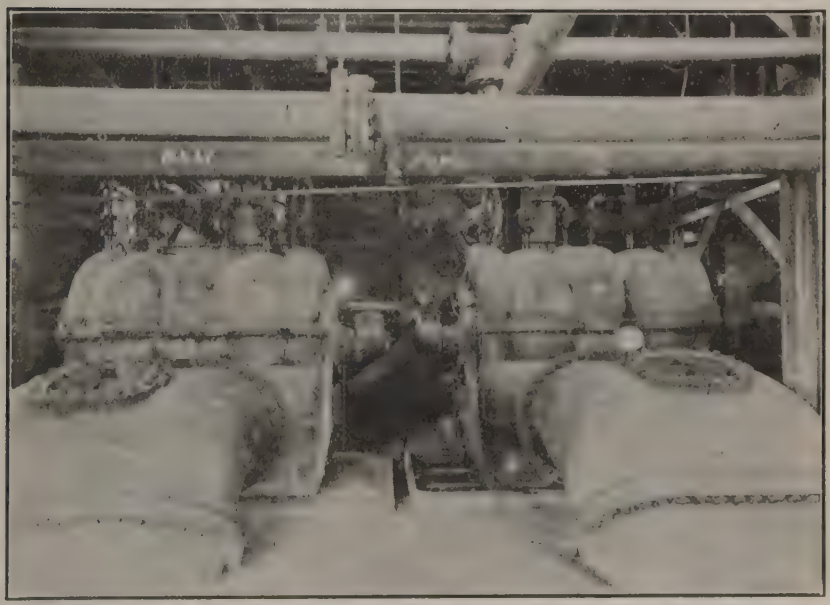

FIG. 21.—VIEW OF SUCTION PIPES AND CENTRIFUGAL PUMPS, HELL GATE STATION.

used to any extent since the cheapest coal that could be received in the harbor naturally comes by boat. As an emergency measure, however, coal might be received by rail.

The exterior finish of the building is a red face brick with precast imitation granite base and trim. The reinforced concrete electrical galleries are veneered with the same brick secured to the concrete by metal clips which gives an outward appearance of continuous steel and brick construction. The exterior window frames and sashes are of metal, the size of the openings being designed to use standard frames of a stock pattern.

The Hell Gate Station was put into service in the fall of 1921. At present (1927) there are seven turbo-generator units in operation with an aggregate capacity of 275 000 kw., of which 105 000 kw. has a frequency of 25 cycles and 170 000 kw. a frequency of 60 cycles. There is also a frequency changer of 35 000 kw. capacity. The eighth and last generator of 160 000 kw. capacity has been ordered and will be in service in 1928.

DISCUSSION

GEORGE A. ORROK,* M. AM. SOC. C. E.—The Waterside Station of The New York Edison Company was designed and built in 1899. Although the machinery in this station has been enlarged three and one-half times since then, most of the original steel work is in place. An extra expenditure at the time of building (possibly $150 000) has saved several millions of dollars in these reconstructions.

The quantity of condensing water involves two questions—the summer water temperature and the water-rate curve of the turbine with respect to vacuum. If the designer is satisfied with 26 in. of vacuum in the summer, increasing the water rate of the turbine ½ lb. or more, then a 30 to 1 ratio may be used; but if the water rates are to be kept at the guaranteed quantities and the best efficiency secured, then the ratio should be between 60 and 90 to 1, depending on the summer temperature. If the temperature of intake water rises to 90° Fahr., the ratio should be more than 100 to 1.

A. STREIFF,† M. AM. SOC. C. E. (by letter).—Apparently, there is still a great deal of difference among engineers as to how the modern large steam turbine should be supported. The usual specification issued by the Turbine Departments of the Westinghouse and General Electric Companies prescribes that the turbine foundation shall be detached from the building structure. On the other hand, the Allis-Chalmers Company favors the opposite practice of a monolithic building.

Detached foundations are made for seismographs and equatorials of astronomical observatories, but to require such a foundation for the steam turbine seems unwarranted. The modern steam turbine is marvelously well balanced, and fear of damage to the structure by reason of undue vibrations seems illusory. The large mass of the building naturally diminishes the amplitude of the vibrations and if these are objectionable, they surely would be excessive for a separate turbine support.

In a shop test on running balance the practice of the Allis Chalmers Company is to remove the foundation bolts one by one until the machine is entirely free from its temporary foundations. Such a machine would hardly need to be entirely detached from the remaining building.

The Hell Gate Station shows the turbine supports interconnected with the main structure, whereas in other very large stations as at Kearny, N. J., the turbine supports are separate. The former practice results in a roomy and simple supporting structure and is greatly to be preferred if both systems are equally satisfactory under running conditions.

Again, the requirement of applying a horizontal thrust equal to 25% of the vertical weight on the supporting frames of the turbine, as given by the Westinghouse and General Electric Companies, seems absurd. Such a thrust does not occur under any circumstance. In the direction of the shaft the largest thrust is the one possibly exerted by the steam main, which should be

* Cons. Engr., New York, N. Y.
† Cons. Engr., Jackson, Mich.

kept small. At right angles to the shaft the largest impact occurs during a short circuit, but this is an internal stress affecting only the supporting beams of the stator frames and does not introduce a horizontal thrust. Such a requirement causes heavy bracing and this interferes more or less with air coolers, condensers, bleeder connections, heaters, etc. The Allis Chalmers Company does not require such a horizontal thrust to be applied to the frame.

The arrangement of the turbine support followed at the Hell Gate Station seems to the writer the correct form. A statement as to its behavior under operating conditions would be of interest.

Ernest M. Van Norden,* M. Am. Soc. C. E. (by letter).—The writer appreciates the interest shown by Mr. Streiff and agrees with him that it is not essential to isolate the foundations of the turbo-generators from the structural steel framework of the building. Owing to the nature of the design, however, the steel foundations are not as rigidly connected to that framework as would be the case if a floor had to be designed to carry the loads to the main columns of the building. All the columns carrying the turbo-generator loads are independent of the building columns and the connections to the main structure are only useful in carrying a floor load for operating purposes.

It would be difficult to determine a formula for calculating the sections of the steel members, because the necessity for rigidity requires a factor of safety so high that erroneous conclusions are drawn as to the reason for using what appears to be extremely low unit stresses. The allowance of 25% of the vertical load for the horizontal thrust may seem excessive, and this may be a poor way of determining the sections, but it is quite likely that the usual design for this class of construction carries with it sufficient rigidity to take care of such stresses and perhaps greater ones in the horizontal direction.

The design that has given excellent results was made during the period when the turbine manufacturers believed that only concrete could be used for this purpose. The doubt concerning the rigidity of a steel structure was so strong that the steel designers were undoubtedly influenced by the fear shown by the turbine manufacturers and, therefore, very low unit stresses were used, care being taken to introduce rivets in shear only. It is fortunate, perhaps, that the steel design was started in this way, because it has been demonstrated beyond question that the low unit stresses, which cannot be well determined by any formula, and which were the result of extreme caution, have proved safe and economic.

The results of several years' operation at the Hell Gate Station indicate that the steel framework was well designed and can be recommended without hesitation for any other turbine foundation. The vibration from unbalanced machines, which occurred on several occasions due to accidents, was taken up by the steel foundations without transferring any perceptible vibration to the building structure.

Paper No. 1659

THE CIVIL ENGINEERING FEATURES OF THE KEARNY POWER STATION*

By Roman von Fabrice,† Assoc. M. Am. Soc. C. E.

With Discussion by George A. Orrok, M. Am. Soc. C. E.

Synopsis

The object of this paper is to set forth the problems that the civil engineer is called upon to solve in order to make "super-power" a possibility. To this end the civil engineering features of the design and construction of the Kearny Power Station are treated, each phase of the work separately.

The Kearny Power Station is situated on the west bank of the Hackensack River in the Town of Kearny, N. J., about midway between Newark and Jersey City, and is interconnected with the Essex and Marion Stations by a 132 000-volt transmission line supported on steel towers. It is the largest electric generating station in the State of New Jersey and will have a capacity of more than 400 000 kv-a. when completed.

"Super-power" means the production of electrical energy in great magnitudes and its distribution over long distances. Among the public, as well as among the Engineering Profession in general, the impression has been created that developments for this purpose primarily concern electrical engineers. This is erroneous, and although it is true that electrial engineers are responsible for the electrical features, the mechanical engineers and civil engineers are entitled to equal recognition in the problem of making super-power a possibility.

This paper will show the importance of the problems which the civil engineer was called upon to solve in this station, such as foundations and superstructures, high-tension sub-stations, transmission lines, coal and ash-handling structures, cooling water systems, etc. To provide, in co-operation

* Presented at the meeting of the Power Division, New York, N. Y., January 21, 1926.
† Designing Engr., Public Service Production Co., Newark, N. J.

with the architect, the proper structures for the accommodation of the equipment selected by the electrical and mechanical engineers, constitutes the chief problem of the civil engineer in such undertakings.

In order to accomplish these results properly he must be familiar, not only with the construction and requirements of the various types of electrical and mechanical equipment, but also with their operation, so as to be able to produce suitable and economical structures both for the support and housing of such apparatus.

General Description of Plant and Property

The Kearny Power Station, New Jersey's largest and newest generating station, built by the Public Service Production Company for the Public Service Electric Power Company, is situated on the west bank of the Hackensack River in the Town of Kearny, N. J. (Fig. 1). The site selected is near the load center, has adequate condensing-water facilities, and offers both rail and water transportation for the fuel required for the continuous and commercial operation of the station. The property on which the station is located comprises 78.9 acres of salt-water meadow land, partly submerged at high tide and requiring piling for the support of the structures.

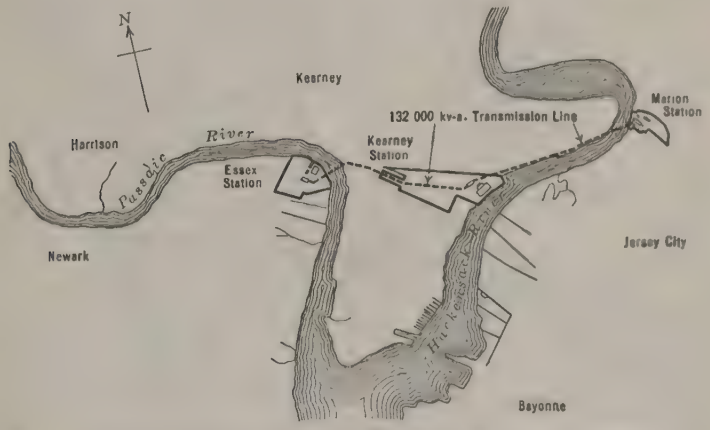

Fig. 1.—Map Showing Relative Locations of Kearny, Essex, and Marion Power Stations.

The initial capacity of the station is 205 100 kv-a., this being the largest ever installed at one time. The ultimate capacity, after the completion of the second half, will be more than 400 000 kv-a.

Beginning at the river the various buildings and structures are arranged in the following sequence (Figs. 2 and 3): Coal-bunker, boiler-house, turbine room, switch-house, service building, high-voltage outdoor sub-station, and transmission towers, the coal and ash-handling system and coal storage being to the west of the other structures. This arrangement was determined after most careful consideration as to the cost of fuel delivery, utilization of real

estate, railroad sidings, fuel-handling and storage, cooling water supply, electrical distribution, and economy of design.

Architectural Features

All buildings have been designed to act as parts of a single unit, the central axis of the plant passing through the center of each building. The service building and switch-house form the central motif of the whole group. The main elevation of the turbine room consists of a series of typical bays, the end bays being paneled. The buildings are classical in style, the Corinthian order being utilized where enrichment occurs. As far as was consistent with power-house architecture, projections were held flat and details were refined. A striking feature is a cast-iron Palladian window, 70 ft. high, at the end of the turbine room and a similar but somewhat smaller one in the center of the front of the switch-house (both are seen in Fig. 4).

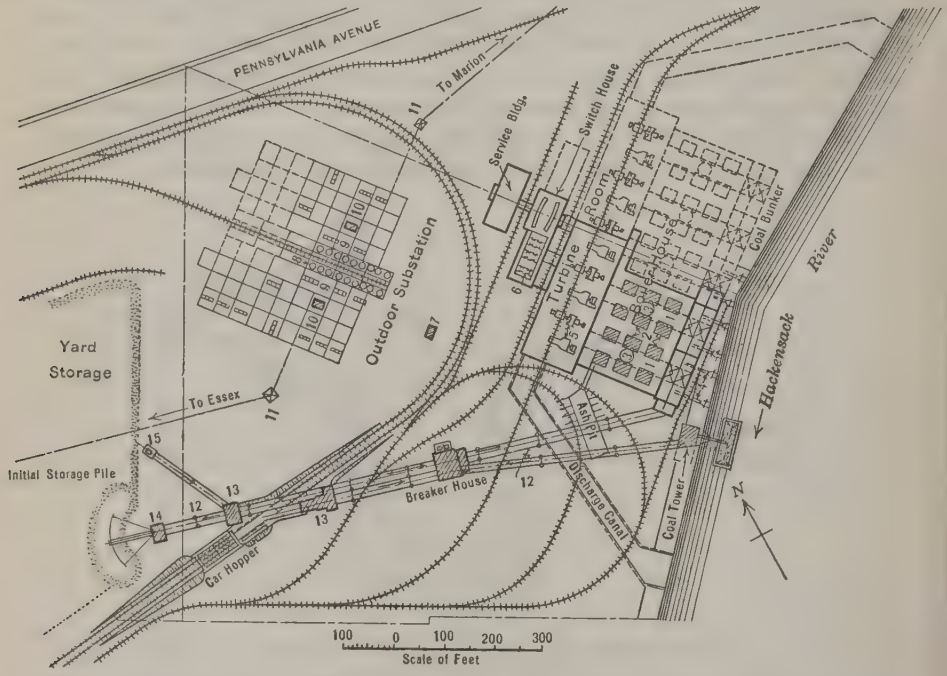

Fig. 2.—Plan of Kearny Power Station: (1) Firing Aisle; (2) Boilers; (3) Stacks; (4) Intake Tunnels; (5) Turbo-Generator; (6) Cell Structures for Isolated Switching Equipment; (7) Oil Purifying Plant; (8) 132-kv-a. Transmission Transformers; (9) Oil-Circuit Breaker; (10) Relay House; (11) Transmission Towers; (12) Conveyors for Fuel-Handling System; (13) Drive House for Conveyors; (14) Swinging Boom Tower; and (15) Reclaiming Pit and Hopper.

The interior of all buildings is severely utilitarian with the exception of the turbine room (Fig. 5), which is finished with gray face-brick panels and pilasters and a red tile floor. The control room in the switch-house has plastered walls and ceiling, a plaster cornice, and a rubber tile flooring.

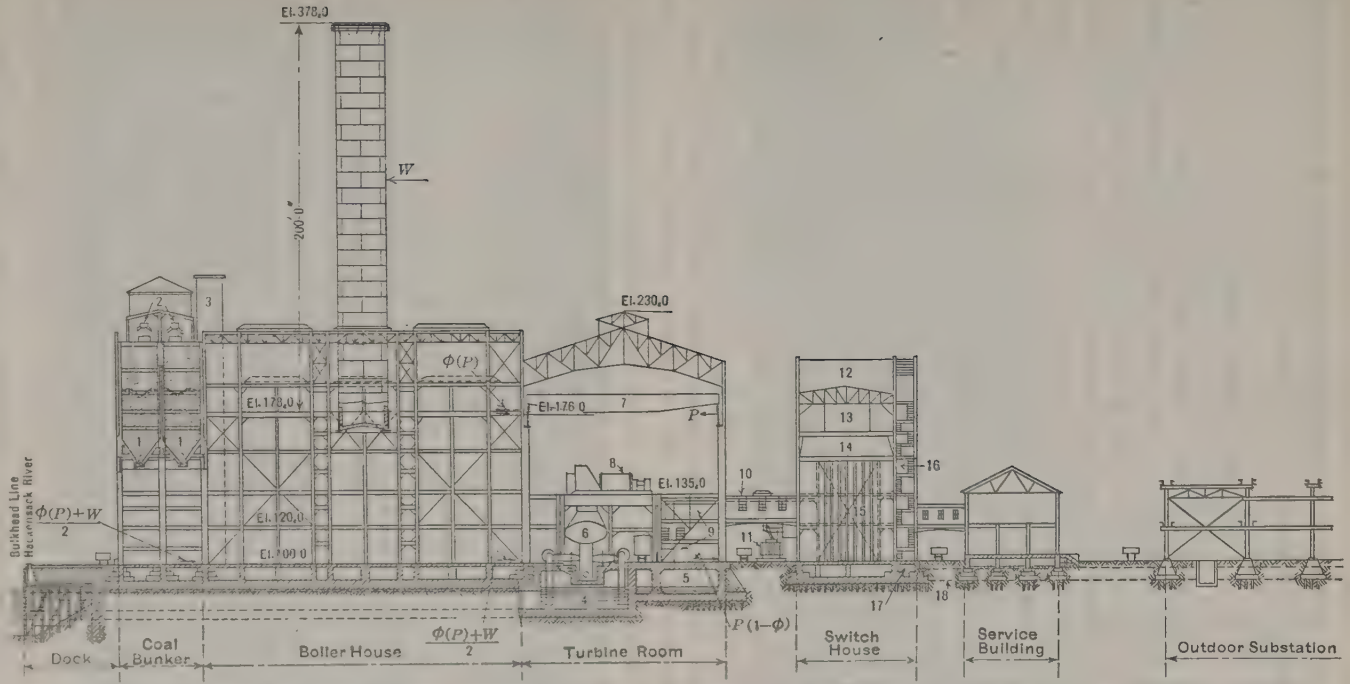

FIG. 3.—CROSS-SECTION THROUGH KEARNY STATION: (1) COAL POCKETS; (2) CONVEYORS; (3) ELEVATORS; (4) SUCTION CHAMBER; (5) DISCHARGE TUNNEL; (6) CONDENSERS; (7) 125-TON CRANE; (8) TURBO-GENERATOR; (9) MAIN AUXILIARY DISTRIBUTION SUB-STATION; (10) BRIDGE FOR GENERATOR MAIN LEADS AND MAIN VALVE CONTROL BOARD; (11) TRANSFORMERS FOR MAIN AUXILIARY SUB-STATION; (12) MAIN CONTROL GALLERY; (13) CONTROL BATTERY, CONDUIT ROOM, REPAIR SHOP, STORE-ROOM, TOILETS, AND LOCKER ROOM; (14) MAIN SWITCHING MECHANISM; (15) CELL WORK FOR ISOLATED PHASES, CIRCUIT BREAKER, REACTORS, ETC.; (16) STAIRWAYS, ELEVATORS, AND CONDUIT SHAFTS; (17) MANHOLE FOR MAIN LEADS TO OUTDOOR SUB-STATIONS; AND (18) DUCT RUNS TO OUTDOOR SUB-STATIONS.

The exterior walls of all buildings are of common red brick trimmed with limestone. The general architectural appearance of the entire station is dignified, quiet, and massive in character.

General Specifications

The structural steel for Kearny Power Station was designed on the basis of a stress of 18 000 lb. per sq. in., as against the usual practice of 16 000 lb. per sq. in. This economy effected a saving of approximately 12% in the weight of steel. Wind-bracing was designed for a wind load of 30 lb. per sq. ft. and a maximum allowable fiber stress of 24 000 lb. per sq. in. Wherever possible tension members were used; in addition, many other features of economy were introduced, such as three-hinged trusses, the maximum application of cantilever and suspended sections, and the adoption of rolled shapes rather than lattice sections.

All floors throughout the entire plant were designed for the actual loadings obtainable under operating conditions, rather than for an arbitrary assumed uniform loading, intended to meet any probable future demands.

The concrete mats and other foundation parts were designed to distribute safely the calculated concentrated loads over the required number of piles with the minimum mass of concrete. The piles throughout were computed for a maximum carrying capacity of 15 tons each. In order to increase the stiffness of the entire foundation all vertical walls of intake tunnels and suction and discharge chambers were considered and utilized as rib reinforcement for the mats. In many instances reinforcing steel was added, not only for strength, but also to prevent cracks due to temperature changes and shrinkage. The concrete in the foundations was designed for 40 lb. per sq. in. in shear and 600 lb. per sq. in. in compression, and that in the floor and roof slabs for 40 lb. per sq. in. in shear and 700 lb. per sq. in. in compression. The mix of the concrete for the entire job was 1:2:4.

Scope of Project

For the initial installation of the Kearny Power Station the following major items are included and will be more fully described under their respective headings:

(1) Preparation of site.
(2) Construction buildings for field superintendence, maintenance, repair, and storage of equipment and materials.
(3) Coal-bunker with adequate overhead coal storage capacity, and repair shops, storeroom for materials, toilet and locker rooms beneath.
(4) Boiler-house of proper design for the boiler equipment and necessary auxiliaries.
(5) Turbine room for the main generating units, complete with condensers, auxiliaries, heat-balance equipment, cranes, auxiliary power distribution sub-station, and other essential miscellaneous items.
(6) Canals and tunnels for supplying water required for service and condenser equipment.

FIG. 4.—GENERAL VIEW, KEARNY POWER STATION; (1) SERVICE BUILDING; (2) SWITCH-HOUSE; (3) TURBINE ROOM; (4) BOILER-HOUSE; (5) COAL BUNKER; AND (6) HEAD TOWER OF CONVEYOR TRESTLE.

FIG. 5.—INTERIOR VIEW OF TURBINE ROOM, KEARNY POWER STATION.

(7) Switch-house to accommodate the necessary switching equipment, busses, conduits, switchboards, storage batteries, and other miscellaneous items.
(8) Service building for offices, restaurant, hospital, and other administrative facilities.
(9) Coal-handling system with storage and reclaiming system, yard trackage, unloading equipment from barges and railroad cars, bridges, towers, conveyors, and miscellaneous apparatus.
(10) Ash-handling system with pits, hoppers, bridges, and other disposal facilities.
(11) Sewerage and drainage system.
(12) Supply of fresh water, with sufficient storage facilities to insure against interruption of service.
(13) Dock, railroad sidings, and roadways.
(14) Outdoor step-up sub-station, including superstructures and foundations for transformers, switching equipment, duct runs and overhead busses, and transmission lines to sub-stations at Marion and Essex Stations.
(15) Transformer stations at Essex and Marion Stations.

The materials required for the initial construction at the Kearny Power Station are as follows:

Bricks	7 500 000
Wooden piles, 30 to 70 ft. in length (Fig. 14)	29 000
Structural steel, in tons	16 000
Concrete for foundations, canals, and substructures, in cubic yards	72 000
Reinforced concrete floors, requiring 5 000 cu. yd. of concrete, in square feet	235 000
Reinforced concrete roof slabs, requiring 1 900 cu. yd. of concrete, in square feet	92 000
Heavy type steel sash, in square feet	35 500
Excavation for foundations and canals, in cubic yards	125 000
Dredging in front of the dock, in cubic yards	120 000
Iron conduit, in miles	68
Fiber conduit, in miles	10
Electrical wire (in cables), in miles	585
Boiler tubes, 4 in. in outside diameter, in miles	46
Admiralty condenser tubes, 1 in. in outside diameter by 16 gauge, in miles	184
Lumber for dock, in board-feet	1 300 000
Cinders for fill, in cubic yards	700 000

These items do not include the lumber used for forms, steel required for reinforcement for canals, foundations, floor and roof slabs, and steel for flues, ducts, and galleries, nor brickwork for boiler settings. The volume of all buildings, exclusive of those for the coal-handling system, is 10 500 000 cu. ft.

Preparation of Site

Careful consideration had to be given, when laying out the construction program, to the proper location of the various final structures and of the temporary construction sheds, office buildings, railroad tracks, storage space, etc. (Fig. 6), in order not to interfere with the permanent buildings. The swampy nature of the land (Fig. 7) made it necessary to build embankments

for railroad tracks and to improve and extend the present roads across the marshes linking them to the existing main highways for access of heavy trucks to the site (Fig. 7).

About 700 000 cu. yd. of ashes hauled to the site by motor trucks were used in filling the land on which the various construction buildings (Fig. 8), roadways, and railroad tracks were located and to provide space for storage of materials. Office buildings for the field force, wash and locker rooms for the workmen, a hospital, storage houses for material and smaller apparatus, a compressor plant, a distribution sub-station, and various work and repair shops were also erected to prepare for actual construction of the project.

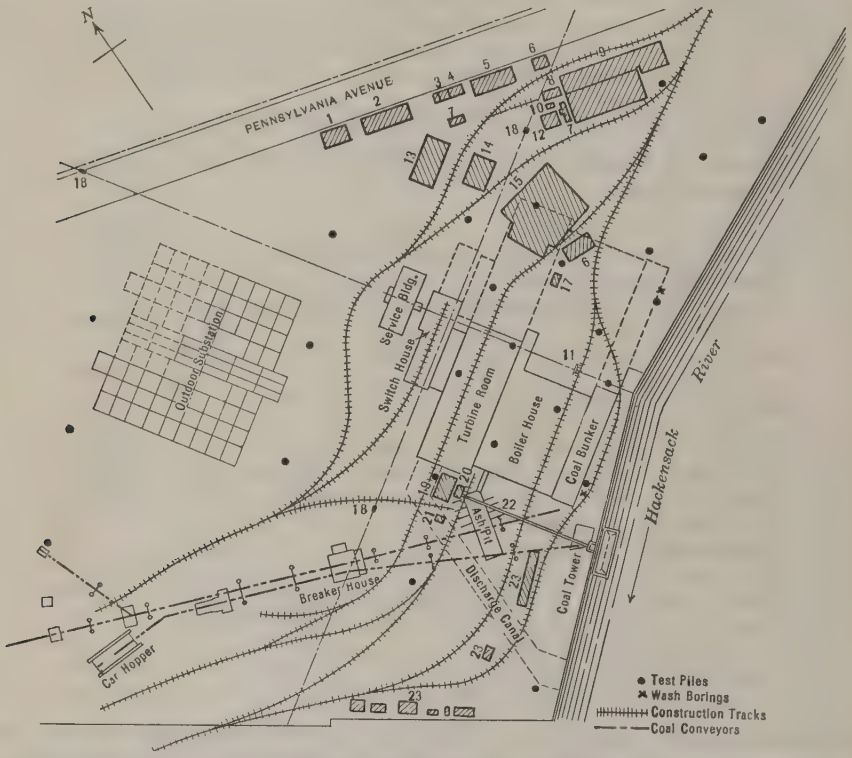

FIG. 6.—PLAN SHOWING CONSTRUCTION SHEDS AND TRACKS, KEARNY POWER STATION: (1) MESS HALL; (2) OFFICES; (3) GATE-HOUSE; (4) EMERGENCY HOSPITAL; (5) LOCKER AND WASH HOUSE; (6) SUB-STATION; (7) BOILER HOUSE; (8) HOUSE FOR LOCOMOTIVE CRANES; (9) STORAGE AND SHOPS; (10) GARAGE; (11) CORE BORING; (12) AIR COMPRESSOR; (13) STORE HOUSE NO. 1; (14) STORE HOUSE NO. 2; (15) BRICK SHED; (16) CEMENT SHED; (17) SHED FOR LUMBER SAW; (18) MONUMENTS ON BASE LINE; (19) CEMENT STORE; (20) MIXING PLANT AND CONCRETE TOWER; (21) BOILER HOUSE FOR CONCRETE PLANT; (22) MATERIAL CONVEYOR TRESTLE FOR CONCRETE MIXING PLANT; AND (23) SUB-CONTRACTORS' OFFICES.

The tracks (Fig. 6) were laid in positions to give easy access for the storage of the various materials and to handle them effectively when required during construction, and not to interfere with permanent structure.

FIG. 7.—BUILDING SITE SHOWING MARION POWER STATION IN BACKGROUND: (1) MARION STATION; (2) WEST END GAS PLANT; (3) SEABOARD BY-PRODUCTS COMPANY; (4) HACKENSACK RIVER; AND (5) PILE-DRIVER DRIVING TEST PILES.

FIG. 8.—CONSTRUCTION SHEDS, KEARNY POWER STATION.

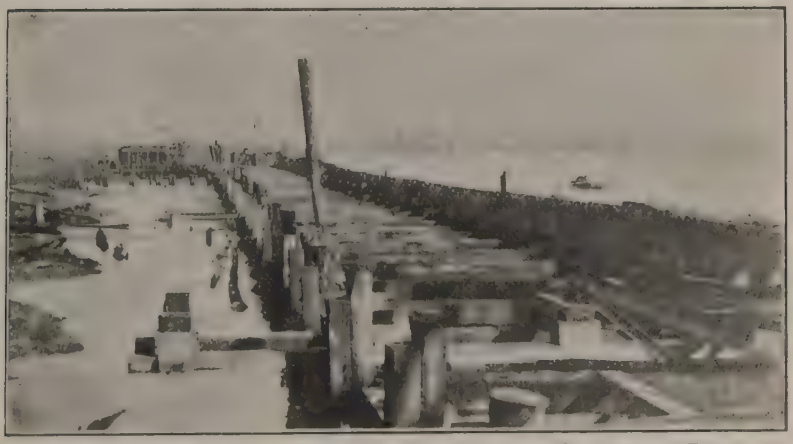

FIG. 9.—VIEW SHOWING TEMPORARY BULKHEAD AT HACKENSACK RIVER.

A fresh-water supply for operating the final station as well as for construction purposes had to be laid across the meadows from the city mains. Similar provisions were made for sanitation.

An unloading station for sand, rock, and gravel was erected at the river and connected by a trestle to the concrete mixing plant and distribution tower, the position of which had been selected so as to give uninterrupted service during the construction of the first half of the ultimate station.

A series of test piles (Fig. 6) were driven to determine the length and carrying capacity of the piling; wash and core borings were also made to ascertain the nature of the subsoil. These borings showed that the strata under the station site were composed of a layer several feet in thickness of vegetable matter underlaid by a mixture of clay and sand with vegetable matter, then layers of sand, becoming coarser as the depth increased, and, finally, shale and rock. In some places strata of quicksand were also found.

In order to keep the site from being flooded by the tides a temporary timber bulkhead (Fig. 9) was constructed along the water-front, and earthen dikes along the sides of the excavation. The excavation was kept dry by pumping.

Coal-Bunker

The coal-bunker (Figs. 2, 3, and 10) is on the water-front of the station. In order to insure the continuous operation of the plant, an ultimate bunker capacity of 19 000 tons was required. The grouping of the boilers around five stacks and firing aisles also necessitated the planning of five individual bunkers, each longitudinally divided by a center wall into two pockets. The initial installment has two bunkers of a total capacity of 7 600 tons, serving twelve boilers.

The coal is conveyed from the bunkers to the boilers by a traveling weigh-larry having a capacity of 25 tons. The bottom elevation of the bunkers was determined by the height of the stoker hoppers, and the head-room needed for the coal larry. The resulting space below the bottom of the coal-bunker was utilized to house the machine and repair shops, stores for material for station equipment maintenance, wash and locker rooms, toilets, and other minor facilities (Fig. 10). The bunker building is of steel frame construction with concrete slabs for floors and coal-pockets. The vertical bunker walls are of concrete, while the walls for the store-rooms are of brick. The longitudinal center wall, dividing each bunker into two pockets, is of hollow construction and designed to withstand the horizontal thrust due to the coal with either pocket full. The bunker walls have smooth surfaces to prevent the coal from arching and are tied together by I-beams protected by concrete (Fig. 10).

The bunker building is 43 ft. 9 in. wide, and 236 ft. 5 in. long for the initial installation and 501 ft. 6 in. for the final station. The conveyor gallery is 114 ft. long and its roof is 131 ft. above grade. The cut-off gates at the bottom of the hoppers are 51 ft. above grade and the maximum height of coal stored in the bunkers is 60 ft.

The inclined bottom of the coal-bunkers forms the roof of the store-room buildings beneath. The heavy vertical loads in the bottom of the pockets were

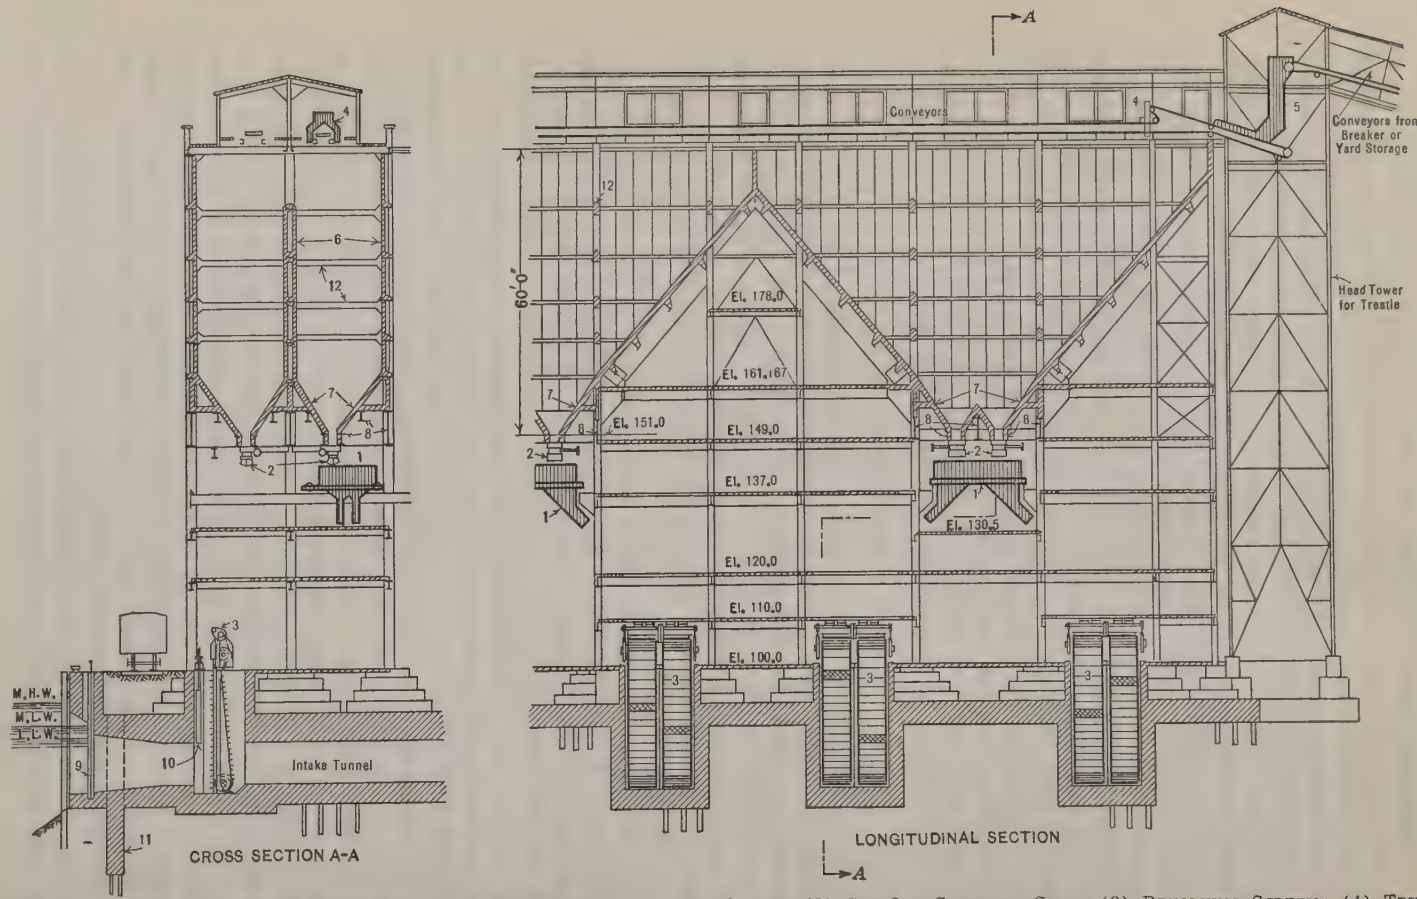

FIG. 10.—SECTIONS OF COAL BUNKER, KEARNY POWER STATION: (1) COAL LARRY; (2) CUT-OFF GATE FOR COAL; (3) REVOLVING SCREEN; (4) TRIPPER; (5) TRANSFER SPOUT; (6) CONCRETE WALLS, SMOOTH FACE; (7) CONCRETE HOPPER BOTTOM; (8) SUPPORTING GIRDERS; (9) TRASH RACK; (10) CUT-OFF GATE; (11) CUT-OFF WALL; (12) TIE-BEAMS PROTECTED BY CONCRETE.

taken by steel plate girders, while the hopper shape itself was obtained by the use of concrete, reinforced to take the horizontal components of the loads (Fig. 11). This proved more economical than a suspended hip-and-valley steel construction which would have been necessary to form this lower portion.

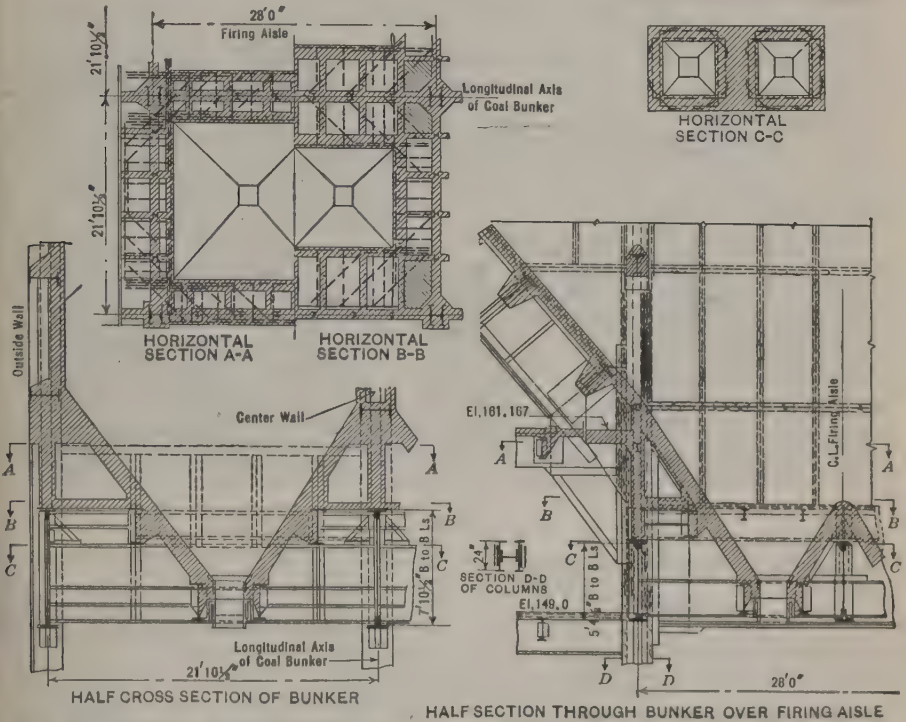

FIG. 11.—DETAILS OF STEEL AND CONCRETE IN BOTTOM OF COAL BUNKERS, KEARNY STATION.

All calculations for the coal-bunker were based on a weight, w, of 50 lb. per cu. ft. of coal. The horizontal pressure, P, for a depth, h, of coal, and an angle of repose, ϕ, was defined by the well-known formula,

$$P = \frac{1}{2} w h^2 \frac{1 - \sin \phi}{1 + \sin \phi}$$

The bunker foundations are supported on piles. The design of the foundations took advantage of the vertical walls of the intake tunnels under the foundation mat, also utilizing the outside building wall foundation as reinforcing ribs for the comparatively thin mat. A satisfactory distribution of the heavy concentrated column loads was thus obtained. The foundation problem was further complicated by the large wells for the revolving screens installed inside the bunker-house in the intake canals (Fig. 13).

In front of the coal-bunker house was a cut-off wall extending below the line of deepest dredging; this concrete wall was reinforced and tied to the intake tunnels and foundation mat. Its purpose was, first, to prevent the

subsoil from being washed out from under the foundation due to dredging; and, second, to form a seal against the possible entrance of marine borers in case they should infest these waters at some later date.

The bunker building is held laterally by the main bracing system of the boiler-house; no other special provisions, except tying to the boiler-house steel, were deemed necessary (see Figs. 3 and 29).

The column loads varied from 475 to 1 450 tons, due to coal, floor loading, and dead loads. The columns are H-beams reinforced with plates or I-beams on both flanges as required by the load. The grillage system (Figs. 12 and 13) consists of two or three tiers of I-beams embedded in concrete. The column bases are steel billets of proper dimensions.

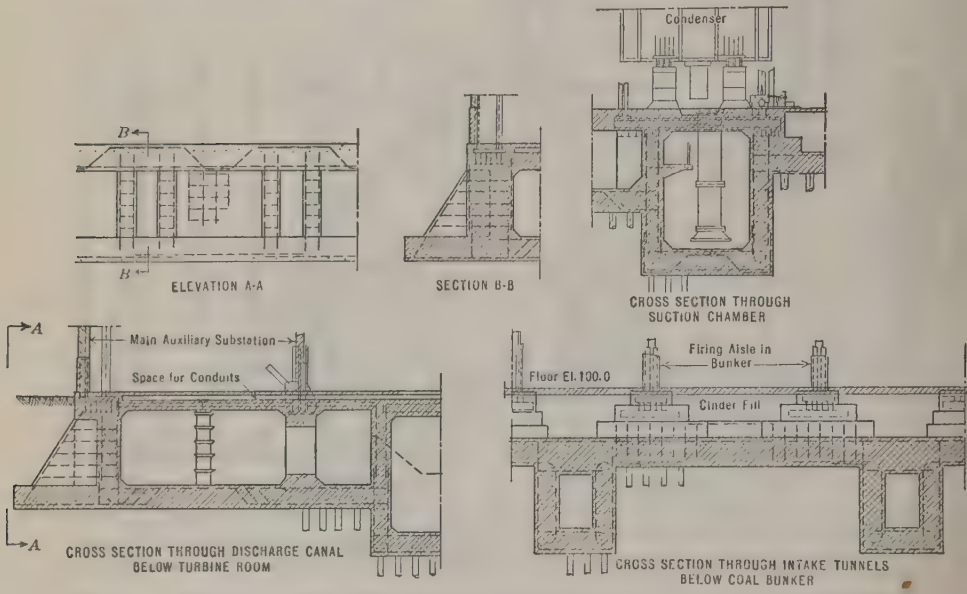

FIG. 12.—DETAILS OF FOUNDATIONS AND REINFORCING IN COAL BUNKER AND TURBINE ROOM, KEARNY POWER STATION.

BOILER-HOUSE

The design of the boiler-house steel and foundations (Fig. 14) was governed primarily by the equipment to be installed. Briefly, this equipment consists of twelve Babcock and Wilcox Company 3-pass, water-tube, cross-drum boilers, each having 23 600 sq. ft. of heating surface and 4 130 sq. ft. of superheating surface, designed for a maximum steam pressure in the tubes of 385 lb. (gauge) and 720° Fahr. at 200% of rating and capable of operating at a maximum rating of 350 per cent.

The general layout of the boiler-house is shown in Figs. 15 and 16 and the steel work in Fig. 17. The boiler settings are 22 ft. high and arranged in single units with solid walls and steel jackets. Provisions are made for ventilating and cooling the settings. The brickwork is clear of the building columns and supported on heavy girders designed for the loading imposed and the special requirements for stokers and their mechanism.

FIG. 13.—FOUNDATIONS FOR COAL BUNKER, KEARNY POWER STATION: (1) CONCRETE TOWER; (2) BULKHEAD; (3) INTAKE; AND (4) SCREEN WELL.

FIG. 14.—PILING UNDER BOILER-HOUSE, KEARNY POWER STATION: (1) INTAKE TUNNELS; AND (2) TEMPORARY BULKHEAD.

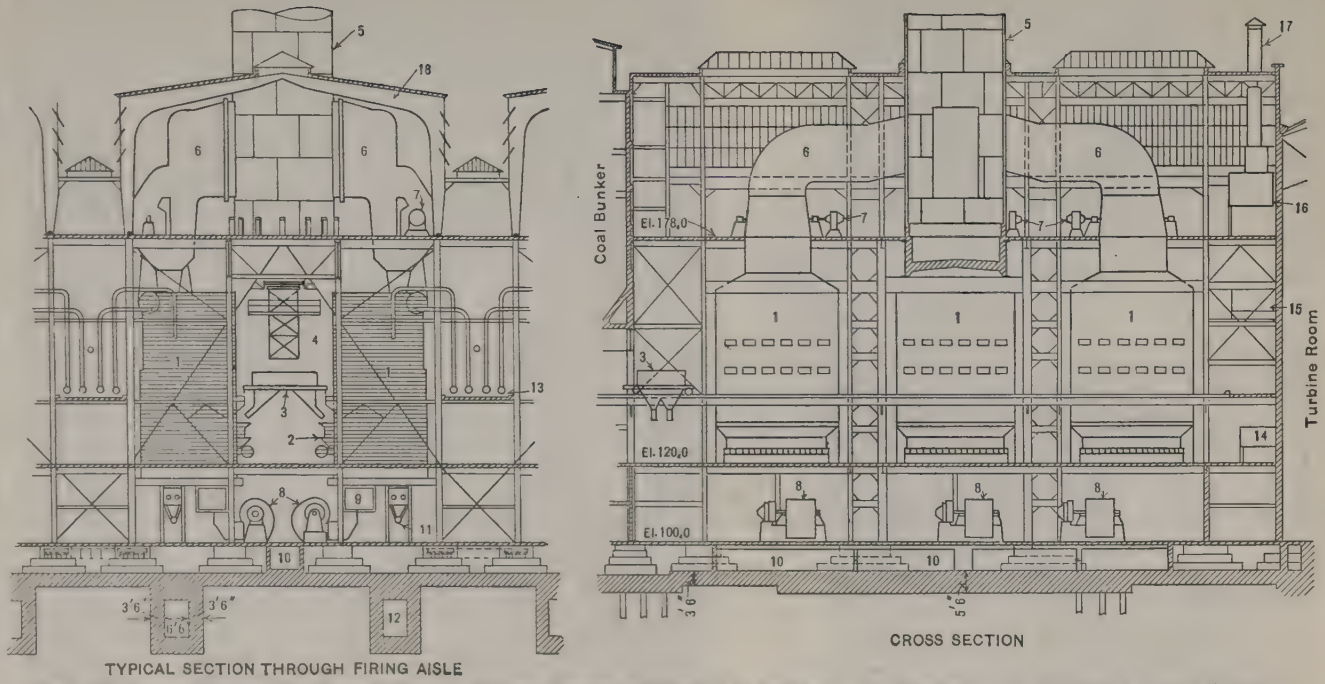

FIG. 15.—CROSS-SECTION OF BOILER HOUSE, KEARNY POWER STATION: (1) BOILERS; (2) STOKERS; (3) TRAVELING WEIGH LARRY; (4) MOVABLE PLATFORM; (5) STACK; (6) SMOKE FLUES; (7) INDUCED DRAFT FAN; (8) FORCED DRAFT FAN; (9) FORCED DRAFT AIR DUCT; (10) FRESH WATER STORAGE TANKS; (11) ASH SLUICEWAY; (12) INTAKE TUNNELS; (13) PIPE GALLERY; (14) OPEN FEED WATER HEATERS; (15) SERVICE TANKS; (16) SURGE AND COOLING WATER TANKS; (17) FREE EXHAUST PIPE; AND (18) THREE-HINGED ROOF TRUSS.

The side-walls above the combustion chambers are supported on specially constructed box-girders which form a main ventilating duct from which the air is distributed to the various sections of the side-walls as required for ventilation.

Six of these boilers are equipped with fifteen-retort, Sanford Riley stokers having a projected grate area of 479 sq. ft. of grate surface and furnace volume, above the coal bed and including the first pass, of 8 985 cu. ft. The other six boilers are equipped with sixteen-retort, Taylor stokers having a projected grate surface of 459.9 sq. ft. and a furnace volume above the coal bed and including the first pass of 8 472 cu. ft. (Fig. 18).

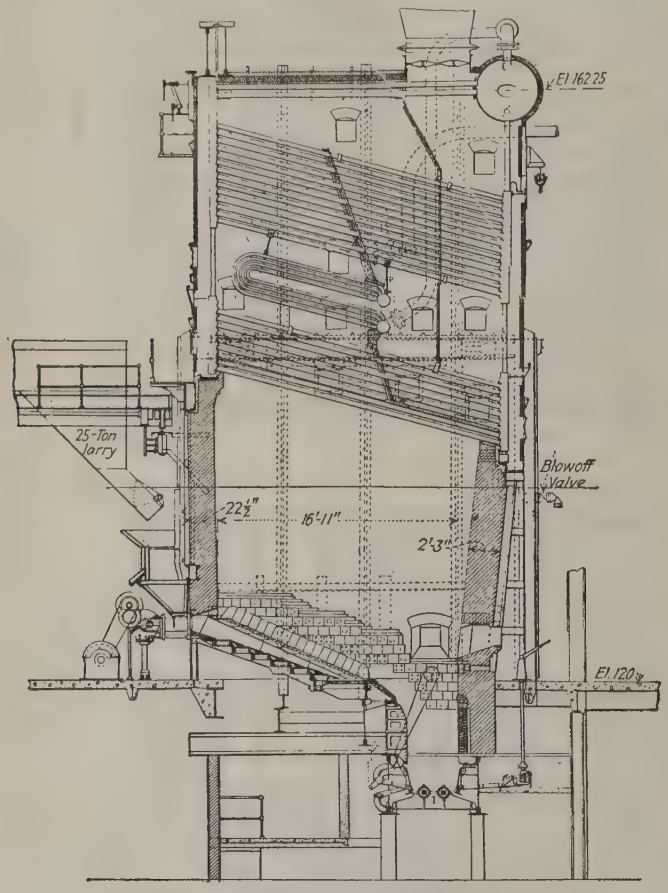

Fig. 16.—Plan of Boiler Setting.

Each group of three boilers is equipped with a common forced-draft air duct into which three Buffalo Forge Company fans discharge. Each of these fans has a capacity of 134 000 cu. ft. per min. at 65° Fahr. and 7-in. water pressure. The fans are driven by a two-speed, 2 300-volt, 225-h. p. General Electric motor. Two of these fans will supply all the air necessary for com-

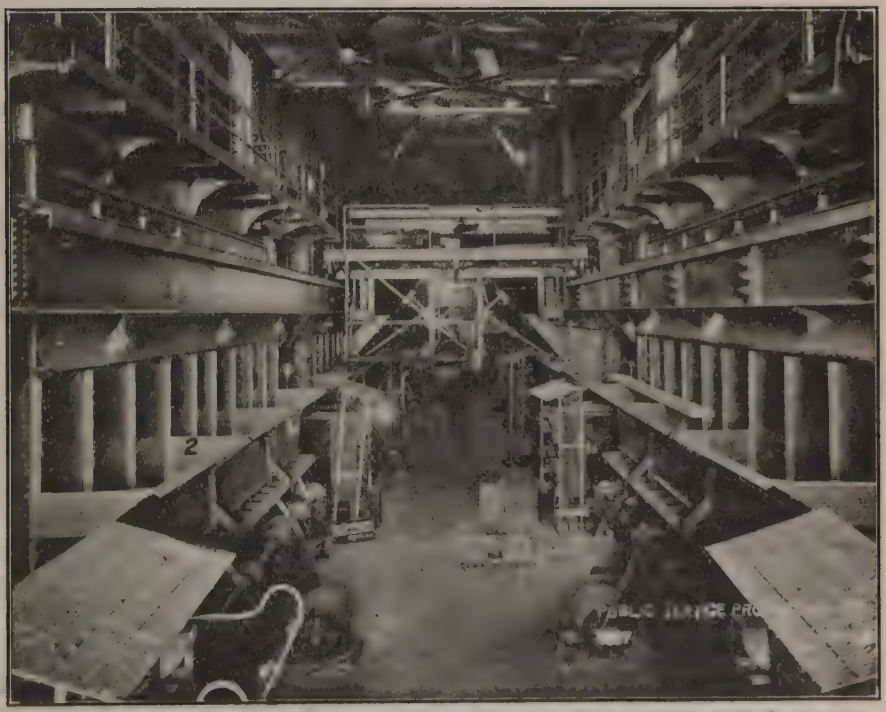

FIG. 18.—FIRING AISLE AND STOKERS, WEIGH LARRY IN BACKGROUND: (1) STOKERS; AND (2) EXTENSION HOPPERS.

bustion under normal operating conditions for three boilers, leaving one fan as a spare unit.

The forced-draft air duct is constructed of brick and concrete, utilizing the main floor as the top and the wall between the ash cellar and the forced-draft fan room as one side. This arrangement (Fig. 16) proved to be more economical in design and operation than the conventional steel ducts.

Each boiler has one double width, double inlet, multi-vane Sturtevant induced draft fan, having a capacity of 275 000 cu. ft. per min., at 650° Fahr., and 3.5 in. of water suction, driven by a two-speed, 300-h. p., 2 300-volt General Electric motor. Each fan inlet is directly connected to the breeching of the boiler and the fan discharges into the flues leading to the stacks. Arrangements are also made to by-pass the fans, so that the products of combustion may go directly from the boilers to the stacks under normal rating. (See Fig. 15.)

Five de-aerating and metering water heaters with jet heater open feed and with a capacity of 400 000 to 1 000 000 lb. of water per hour, which were furnished by the Cochrane Corporation, are installed in the bay adjoining the turbine room.

Additional equipment, such as boiler feed pumps, service pumps, air compressors, sluiceways and sluice pumps, ash-disposal piping, feed-water heaters, fresh-water storage tanks, service tanks, storage battery, elevators, oil-purification system, power-distribution sub-stations, and other incidental equipment (Fig. 15) were provided in the design of the building.

Each group of six boilers is arranged to discharge the products of combustion into one stack. For the ultimate station it is planned that five stacks will be installed, two being furnished in the initial section. The stacks have an exterior diameter of 26 ft. 0 in. and are brick-lined throughout, the internal diameter being 24 ft. 7 in. The stacks are 200 ft. high, and supported on steelwork 78 ft. above grade; they are designed to withstand the wind pressure of a gale blowing 120 miles per hour. This wind velocity striking the cylindrical surface of the stack produces a horizontal wind load equivalent to 33.3 lb. acting upon a vertical plane area. The stacks are built of overlapping steel plates having a thickness of $\frac{3}{8}$ in. at the top and $\frac{3}{4}$ in. at the bottom. These plates are stiffened by vertical angle stiffeners and by horizontal rings made of angles and plates. The horizontal stiffeners are closer together at the bottom than at the top and serve to support and keep the brick lining in position.

The lining was grouted to the steel shell and a space was left between the top of the brickwork and the underside of the next ring or support for the following section. The vertical plate of the horizontal stiffeners was bolted to the angle ring after the lower brick lining was in place and before the following section of brickwork was built.

The stacks are supported on a heavy steel plate-girder platform at the level of the blower floor; the simple arrangement of this platform is shown in Fig. 19. Oblique girders have been avoided as much as possible to simplify fabrication and erection. The anchorage of the steel stack to the supporting

structure is also shown. A graphical solution for the determination of the zero line (neutral axis) of the horizontal cross-section at the anchorage is shown on Fig. 19. Since the directions of the wind causing the most unfavorable stresses in the various girders could not be determined offhand, the bending moments, etc., have been found for several conditions, varying with the direction of the wind. The envelope line enclosing these various moment curves (Fig. 19) was taken as the maximum moment curve and the girders were proportioned accordingly.

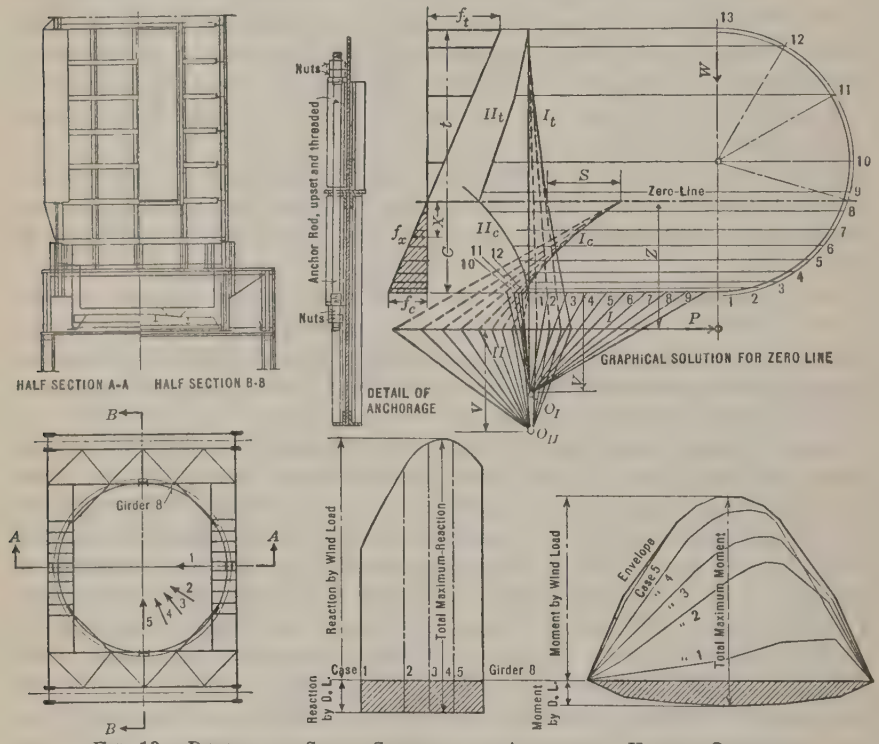

FIG. 19.—DETAILS OF STACK SUPPORT AND ANCHORAGE, KEARNY STATION.

The following stresses were used in the design for the shell of the stack:

Axial tension	10 000 lb. per sq. in.
Axial compression	9 000 " " " "
Rivet shear	10 000 " " " "
Rivet bearing	20 000 " " " "

Rivets in horizontal and vertical seams were computed at 70% efficiency. The opening in the stack for the flue has been heavily reinforced by angles and plates to compensate for the reduction in area.

To obtain the zero line (Fig. 19), Compression Areas 1 to 9 and Tension Areas 10 to 13 are laid off to a convenient scale and any pole distance, V, is taken. Draw the funicular polygons, I_c and I_t. The sides of these polygons

are prolonged until they intersect the resultant, P. With these intercepts and the pole distance, V, the funicular polygons, $I\,I_c$ and $I\,I_t$, are drawn. Their intersection point will locate the zero line.

With $f_x = b\,x$,

$$Z = \frac{\int x^2\,d\,I}{\int x\,d\,A}$$

The maximum compression in rim is,

$$f_c' = \frac{P\,c}{2\,S\,V}$$

The maximum tension in anchors is,

$$f_t = f_c\ \frac{t}{c}$$

Each group of six boilers is provided with one double-hopper, 25-ton, coal-weighing larry (Figs. 15 and 18), traveling along the firing aisle, receiving coal from the bottom of the bunkers, and delivering it to the stokers under the boilers. In addition to the weigh larry a movable platform (Fig. 15), which serves a group of six boilers, has also been provided. This platform is designed to travel the entire length of the firing aisle and is adjustable in height to suit the requirement of the work at hand on the boilers. The runways for this platform are bracketed from the overhead steel above the firing aisle. The ashes from the boilers after passing through the clinker grinders on the stokers are dropped into a sluiceway and then delivered into a settling pit whence they are removed as will be described subsequently.

Since adequate bracing for the stacks was necessary, it was made the nucleus of the entire bracing system for the station, as may be seen from Fig. 3.

The turbine room and bunker building have no major bracing; they obtain their stability from the boiler-house. Due to boilers and stokers projecting into the firing aisle, the transverse bracing had to be brought into the vertical plane of the rear boiler columns. This necessitated the arrangement of a horizontal bracing system at the level of the stack support, in order that the wind loads acting on the stack might be transmitted into the transverse bracing system.

The boiler-house roof is carried by three-hinged trusses (Figs. 15 and 17). This three-hinged system above the induced draft blower floor was adopted after making careful studies to determine the most economical solution of this problem, and also to simplify the installation of the flues and induced draft equipment. This design is lighter than conventional straight bottom chord roof trusses, showing a net ultimate saving of 110 800 lb. of steel for this portion of the work. Three-hinged arches are statically determined in regard to outer forces. Reactions and stresses are easily found, and the latter are not affected by changes of temperature. The arches provided an open space, free from obstructions, and resulted in obtaining a spacious room for the equipment at a reduction in the height of the building of more than 4 ft. and in the cubic contents of the buildings by 27 690 cu. ft. per section, or an ultimate total reduction of 138 450 cu. ft. of building volume.

The boiler-house building is 167 ft. 6 in. wide, 206 ft. 3 in. long for the initial installation, and 495 ft. 2 in. for the ultimate station, which will consist of five units each containing six boilers, one stack, and auxiliary equipment.

Turbine Room

The turbine-room building (Figs. 15 and 20) was designed to take the following equipment:

(*a*) Three General Electric Company, 39 200-kv-a. turbo-generators, 1800 rev. per min., designed to operate at a steam pressure of 325 lb. gauge and superheat of 271° Fahr. at the throttles; and

(*b*) Two Westinghouse Electric and Manufacturing Company, 43 750-kv-a., turbo-generators operating under the same conditions.

These turbo-generators are supported on structural steel foundations. Each is equipped with one surface condenser having 50 000 sq. ft. of tube surface, the water-boxes having vertical diaphragms so that one-half the condenser can be cleaned while the other half is in operation. The condensers weigh 700 000 lb. (full) and are supported on springs. Special rubber expansion joints are inserted in the water inlet and discharge pipes.

For each condenser two circulating pumps (Fig. 21) are installed, each having a capacity of 38 000 gal. per min., and being driven by one 500-h. p., 2 300-volt motor. In addition to these pumps, two motor-driven 1 000 gal. per min. condensate pumps and two twin two-stage steam-jet air pumps are installed for each condenser.

Each generator is equipped with one Griscom-Russell, two-pass, "U-Fin" cooler for cooling the air for the generators. The coolers for the General Electric units have a tube surface of 1 820 sq. ft. and a fin surface of 18 240 sq. ft., while the Westinghouse units are provided with air coolers having a tube surface of 2 280 sq. ft. and a fin surface of 22 800 sq. ft. each. The larger size of the latter coolers is due to the greater generator capacity of the Westinghouse machines.

To secure the greatest economy, motor-driven auxiliaries are used throughout, except the minimum spare equipment. For feed-water heating purposes a four-stage bleeding system from the main units has been installed. All possible precautions have been taken for the proper operation of the heat balance system including the bleeding of steam from the main units. To accomplish the desired results, one high-pressure, one intermediate-pressure, and one low-pressure, closed, feed-water heater complete with all necessary valves, piping, controls, etc., were installed for each unit.

For the erection and operation of the turbine room equipment two 125-ton Cleveland Crane and Engineering Company cranes were installed (Figs. 3 and 20). The runway girders supporting the crane were designed for the two cranes in closest position with a vertical live load impact of 25% and a horizontal impact of 10% acting along the longitudinal axis of the crane. The impact in the direction of travel of the crane, due to sudden stops, was assumed at 14% of the maximum total reaction of the crane, governing the design of the longitudinal bracing in the side-walls of the turbine room. This

FIG. 23.—CONDUITS IN FLOOR OF MAIN AUXILIARY SUB-STATION.

bracing of the initial portion was placed in only three bays for structural economy and in order not to detract from the architectural appearance. Wherever possible the bracing was placed in the panel bays. Architectural demands also governed the shape of the roof trusses, which were designed with arched bottom chords (Fig. 3), thus lending to the gracefulness of the turbine-room interior.

The dimensions of the turbine room were governed by the space required for the installation and operation of the main equipment. The building is 106 ft. 8 in. wide, 283 ft. 8 in. long for the initial installation, and will be 543 ft. 0 in. long after the ultimate ten generating units are installed. The main operating floor is 35 ft. 0 in. above grade, or basement, level, while the turbine-room cranes are supported on girders 41 ft. above the main floor, or 76 ft. above the basement.

The structure of the turbine room receives its stability from the bracing system of the boiler-house. The columns of the turbine room do not line up with those of the boiler-house and the transmission of the horizontal forces was accomplished at the blower-floor elevation (or 78 ft. 0 in. above the basement) by a horizontal plate girder, riveted to the beams of the blower floor, and in part by the roof trusses (Fig. 3).

The turbo-generators are supported on individual structural steel foundations 35 ft. in height; these foundations are entirely isolated from the main building steel (Fig. 21). The design of the turbine-supporting structures was based principally on deflections, care being taken that the deflection along the longitudinal axis of the foundations was uniform under each bearing. All connections and web sections were properly proportioned for impact. The horizontal bracing was designed by assuming 30% of the vertical loads as acting horizontally.

The entire upper platform of these turbine foundations was reinforced against vibration by the addition of diaphragms and concrete fill between parallel members. The design of the foundation steel was complicated by the space requirements of the condensers, pumps, air coolers for the generator, piping, generator leads, etc., thereby limiting the space available for bracing.

In addition to the turbo-generator equipment, the turbine-room building contains the main auxiliary distribution sub-station, situated under the main floor of the turbine room and consisting of three-phase, 2 300-volt, and 440-volt busses, which are supplied from the main tie bus in the switch-house through 5% reactors, and of three 7 500-kv-a. transformer banks. Two boiler-house and three coal-handling sub-stations are at present supplied from the main auxiliary sub-station, which ultimately will supply four boiler-house and four coal-handling sub-stations. All auxiliaries have duplicate feeds and panels of the truck type. The equipment of this main auxiliary sub-station is located on three floors, the upper one carrying also the leads from the generators to the switch-house on separate supports. All sub-station floors are suspended from a triangular truss (Figs. 3 and 22) which also serves to brace the lower portion of the outside turbine-room columns. An idea of the work of conduits in the floor of this sub-station may be gained from Fig. 23.

The system of intake and discharge tunnels, suction chambers, discharge chambers, etc., complicated the foundation design both for the building and equipment. The designs, however, were developed so that the walls of the various chambers were utilized to stiffen the entire structure and consequently operated to reduce the thickness of the mat (see Fig. 12).

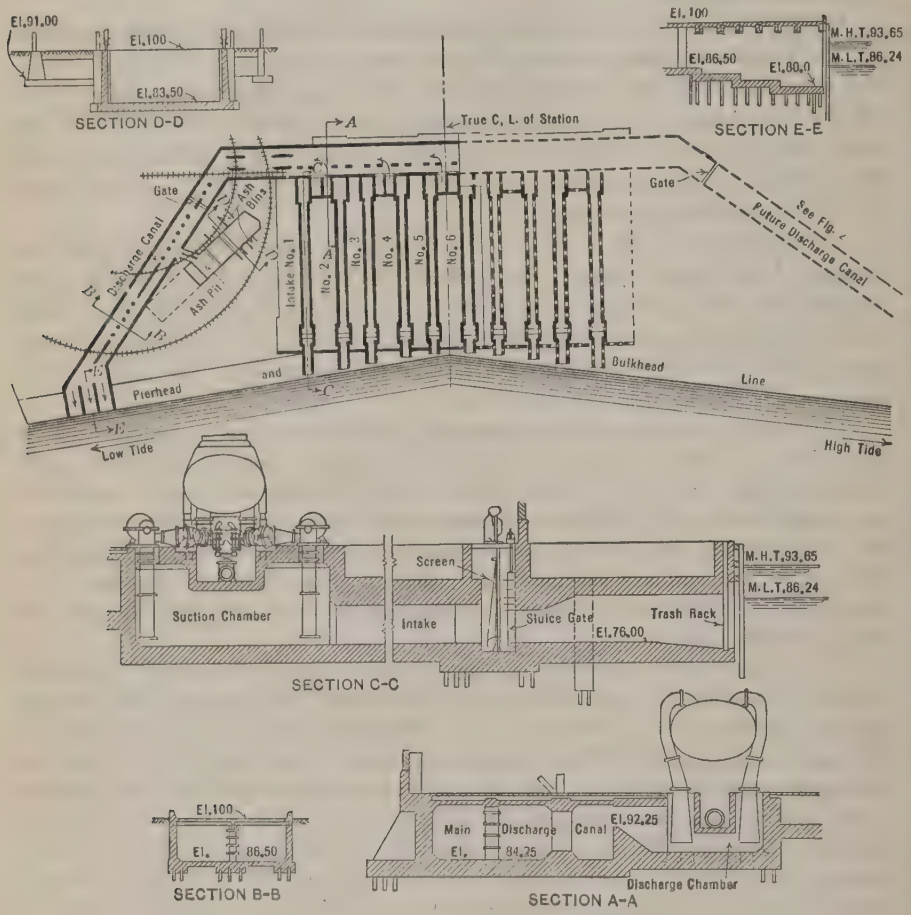

FIG. 24.—DETAILS OF CIRCULATING WATER SYSTEM, KEARNY STATION.

INTAKE TUNNELS AND DISCHARGE CANAL

The location of the station on the Hackensack River gives it an unlimited supply of condensing water. This water enters the intake tunnels through trash racks, is cleaned by revolving screens installed in the bunker-house, and then passes to the suction chambers and through circulating pumps into the condensers. From the condensers the water goes into the discharge chambers and then overflows into the common discharge canal, which delivers the warm water to the river. An individual intake tunnel, suction chamber, and discharge chamber are provided for each turbine unit (Fig. 24).

Each intake tunnel was designed to furnish 78 000 gal. of water per min. for condensing purposes and 10 000 gal. per min. for miscellaneous other station requirements, at a velocity of 3.2 ft. per sec. The discharge tunnel is designed to take care of the entire condensing water from ten units, or 780 000 gal. per min., at a velocity of 3.8 to 7.5 ft. per sec., depending on the tide.

The Hackensack River is subjected to variations of flow and of tide. To insure a continuous water supply irrespective of the tidal stage, the underside of the roof of the intake tunnels was fixed at 2 ft. below lowest tide (Fig. 10). The ultimate arrangement is to return the water to the river at two points, one up stream and the other down stream from the intake tunnels (Figs. 2 and 24), so that the danger of re-circulation may be eliminated. Ultimately it is planned to discharge the water into the river corresponding to the direction of the tide. This is accomplished by the introduction of balanced segmental gates as shown in Fig. 24. The discharge canal terminates at the face of the dock in a forebay, which was designed to reduce the velocity of the water emerging from the tunnel, thereby facilitating the handling of barges along the dock front. The forebay was roofed over to support loadings due to 10-ton trucks over the area along the dock.

The intake tunnels are built of reinforced concrete and extend from the front of the dock under the bunker and boiler-house to the suction chamber under the turbine foundations. The face of the intake tunnels was brought inward about 4 ft. from the edge of the dock to prevent obstruction to the flow by barges tied to the wharf. The rectangular cross-section of the intake tunnels is 6 ft. 6 in. wide and 8 ft. 6 in. high.

The position of the tunnels below the foundation mat was utilized to make them an integral part of the foundations of the turbine room, boiler-house, and bunkers. The vertical walls were designed to act as ribs, reinforcing the mat and allowing a safe distribution of the heavy concentrated loads over the proper number of piles. The tunnels are provided with trash racks at the entrance and revolving screens inside the bunker basement (Fig. 10). The screen wells can be shut off for cleaning and necessary repairs by a motor-operated sluice-gate.

The discharge chambers spill the water into the main discharge canal over a weir (Fig. 24, Section *A-A*). This was necessary to insure that the overflow, or tail-pipes, from the condensers should always be submerged to maintain the siphon effect, irrespective of the water level in the discharge canal, due either to the quantity of water handled or the condition of the tides. The opening above the weir was made of sufficient size to reduce the velocity of the water and to minimize the effect of erosion.

The bottoms of the discharge chambers directly below the condenser overflow as well as the top of the weir were protected against possible erosion from the condenser discharge water by heavy cast-iron plates set in place. Cast-iron plates were also inserted under the pump suction.

The discharge canal is of rectangular cross-section and extends along the entire northern side of the turbine room. The foundation walls for the main building as well as the foundations for the turbo-generators, were utilized

as side-walls for the discharge canal, requiring only a slight increase in depth for obtaining the required area. To distribute the heavy turbine-room loads over the piles, the floor of the discharge canal was heavily reinforced. The roof is a concrete slab supported between heavy steel girders and carrying railroad tracks and sub-station equipment (see Fig. 12.)

Beyond the turbine room the bottom of the discharge canal was raised and the rectangular cross-section was changed to maintain the net area required. This proved more economical, since it reduced the depth of excavation and also the height of the outside walls. The construction of the discharge canal outside the turbine room is similar to that inside, including a concrete roof supported on steel beams, reinforced to take care of railroad and truck loading, whenever they occur. The roof structure, except for railroad crossings, was supported in the center of the canals by concrete piers cast inside vertical 30-in. tile-pipe spaced 15 ft. centers (Figs. 24 and 25). The pipe was used as a form for pouring the concrete and was left in place to protect the piers against erosion. At railroad crossings regular concrete piers are used (Fig. 24).

Switch-House

The switch-house structure and foundation were designed to accommodate vertically isolated phases on the three lower floors, and complete separation of oil-immersed apparatus; also manual gang-operated disconnecting switches, and solenoid-operated oil circuit breakers with a rupturing capacity of 1 500 000 kv-a., all mechanically and electrically interlocked. The operating mechanism is on the fourth floor, and the main control room on the sixth floor, with the conduit room below.

The requirements imposed many complications in regard to obtaining a stable and suitable structure. This can readily be seen in Fig. 26. The entire central portion of the first four floors of the building is occupied by the cell structures for busses, circuit breakers, reactors, mechanism, etc. One rigid requirement was that no steel should be used which would cross through the floors from one side of the building to the other; this was to insure the greatest effect of the electrical isolation of phases.

The lowest main steel crossing the building is on the fifth floor, which carries the main storage batteries for control purposes, motor generator sets, machine and repair shops, storerooms, toilets, and conduit room. The total loading of this floor, due to these items and to the large number of conduits embedded in concrete, amounted to 375 lb. per sq. ft. This floor is suspended by hangers from the roof truss, except in those bays containing the control and conduit room. The suspended floor girders are connected by brackets to the outside columns for stiffeners (see Figs. 3 and 26).

The entire building is designed as a shell surrounding the inner cell structures for electrical equipment, and is independent of these structures for stability. For the three lower floors the stability of the building was obtained by the introduction of secondary columns opposite every second outer main column, and by the use of a horizontal bracing system at each floor

level (Fig. 27). This also reduced the amount of steel required and facilitated erection.

The control of all apparatus and the operation of the generators are supervised from the main control room on the sixth floor in the center of the future complete building. The complexity of the main control system necessitated thousands of conduits, and made it essential to include provisions for terminating the conduits at or near the switchboard. Therefore, a conduit room, or vault, was built under the main switchboard for properly manipulating the conduits (Fig. 28). The control room floor is carried by the top chords of the trusses spanning across the width of the building, while the conduit floor beneath is carried on the bottom chords of the same trusses (Figs. 28 and 29).

The foundation for the building consists of a reinforced concrete mat proportioned to distribute the weight over the piling. The cell structures are supported on transverse walls, which also allowed a simple and economical installation of conduits and cables. All floors were reinforced with a minimum amount of steel; great care was exercised to isolate this reinforcement in order to prevent undesired magnetic fields. All precautions were taken to isolate the phases as perfectly as possible and to minimize all disturbances, thus assuring a safe, continuous operation of the plant.

The generator leads were brought over from the turbo-generators in concrete compartments cast integrally with the roof slabs of the bridges between the turbine room and switch-house. The leads were carried in inverted concrete troughs supported on separate steel work through the auxiliary sub-station in the turbine room.

Service Building

The service building is designed as the central architectural feature of the ultimate station (see Fig. 4). It was planned to house all the administrative offices required for the operation of the station, as well as a restaurant, assembly room, hospital, paymasters' offices, and other minor facilities.

The building is a two-story, steel-frame structure with exterior walls of common brick, trimmed with limestone. It is carried on a pile foundation designed to meet the requirements imposed by the structure itself as well as the conditions due to various conduit and duct lines (Fig. 35) leading from the switch-house to the outdoor sub-station. These duct lines are separated from the foundations of the building, to avoid possible damage by unexpected settlement. Special features were provided to bridge the foundation walls over these conduits.

Coal Handling

The location of the Kearny Station on the Hackensack River permits the receipt of coal by water as well as by rail. A yard storage of 125 000 tons was provided. The pockets in the coal-bunker have a capacity of 3 800 tons for each group of six boilers, or a total of 19 000 tons for the ultimate station. This bunker capacity constitutes an insurance for continuity of service in case of break-down of any part of the coal-handling machinery.

The entire coal-handling system, as installed, is shown in plan on Fig. 2 and in elevation on Fig. 30. It is designed for the use of belt conveyors throughout, which gives the most satisfactory and economical service both as to construction and operation.

Coal arriving by water is hoisted from the barges by a Mead-Morrison, motor-driven, grab-bucket hoist having a capacity of 350 tons per hour; and delivered by an inclined conveyor to a Bradford breaker in the breaker-house. Thence, it may either be conveyed to the yard storage or to the bunkers. Coal arriving by rail is unloaded in the car-hopper house and dumped on the inclined conveyors leading to the breaker-house, passing through the Bradford breaker, etc., as before.

All coal designated for yard storage is carried by the conveyors to a swinging boom 90 ft. long itself having a conveyor, which builds up an initial pile from which the coal is dragged to storage by a drag scraper. The tower for the swinging boom is designed to take the loads of the boom and to provide for the support of the conveyor trestle (Fig. 30). It is tied to the drive-house through the conveyor bridge trusses, thereby stiffening the tower against overturning due to boom loads and consequently reducing the cost of both foundations and steel.

The drag scraper also reclaims the coal and delivers it to a pit, from which it is elevated by a conveyor to the horizontal reversible conveyors between the breaker-house and the yard storage (Fig. 30). These, in turn, transfer the coal to the breaker-house and thence to the inclined conveyors leading up to the bunkers, where it is distributed to the various pockets as required.

The entire conveyor-storage and reclaiming system is designed to handle 400 tons of coal per hour, duplicate belts in the initial installation being provided over the bunkers and from the breaker-house to the bunkers. Provisions are made throughout for duplicate conveyors for the ultimate installation, except the conveyor from the coal tower to the breakers, the conveyor on the swinging boom, the belt feeder in the reclaiming pit, and the conveyor from the pit to the reversible conveyors.

The drag-scraper equipment, furnished by the Maine Electric Company, has a maximum capacity of 400 tons per hour, and is driven by a 200-h.p., General Electric motor, working on a maximum haul of 600 ft. and giving a yard storage of 125 000 tons for a pile 15 ft. deep. Future extensions to the coal-storage system will provide for an ultimate capacity of 275 000 tons, while an additional 90 000 tons of coal can be stored and reclaimed by locomotive cranes.

The design of the trestles, bents, and other structures was governed to a great extent by tunnels, railroad clearances, ash-handling equipment, roadways etc. These conditions made it necessary to utilize long spans for the trusses. In order to decrease the weight of steel and reduce deflection, these long spans were built with cantilever arms, 20 to 25 ft. in length, and with suspended spans 100 ft. in length (Fig. 30). The main trusses were built up of "star" web sections and channel or angle chords. The flooring consists of 3½-in. reinforced concrete, and the roof and siding of asbestos-protected metal.

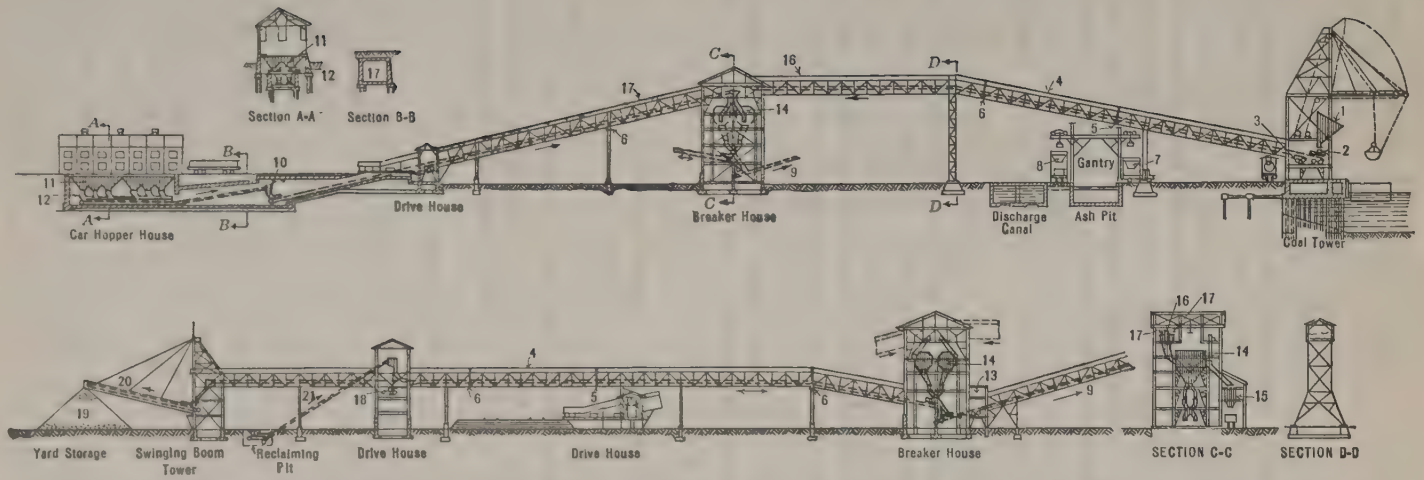

FIG. 30.—CROSS-SECTION OF COAL-HANDLING SYSTEM, KEARNY POWER STATION: (1) RECEIVING HOPPER; (2) FEEDER; (3) DRIVE; (4) SUSPENDED TRUSS; (5) HINGE; (6) EXPANSION JOINT; (7) ASH HOPPER FOR MOTOR TRUCK DISPOSAL; (8) HOPPER FOR RAILROAD CAR DISPOSAL; (9) CONVEYOR TO BUNKERS; (10) CHANGE IN DIRECTION IN PLAN (SEE FIG. 2); (11) CAR-UNLOADING HOPPERS; (12) FEEDERS; (13) DRIVE HOUSE FOR CONVEYORS TO BUNKER; (14) BRADFORD BREAKER; (15) REFUSE BIN; (16) CONVEYORS FROM COAL TOWER; (17) CONVEYORS FROM CAR-UNLOADING HOPPERS; (18) REVERSIBLE DRIVE FOR STORAGE AND RECLAIMING CONVEYORS; (19) INITIAL STORAGE PILE; (20) SWINGING BOOM CONVEYOR; AND (21) RECLAIMING CONVEYOR.

The bents throughout are designed with vertical upper posts, and tower legs spreading out at the bottom (Fig. 30, Section *D-D*), thus providing for simpler shop details and presenting a more attractive structure. Due to the height of the conveyor galleries between breaker-house, coal tower, and coal-bunker the bents for these spans were built of latticed angles. The trusses were supported on both columns of the bents and made statically determined by the omission of the diagonal in the end panel (Fig. 30).

To avoid secondary stresses in these bents, the bottom diagonal was merely bolted during erection and not riveted in place until after the full load was on the bents. Wherever possible the concrete footings for the columns of these bents were tied together with concrete ribs to insure against spreading or unequal settlement (see Section *D-D*, Fig. 30). Provisions were made in the design of the trusses and bents for expansion and contraction due to temperature changes.

The breaker-house (Figs. 30 and 32) is 54 ft. wide and 50 ft. 6 in. long by 90 ft. high. It was designed for an ultimate installation of two Bradford breakers, each 12 ft. 0 in. in diameter, 22 ft. 0 in. long, 102 000 lb. in weight, and having a capacity of 400 tons per hour. These breakers are driven by one 150-h.p. General Electric motor. In addition to spouts and transfers for coal, space for a distribution sub-station has been provided in this building.

The coal is delivered to the breaker by the conveyors from the car hoppers or coal tower, thence by a bifurcated spout to the belts conveying it either to the coal-bunkers or to the yard storage. All refuse material is dumped into bins, each bin having a capacity of 20 tons, and arranged to empty into cars for disposal.

The breakers are supported on a separate set of colums in order to minimize vibrations. Accumulation of dust is reduced to the minimum by covering all horizontal projecting girts, beams, etc., with an inclined flashing. To permit the concrete floors to be washed down, curbs projecting 4 in. above the floor level are furnished, which prevent coal dust and water from getting into the joints between the siding and steel, and, consequently, reduce corrosion.

Car Hopper

The initial installation of the car-hopper house (Figs. 2 and 30) and unloading pit permits four cars to be dumped at a time. One large steel hopper with three discharge spouts has been provided for each car and delivers the coal to horizontal feeders which, in turn, deposit it on a 36-in. conveyor. This conveyor runs horizontally beneath the hoppers and then rises to a spout delivering it on the conveyors leading to the breakers, from which it is transferred either to the bunkers or to yard storage. The design allows for a duplicate installation at the west end, which will increase the capacity of this unit from four to eight cars, or a maximum total of 800 tons of coal per hour.

The unloading pit is of reinforced concrete, water-proofed throughout (Fig. 30, Section *A-A*). The track girders over the hoppers are designed to take a maximum wheel loading of 25 000 lb. The tunnel beyond the hopper

building is also water-proofed and its roof is of sufficient strength to take the maximum railroad loading and fill.

Coal Tower

The coal tower on the river-front was designed for the initial installation of one hoisting unit. Foundations, however, have been built for the ultimate installation of two units.

Each tower unit consists of one 350-ton per hour, Mead-Morrison, hoisting machine, with one 5 500-lb. bucket having a capacity of 5 000 lb. of coal, driven by a 300-h.p., General Electric Company, 2 300-volt motor, and designed to make a round trip in 26 sec. In addition to one motor-driven air compressor, receiving hopper, feeder, chute, conveyor drives, and other miscellaneous equipment, the coal tower also contains one distribution sub-station.

The height of the tower was governed by railroad clearances under the conveyor trestle leading to the breakers. The boom, 60 ft. long, is arranged to swing clear of the dock line. The entire lower portion of the tower is enclosed with asbestos-protected, corrugated sheet metal. The foundations were designed for the maximum stresses due to snow, wind, bucket-loading, dead loads, and loads due to equipment and inclined conveyor trestle.

The piling was driven in two coffer-dams, which were excavated to 30 ft. below mean tide and filled with concrete, as shown on Fig. 30. The coffer-dams under both the front and the rear columns were tied together at the top by a concrete mat and also anchored back to "dead men". This was deemed advisable owing to the soil conditions at this point. The encasement of the piles by concrete also protects them against an eventual attack by marine borers, which are known to be in the vicinity of New York Harbor.

Ash Handling

The ashes from the boilers are washed through sluice-ways to a settling pit at the west of the building (Figs. 2 and 31).

The sluice-ways are arranged so that each group of three boilers deposits into one short continuous trough, or sluice, which leads into the main sluice-way carrying the ashes to the settling pit. An electrically operated Cleveland gantry crane, equipped with a grab-bucket, travels along the entire length of the settling pit and hoists the ashes into overhead hoppers from which they can be dumped either into trucks or railroad cars (Fig. 31). A large overhead hopper capacity was provided to make the operation of the gantry crane independent of cars or trucks for ash disposal. The pits have a storage capacity of 600 cu. yd. of ashes, which will take care of somewhat more than a maximum day's use of the ultimate station. Extensions to the pit can be made without impairing the operation, if later demands should require.

The two interior partition walls in the settling pit are made of timbers for easy removal if required for pit extensions. Overflow openings in the partitions and end walls are installed, with skimmers to prevent floating cinders from being carried into the discharge canal. The settling pit was designed to withstand hydrostatic head on the bottom, and car and truck loading on the sides. The hopper foundations were combined with the pit structure (Fig. 31).

Docks

In order to receive coal and materials shipped by water, it was necessary to build a dock along a part of the river-front of the property. With the exception of those sections in front of the bunker-house and the coal tower, the dock has been constructed of wooden piles and timber deck supporting a 9-ft. cinder fill, with a reinforced concrete retaining wall 9 ft. high. along the face. The concrete face is protected against injuries from boats, etc., by timbers and fender piles (Fig. 3).

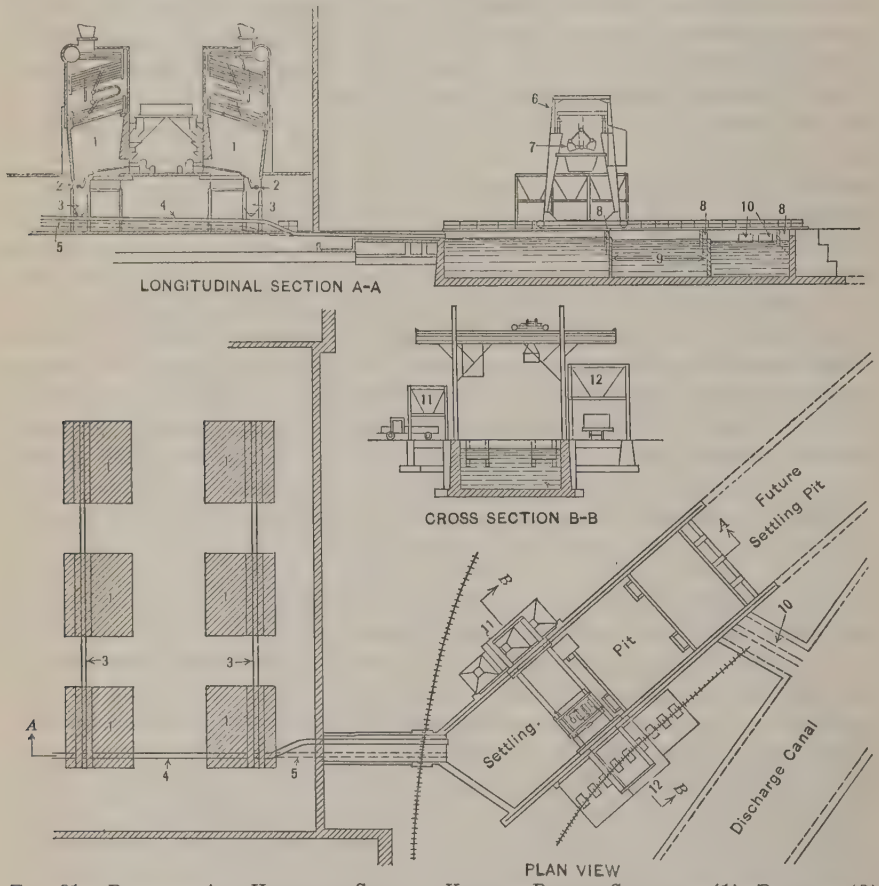

Fig. 31.—Plan of Ash-Handling System, Kearny Power Station: (1) Boiler; (2) Clinker Grinder; (3) Branch Sluice; (4) Main Sluice; (5) Future Main Sluice; (6) Traveling Gantry; (7) Bucket; (8) Skimmer; (9) Temporary Walls; (10) Overflow to Discharge Canal; (11) Ash Hopper for Motor Truck Disposal; (12) Ash Hopper for Railroad Car Disposal.

The design of the dock was based on a dead load of 500 lb. per sq. ft., a uniformly distributed, superimposed live load of 500 lb. per sq. ft., for storage purposes, equivalent to a Cooper E-50 railroad load.

At the rear of the dock, sheet-piling was driven to prevent the earth from sliding and being washed out. To resist the resulting horizontal earth pressure a number of batter piles were provided (Fig. 3).

The Outdoor Sub-Station

The outdoor sub-station (Figs. 2 and 33) was designed to step-up the entire electrical output of the generators from 13 200 to 132 000 volts for transmission purposes.

The initial installation is: Fifteen 15 000-kv-a., Allis-Chalmers, single-phase, oil-insulated, self-cooled transformers; four 90 000-kv-a., 132 000-volt, three-phase, sixty-cycle, outgoing feeders; thirteen General Electric (type "FHKO-39"), 132 000-volt, oil circuit breakers, with remote control, having a rupturing capacity of 1 500 000 kv-a.; fifty-five Westinghouse (Type 800 A), 154 000-volt, motor-operated, remote-control, disconnecting switches; thirty-three transformers; ten feeders; thirty-three oil circuit breakers; and one hundred and twenty-five disconnecting switches, of the types just mentioned.

The design of the sub-station includes two relay houses with vaults, oil purification house, and oil storage system, together with all the mechanical equipment and piping for treating and handling the oil.

The axis of the sub-station was determined by the direction of the outgoing feeders, property limitations, and coal storage and handling system for the operation of the station. The transformers, therefore, were arranged in two parallel rows along the center line of the sub-station and the oil circuit breakers in the adjoining bays as shown in Figs. 2, 34, and 35.

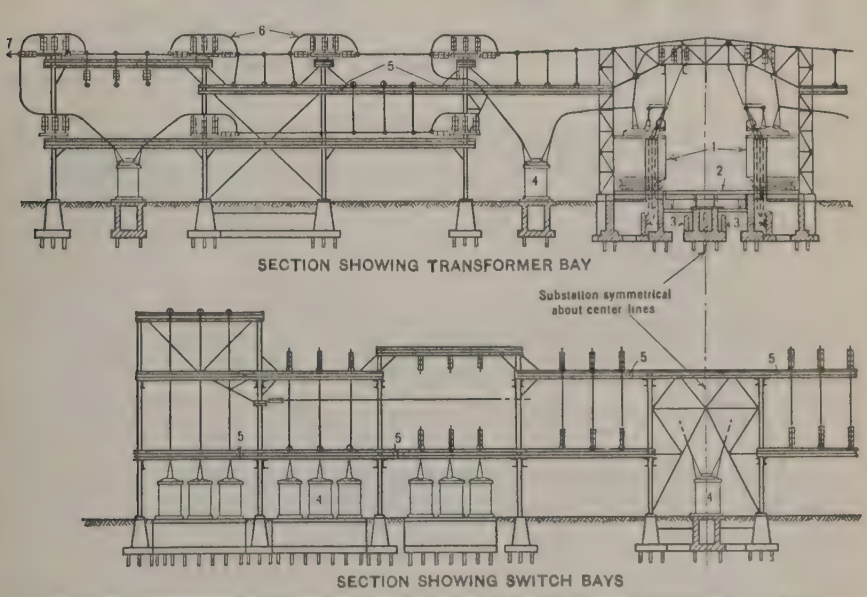

Fig. 34.—Sections of Outdoor Sub-Station, Kearny Power Station: (1) 132 Kv-a. Transformers; (2) Transfer Car; (3) Duct Runs; (4) Oil Circuit Breakers; (5) Splice; (6) Disconnecting Switches; and (7) To Transmission Line.

The electrical requirements as to clearances were determined at 8 ft. 0 in. between phases and 6 ft. 0 in. to ground, thereby establishing the general dimensions of the sub-station. The steelwork involved a departure from gen-

eral practice by replacing latticed sections with solid shapes. H-sections were used for columns and channels for overhead supporting steel, except in the transformer aisle (Fig. 34), where the columns consist of four angles latticed, supporting an arched truss which carries the busses and the necessary apparatus for the overhead transformer connections.

The stability of the entire structure is obtained by diagonal bracing in the center or end bays (Fig. 34). The horizontal members supporting the busses and disconnecting switches consist of two 15-in. channels, braced laterally and designed as continuous beams over two or more supports with splices at the points of contraflexure. This arrangement was found to be considerably more economical than the usual lattice sections and simplified the shop details and erection, as well as the maintenance of the structure.

The foundations for the steel and equipment are carried on piling throughout. The transformers weigh 170 000 lb. each, and their transfer for repair makes it necessary that the tracks supporting the transfer car be on a solid footing so that they can be handled (Fig. 33).

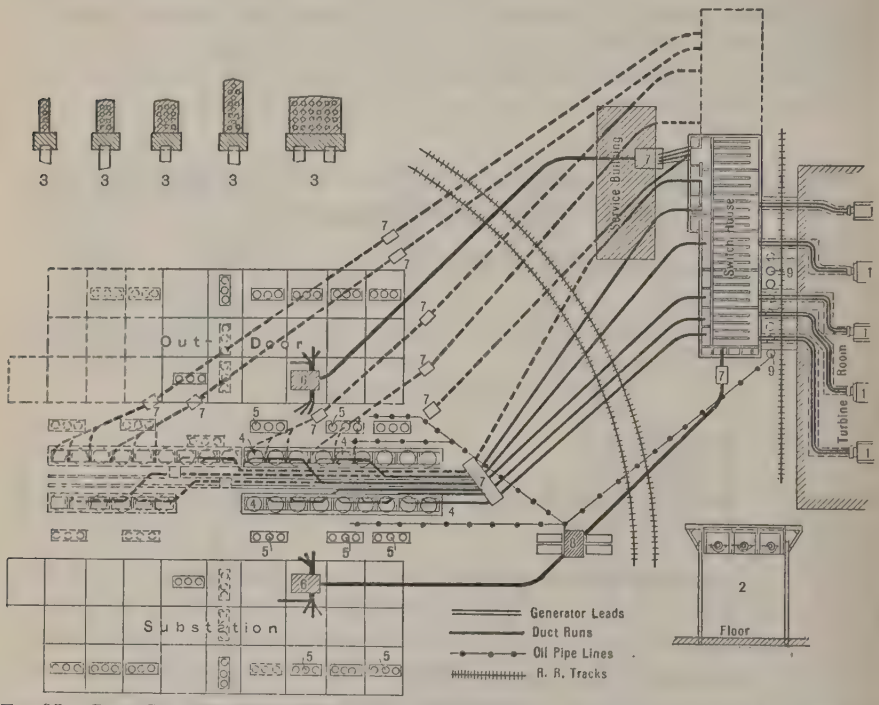

FIG. 35.—PLAN SHOWING GENERATOR LEADS AND DUCT RUNS FROM SWITCH-HOUSE TO OUTDOOR SUB-STATION, KEARNY STATION: (1) GENERATORS; (2) SUSPENDER GENERATOR LEAD COMPARTMENTS IN AUXILIARY SUB-STATION; (3) CROSS-SECTION, DUCT RUNS; (4) 132 KV-A. TRANSFORMERS; (5) OIL CIRCUIT BREAKERS; (6) RELAY HOUSE; (7) MANHOLES; (8) OIL STORAGE AND PURIFYING PLANT; AND (9) TRANSFORMERS FOR AUXILIARY SUB-STATION.

The duct runs, feeding each transformer, consist of 5-in. fiber ducts encased in concrete; one 5-in. fiber duct was provided as a spare for emergency use. These ducts are carried to the top of the transformers in con-

crete piers (Figs. 34 and 35). Between the sub-station and the switch-house the duct runs are supported on piles, care being taken to leave sufficient space between adjacent lines for heat radiation, and also to pitch the ducts toward the manholes for drainage. Several specially supported duct groups or conduit lines for control cable were installed.

The transmission lines from Kearny to Marion and Essex Stations consist of a high-tension bus suspended from steel towers connecting the three stations. The tower line uses a private right of way over the "Meadows" and is designed to meet railroad and harbor regulations at railroad and river crossings. The towers are designed to carry two lines and a ground. The transmission wires are 500 000 cir. mils copper strand supported from the cross-arms by suspension insulators. The energy is transformed at the Marion and Essex Stations to lower voltages as desired and distributed over the 26 400 and 13 200-volt system of the Company.

Eighteen towers were installed on the line between Essex, Kearny, and Marion, varying in height from 116 ft. 0 in. to 231 ft. 6 in. and having spans from 600 ft. 0 in. to 1 136 ft. 0 in. Along the entire right of way a roadway was built to facilitate construction and maintenance. All the steel was galvanized and all field connections were bolted with galvanized bolts and nuts.

The corner piers of all tower foundations were tied together to insure stability. The foundations on the river banks where no docks are installed, are protected against damage from ice by wooden sheet-pile coffer-dams. The entire space inside these coffer-dams was filled with cinders. The foundations for all towers are supported on piles, designed to sustain the loading from wind, snow, ice, wires, and pull due to angularity in the transmission line.

The tower footings for the terminal tower at Marion Station were complicated by space limitations, an angle in the line, dock construction, and the great depth to which piles had to be driven to get proper bearing. Due to these conditions it was found necessary to anchor the foundation against overturning; this was accomplished by the introduction of ties, utilizing the foundations of the building for anchorages. The gas and oil lines governed the location of these ties.

The 13 200-volt feeders from the outdoor sub-station at Marion to the switch-house were carried on steel bridges on account of existing conduit lines, and gas and water mains, which made it practically impossible to use an underground cable system. The design for the steel and foundations for this structure (Fig. 36) is similar to that for the Kearny Station, that is, H-sections were used for columns and rolled sections for supporting the miscellaneous electrical apparatus.

The present installation consists of: Seven 15 000-kv-a., single-phase, oil-insulated, self-cooled transformers; five 132 000-volt, oil circuit breakers, with remote control, having a rupturing capacity of 1 500 000 kv-a.; and fourteen 154 000-volt, motor-operated, remote-control disconnecting switches. The ultimate sub-station will have thirteen transformers, ten oil circuit breakers, and twenty-eight disconnecting switches.

The general design of the outdoor sub-station at Essex (Fig. 37) follows that of Marion and Kearny. At Essex, as at Marion, the 13 200-volt feeds

for the outdoor sub-stations to the switch-house were carried on a light overhead trestle. Difficulty in spacing of bents, due to railroad tracks and other local obstructions, made it necessary to select long spans. In order to reduce the weight of the steel to the minimum, cantilevers and suspended spans were used. The length of this bridge is 508 ft. Expansion joints are provided as well as pivot bearings at the base of the bents to allow for movement due to temperature changes.

The present installation at the outdoor sub-station at Essex consists of: Seven 15 000-kv-a., single-phase, oil-insulated, self-cooled transformers; five 132 000-volt, oil circuit breakers with remote control, having a rupturing capacity of 1 500 000 kv-a.; and fourteen 154 000-volt, motor-operated, remote-control disconnecting switches.

Future Developments

The completion of the present portion of the new Kearny Power Station, together with the outdoor sub-stations at the Kearny, Marion, and Essex Stations and the 132 000-volt interconnecting transmission lines, will form the first link of the ultimate State-wide high-tension transmission system as planned by the Public Service Electric and Gas Company. This ultimate high-tension transmission system will consist of more than 100 miles of 132 000-volt transmission lines, together with not less than nine 132 000-volt distribution sub-stations.

This high-tension transmission project will eventually spread across the entire State of New Jersey and will take the form of an immense letter, P. It will provide carrying capacity for practically the entire load of the system not radially distributed from the main generating stations. The upper portion of the loop of this transmission system will include about 50% of the system's load and the tail will extend at least as far as Trenton and possibly will include Camden. This transmission system when completed will provide facilities for the location of new super-power stations at any point of the loop or system that may be determined by geographical considerations, and will make it possible to feed the entire output of these new super-power stations directly into this high-tension distribution system.

The design and the construction of the Kearny Power Station, of the Marion, Essex, and Kearny Outdoor Sub-Stations, as well as of the high-tension transmission line connecting these sub-stations, was done by the Public Service Production Company.

Acknowledgment is due to E. Rothenburg, Structural Designer with the Public Service Production Company and associated with the writer on the design of the steel and foundations of the Kearny Power Station, for valuable suggestions and assistance in the preparation of this paper.

DISCUSSION

GEORGE A. ORROK,* M. AM. SOC. C. E.—A distinction should be drawn between the two types of foundations—the Hell Gate type,† on New York shale, and the Kearny type on the mud and silt of the Jersey meadows. In both cases the proportioning appears to be well done. When the foundation is sufficient, nothing more can be said.

As to the use of 18 000 lb. as the fiber stress in the steel design, this policy might be correct when the weights to be carried by the structure are well known or when the static load is many times greater than the moving load. Where, however, constant improvements are to be made in the machinery in both power and weight, it appears wiser to use both lower fiber stress and an excessive loading. Within less than two years structures designed for 30 000 kw. may be used for 60 000 kw., or possibly 100 000 kw. This is true of boilers and auxiliaries as well as of generating machinery.

It makes little difference what is spent on the steel work since this rarely exceeds 10 to 12% of the station cost, usually much less. Ordinarily, it is better to allow for future developments than to consider rebuilding the station within a few years. In a certain station, several years ago, a load of 600 lb. per sq. ft. of floor was used in the design of the steel work. Before the steel was erected two of the floors had to be increased to 1 000 lb. per sq. ft. and within five years one of these floors was carrying 2 000 lb. per sq. ft. Such a difference would vitally affect the use of 18 000 lb. as the fiber stress.

Paper No. 1660

WATER SUPPLY FOR ARMY RAILWAYS IN FRANCE*

By Paul M. LaBach,† M. Am. Soc. C. E.

With Discussion by Messrs. Charles H. Lee, William G. Atwood, and Paul M. LaBach.

Synopsis

This history of water supply development, principally for United States Army railway transportation in France during the World War, 1917-19, outlines briefly the factors ordinarily taken into consideration in problems of supply and distribution of boiler water for commercial railway purposes.

Then follows a discussion of the difficulties encountered in changing the water supply and distributing systems of several light traffic commercial railways into suitable installations for a unified military railway with very dense traffic.

In conclusion, an outline of the organization of forces used in the work, is given, together with a discussion of recommendations for an organization which would aid in simplifying and expediting similar operations.

Introduction

One of the fundamental requirements for railroad operation is water for boiler use. All division points where engines are turned or stored must have small power plants and facilities for washing out boilers. In addition, there must also be roadside stations between terminals so located that the locomotive tenders may be filled at suitable intervals, the intervals or spacing being largely governed by the nature of the traffic as well as its density. Where through

* Published in April, 1927, *Proceedings*.

† Engr., Water Service, Rock Island Lines, Chicago, Ill.

traffic only is handled the spacing may be longer than on lines carrying a large proportion of local freight which requires frequent train stops and much switching. The design of the locomotive also enters into the problem. Where superheaters are used with large tenders, as in modern practice, considerably longer intervals may be economical for through traffic than was formerly allowable.

On most of the world's steam railways the development of equipment for furnishing water to locomotives has been gradual. When railways are first built the traffic is usually light and the coal and water problem is not a very serious one in the aggregate, although neither can be neglected. As traffic increases, however, the size of both coal and water stations must also expand in proportion to the ton-miles per hour per mile of single track. Whether the interval between water stations must increase or decrease with the increase in traffic depends on local conditions and, as mentioned, the design of the power used. The intervals for freight traffic are also different from those required for passenger service. The problem at terminals is based on considerations which have little in common with road service.

In most countries heavy traffic railways have grown up gradually and there has been time to adjust coal and water facilities to the needs of the moment. These needs are seldom static and frequent changes are taking place under ordinary operating conditions. The general term, "operating conditions", covers a multitude of factors. Without some actual practical knowledge of daily train movements over a considerable period of time little can be told as to the practicability of any specific scheme of improvement. Other factors besides those stated enter into the subject of spacing, such as proximity of passenger stops, telegraph offices, signal blocks, passing sidings, grade crossing, and adverse grades.

The fuel problem, although serious, is not as exacting as that of water; coaling stations can be placed farther apart and coal can be stored for use at a future time. It is seldom practicable to store water for a longer period than one day on account of the bulk and resultant tankage required. The weight of the coal used is only about one-fifth that of the water. Coal can be stored in large quantities, hauled in ordinary cars, and put at convenient location for use without regard to its place of origin.

Coal Handling

In France, during the period of American participation in the World War, all coal was unloaded at the base ports by the different colliers, shipped to the points required, and unloaded in piles on platforms from which it was shoveled into the tenders. Although this is not the best economic method according to American standards it was effective. This has always been a common practice in Europe where labor is cheap.

Rainfall and Water Supply

In a well-watered country, such as the States of New York and Pennsylvania, water can be found, as a rule, within a reasonable distance of stations, which may be located to conform to operating conditions. The problem of

finding a suitable supply is largely an economic one, unless the quality of the water is objectionable. In the Western United States one railroad company has to go more than 100 miles for water that is usable. Therefore, in using the term, "water", the word, "pure", should be also added when it is to be used for locomotive boiler purposes. "Pure" in this sense has a special meaning, best defined by the use of negatives. Pure water will not cause pitting, corrosion, boiler scale, or foaming in switch engines.

It would be difficult to persuade a soldier of the American Expeditionary Force that water was not always easily available in large quantities in France, but such was the case. The exclamation of a returned soldier at a movie of some event over there, taken in the rain, a year or two after his return, was "Good Lord, it ain't stopped raining yet!" In many minds this was and still is the popular idea of the French climate. Then there is the expression "sunny France". A sunny country is usually an arid country. Which statement is true? Both are true in a sense, depending on the season. There is a wet season and a dry season. For agricultural purposes the country is all well watered, but that is largely due to humidity. The average annual rainfall varies from 600 mm. (24 in.) to 1 500 mm. (59 in.) within the area of railroad operations. Within the space of 100 km. (62 miles) the variation is from 700 to 1 000 mm., etc.

Each water station was dependent on an entirely separate source of supply. The quantity available was always governed by local conditions. The climate also had to be considered, that is, the ratio of wet to dry seasons. The basis of computation had to be the dry-weather yield, as that was the period of maximum effort anticipated. The geology and topography in the vicinity of any proposed station also frequently added their share of difficulties to the problem.

All roadside water stations of the kind contemplated are practically of equal importance unless they are close enough together for a train to skip one. In this case there was so little material available for construction that it was impossible to make the more extensive installations.

The coal and water needed for the proposed traffic scheme were in direct proportion to the tonnage to be hauled. This statement seems axiomatic, but the lack of appreciation of this fact was the cause of much of the failure of those not familiar with such matters to understand what would happen when a double-track line was given the maximum tonnage it could carry without slowing down train movement to take water. This meant that the station spacing had to be as far apart as practicable and the supply adequate at all times. The channel ports and the railroads north and east of Paris were reserved for the use of the British and French Armies. This left the Port of Brest and the ports on the Bay of Biscay for the American Army. The Ports of Marseilles and Cette in the Mediterranean were in use for transportation to Africa and the Orient. As the route from America was through Gibraltar where the submarine hazard was very great, and also the distance much greater, these ports were not much used except in special cases, until the western ports had become crowded.

Railways of the American Army Area

At the beginning, the so-called American Sector centered on Toul although the American Army operated subsequently in many other sections and had divisions as far west as Flanders on the British front. To bring the necessary supplies into the Toul Sector by rail was the object of the railroads herein discussed.

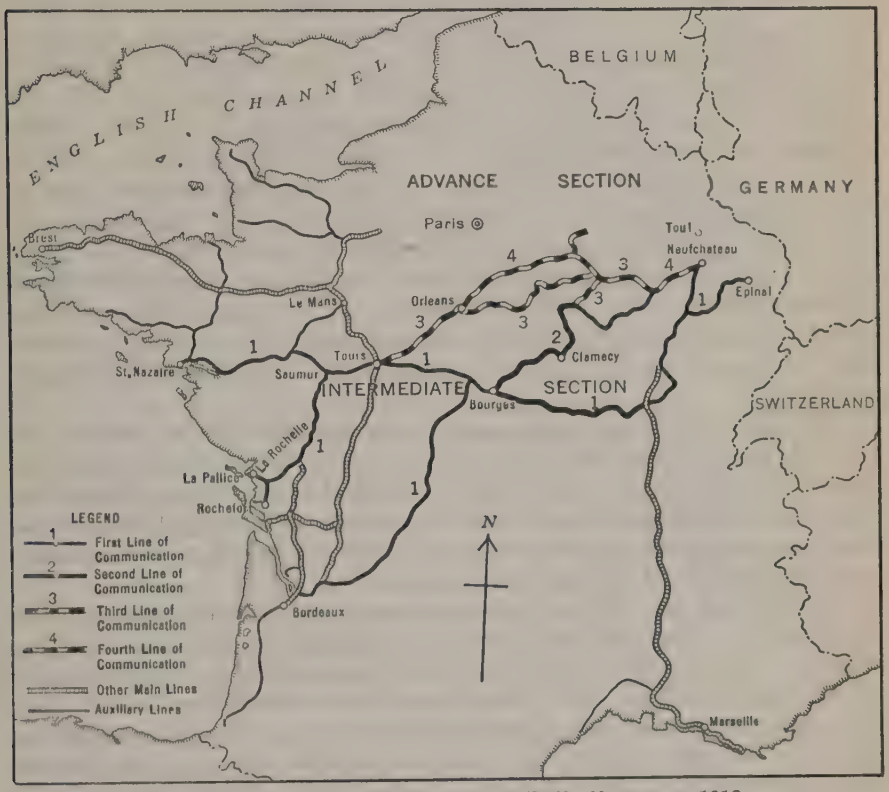

Fig. 1.—Lines of Communication, A. E. F., November, 1918.

The First Line of Communication planned (Fig. 1) started at the base port of St. Nazaire and extended to Neufchateau and Epinal in the Toul Area. In addition, it included the line from the Ports of La Pallice and Rochefort which connected at Saumur with the first line, and also the line from Bordeaux to Bourges. It will be noted (Fig. 1) that if the lines at the base ports were congested there would be a greater density in the line east of Bourges. For this reason the Second Line of Communication, extending from Bourges to Neufchateau by way of Clamecy, was adopted. The Third Line of Communication started at Tours and reached Neufchateau by way of Orleans. Other main lines leading eastwardly from Brest and northwardly from Marseilles will be noted.

The First, Second, and Third Lines of Communication, shown as continuous in Fig. 1, are in reality composed of parts of secondary lines (except east from Brest and north from Marseilles) of the four great systems of French railways, the Etat, Paris-Orleans, Paris-Lyons-Mediterranean, and Est. The six railway systems of France are the Nord, Est, P.-O., Etat, P. L. M., and Midi. With the exception of the Midi, which runs east and west in the south of France, all the systems radiate from Paris. The branches lie on either side of the main line so that the territory is divided into sectors with Paris as a hub. Paris, however, is not near the center of the country. The First Line of Communication with its general east and west direction is composed of secondary lines of four of the principal systems, namely, Etat, P.-O., P. L. M., and Est. The main lines of all these systems could carry very heavy traffic, although the branch lines have never been equipped for that purpose. Fortunately, they were nearly all double-tracked and the roadbeds were substantially built for permanent use. Where the east and west lines crossed the main arteries to and from Paris, the terminals were usually joint. They were located for the Paris-bound train movement and were not spaced with regard to the east and west traffic. This latter feature was of considerable importance as will be shown later. A comparatively small increase in traffic on the Paris lines, which were already crowded, threatened to tie up proposed east and west lines.

With these considerations in mind it was apparent that the new engine terminals, yards, sidings, and water stations would have to be spaced for American traffic independently of such utilities as had already been built for the normal French transportation system. It was expected that the French trains would continue to use the present terminal facilities, but that, on the American lines, they would use American stations.

The fact that four different railway systems were to be used added to the complications. They had been developed independently and had dissimilar practices. The Etat (Government-owned and operated) had antiquated equipment dating from about 1850. Hand pumps and windmills were in use. Distributing pipe lines, 4 in. in (approximated) diameter, were in common use. The P.-O. was more modern, but it also had some of these 4-in. distributing mains, and none of its equipment was large enough for quick watering of locomotives. The P. L. M. was quite modern, and the Est probably came second. The water crane in use everywhere was of old design, whatever its size. The engineer would stop the engine while the fireman adjusted the spout at the tender manhole. The engineer would then climb down to the ground level and turn on the water by opening a gate-valve with a wheel. Altogether the process was slow and the time necessary to fill the tender was from 10 to 30 min.

Each of the four systems naturally had its own method of handling all all questions concerning any changes in its property. Their consent was necessary for matters of large or small importance. After permission had been given, the companies also desired to be kept informed as to the progress of the work. This involved a large number of conferences with their officials. Usu-

ally a number of their men were present to pass on such points as might arise. A knowledge of colloquial French was indispensable; to this had to be added the technical equivalents for engineering terms and special apparatus to be used, little of which could be found in any published dictionary. The way to learn a proper name was usually to point out the object to a Frenchman and inquire its name and gender. The desire of the French officials to help was generally manifest.

Methods of Computation

At the beginning the only basis of calculation for water supply had to be made from a more or less hasty inspection. This showed, beginning at the west, a coastal plain, then river valleys, and, finally, territory that was mountainous. Adjacent streams would drain areas, ranging from a few, to hundreds of square miles, which might be anything from a swamp or permeable sands to steep slopes with impervious soil. The rainfall might range from 600 to 1 500 mm. As time progressed another variable was found; rain falls 150 days per year on the west coast of France, whereas the average is only 55 days at Marseilles. The change is not uniform throughout the intervening territory.

At first, there was considerable difficulty in estimating the tonnage to be hauled and the number of trains to be watered at each point. The quantity, 60 lb. per soldier per day, landing at the base ports, was used. One-third of this would be unloaded before the advance section was reached. From this beginning, the freight to be moved was calculated. The evaporation curves and horse-power curves were then used to get a tonnage rating of the American locomotives on the French tracks. The French profiles were in the metric units and the other figures in English units. A tentative tonnage rating was made and, fortunately, a trial was possible. The actual tonnage was only 3% less than the theoretical rating made by the Engineer Water Supply. The number of French trains was known, so on each line trains were added, to the point of saturation, which was assumed as being 1 train each way for each 15 min.

The accelerated growth of American participation in the war was another variable in the problem, as to quantities of water for transportation at different points. The problem would usually be presented to the Engineer Water Supply in this guise: How much water will be needed at a number of points (probably 25) when there are 500 000 soldiers in France? How much for 1 000 000? How much for 1 500 000? These questions had the advantage of being easier to ask than to answer. There were more unknown quantities than equations.

The record shows that the basis of 500 000 men in France was still being used as late as May 6, 1918. This can be explained by the fact that many of those in high command had doubts whether a large army would ever get across the Atlantic. Published diaries of some of these officers show this very clearly; naturally the same view was reflected by subordinates.

The "get-together" spirit evolved by Ludendorf's drive in March, 1918, resulted in an expansion of American ideas on the subject, and larger figures

than hitherto used were common. In July, 1918, the Engineer Water Supply used as a basis an estimated total force of 4 000 000 men in France by July, 1919. In November, 1918, 2 000 000 men were already there.

The rate of increase in the Army was never officially announced. It had to be assumed by the person making the estimate. It was necessary to keep pace with these changing conditions until at the last the assumption was made that the Army would advance as far as the Rhine. (Fig. 2.) The rapid retreat of the German Army in October, 1918, indicated that it would be necessary to move the former broad-gauge rail-heads from the places they had occupied for several years to new locations across the devastated areas evacuated by the enemy.

Inquiries were made to determine which railroad lines would be available for the movement of supplies for the American Army in an advance to the Rhine. This program was supplemented with estimates of material and locations for water stations which would be needed to replace those destroyed by the retreating enemy. These locations are shown on Fig. 2. Every effort was made to procure all this material well in advance of the necessity for its use.

At this time also, much information was collected and assembled, from which plans were made for water stations on the advanced lines. The studies of available sources were well advanced when the signing of the Armistice put an end to the big army program. A few installations were made in order to carry out the terms of that agreement.

Previous Preparation

Not until one year after the United States entered the war was a department organized that was responsible for all water supplies to be used in the Transportation Service. In April, 1918, the Department of Engineer of Water Service, under the Engineer of Construction, Transportation Service, was formed with the writer (then Major), and H. Malcolm Pirnie, M. Am. Soc. C. E. (then Captain), as Engineer and Assistant Engineer of Water Supply, respectively.*

The new Department was a good many laps behind the other departments which were fortunate in being able to make some preliminary strides before the rush began. However, the need for water for transportation had not been omitted in calculations for future needs.

Engineer Stores Requisition No. 6, prepared July 14, 1917, stands as the keystone in the arch of important steps absolutely needed to carry out the Transportation Service program in France. This requisition ordered material needed immediately for an army of 500 000 men. A monthly supply to be added to this without further requisition was also provided. In addition, this requisition was to be increased in proportion to any additions to the Army above 500 000 men. During the seventeen months from the time this requisition was made until the Armistice, when the proposed strength of the Army

* The Department was afterward augmented by the addition of F. D. Nash, M. Am. Soc. C. E. (then Lieutenant). During the entire period, Sergt. J. T. Brinkley maintained a corner in a barracks called an office, with the aid (part of the time) of Private Thompson. Five was the maximum force on this work while due to illness and other causes the average was about three.

had been increased eight times, this requisition demonstrated the remarkable accuracy of its details.* This was true of large items as well as the smaller ones which included railroad water supply material.

Researches show that, apparently, this requisition is the first mention made of a railroad water supply problem. For an army of 500 000 men, an initial stock of thirty 50 000-gal. tanks and sixty water cranes was specified, with an additional supply of five tanks and ten cranes each month. For an army of 1 500 000, the monthly supply was to be increased to fifteen tanks and thirty cranes, and 4 000 000 men called for forty tanks and eighty cranes each month. If this material had arrived in France according to program, there would have been no difficulty in building proper water service installations up to and including the final advance to the Rhine.

Inter-Departmental Activities

From July, 1917, to April, 1918, many changes were taking place in the organization of the A. E. F., during which water supply for transportation was handled as a side issue in connection with yards, docks, and terminals. The Superintendent of Motive Power, located at Nevers, in Central France, made estimates of the quantity of water needed for mechanical purposes. The location was made by the Engineer of Construction, Transportation Service, H. C. Booz, M. Am. Soc. C. E. (then Colonel).

In January, 1918, the organization was a little more complete as regards other work, but the Water Service was still in confusion. The Transportation Department, one of the technical services of General Headquarters, was charged with the operation and maintenance of railroads, canals, wharves, road, shops, and other appurtenances needed for transportation. The small force of engineer troops in France at that time called for a division of responsibilities. The construction was under the charge of the Chief Engineer Office, Lines of Communication, another technical division of General Headquarters. At the head of the Transportation Department, was the Director General and several Deputy Directors General. Also, there were other officers with duties similar to those found on most American railways. These were General Manager, Superintendent of Motive Power, Business Manager, and Engineer of Construction. The last named was responsible for water supply with other duties in connection with the transportation program. However, under the Chief Engineer Officer, Lines of Communication, there was a Department of Water Supply which planned and constructed water-works for hospitals, camps, and towns. Under the Engineer of Construction water supply had only been considered in connection with certain definite projects which had passed the preliminary stages. These were docks, yards, and terminals.

Under the circumstances, the large development of future roadside water stations was unknown and left for later consideration. A division of the work was then made between the Director General of Transportation and the Chief Engineer Officer, Lines of Communication, in which the responsi-

* This requisition was made under the direction of W. J. Wilgus, M. Am. Soc. C. E. (then Colonel).

bility for the design and construction of supply works for transportation was given to the Chief Engineer Officer.

Under this ruling the Director General of Transportation wrote a letter to the Chief Engineer Officer, Lines of Communication, January 5, 1918, submitting plans of eight yards and terminal projects prepared by the Engineer of Construction. This letter included estimates by the Superintendent of Motive Power, as to the quantity of water desired. In this letter is found a statement that had a great influence on future inter-department relations.

"3.—We would suggest for your approval that your Water Supply Department furnish all water requirements, piping same to the connection to the water tanks, and that we erect the tanks and provide all the piping from the tanks to the service outlets, such as water columns, ash-pits, round-houses, etc. Such an arrangement will allow the one Water Supply Department to consider our requirements in connection with those of other branches of the service, and to equate the existing or new sources of supplies to the total needs."

This was immediately agreed to and left the Engineer of Construction with authority over the design of distributing systems only. As it turned out, more than 75% of the railroad water supply systems planned were at points at which there were no camps, hospitals, or other army activities; hence, the reason for the division of authority did not hold except for the projects then considered. However, this idea was expanded to include various other matters and resulted in the duplication of investigations and calculations by two departments.

Organization of Water Supply Department for Transportation

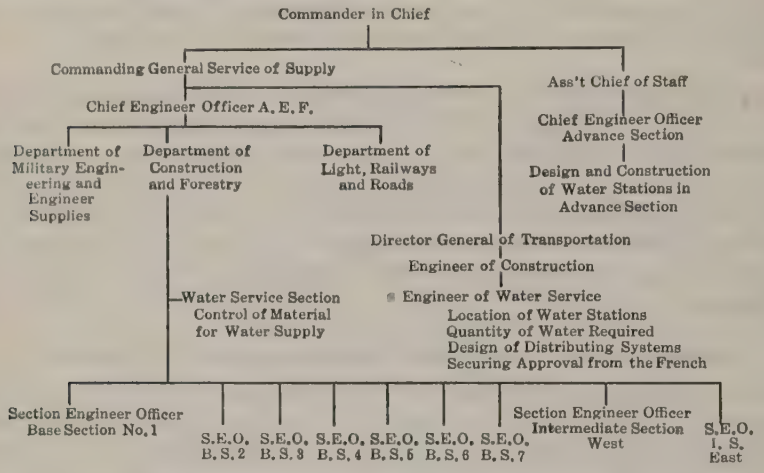
The Department of Engineer of Water Supply was organized April 4, 1918. The organizers and re-organizers had gotten to work and on March 12, 1918, had given all the old authority of the Director General of Transportation to a Chief of Utilities who reported to the Commanding General, Services of Supply, who, in turn, reported to the Commander-in-Chief. The Department of Construction and Forestry was created, which took over all construction matters and the procurement of material required for construction purposes. The Engineer of Construction, Transportation Department, however, still retained the power to design, but had no control over construction. Thus, at the outset, the Engineer Water Supply* could design only the distributing systems while the Department of Construction and Forestry had the authority to investigate and design the supply systems for which it was to procure the material and construct the complete water stations.

In July, 1918, another radical change was made by General Order No. 114, G. H. Q. The Service of Utilities was abolished and the Transportation Service established in much the same position it formerly occupied with respect to design, but construction was vested in the Department of Construction and Forestry. General Order No. 29, S. O. S., July 12, 1918, announced the re-organization of the Office of the Chief Engineer Officer, A. E. F., giving the Department of Construction and Forestry as one of three sub-

* The term, "Engineer Water Supply", and the pronouns used as equivalents refer throughout to the entire Department as a whole and not to the head in person.

divisions. The Director of Construction and Forestry then proceeded to reorganize. The area was divided into sections each in charge of a section engineer officer who handled all construction matters, together with requisitions for materials. The Water Supply Section of the Department of Construction and Forestry only passed upon its requisitions and helped expedite the procurement of materials. The organization was decentralized. The Transportation Department on the contrary had its authority highly centralized, as transportation was a continuous process from the sea coast to the front. (Fig. 3.)

The New Transportation Corps Water Department found itself in a peculiar position as far as its authority and responsibility were concerned. The following is quoted from an official report:



Example of Procedure According to Organization.

1.—Engineer of Water Supply prepares letter from Director General of Transportation to Department of Construction and Forestry stating 200 000 gal. of water per day required at Lothiers. Letter signed by Engineer of Construction by direction of Director General of Transportation.
2.—Received by Department of Construction and Forestry.
3.—Referred to Water Supply Section for action.
4.—Indorsed over to Section Engineer Officer, Intermediate Section West.
5.—Section Engineer Officer sends engineer on ground to investigate.
6.—Engineer reports development is not practicable.
7.—Section Engineer Officer indorses report back to Department of Construction and Forestry.
8.—Referred to Water Supply Section for preparation of indorsement to Director General of Transportation.
9.—Indorsed letter received by Director General of Transportation and referred to Engineer of Construction.
10.—Engineer of Construction refers letter to Engineer of Water Supply showing development of Lothiers impracticable.

The result is that a new spacing of water stations must be devised planning to skip Lothiers; and the above procedure resorted to again.

FIG. 3.—DIAGRAM OF ORGANIZATION AFFECTING RAILROAD WATER STATIONS.

"It had authority to state when and in what quantities water would be required for railroad purposes and to design the distributing systems from the points of delivery of the supply to and including the railroad service, but it did not have authority to select the sources of supply, to specify what kind of supply equipment should be installed, or to superintend the construction in any part of the water stations. However, it was responsible for the selec-

tion of adequate sources, installation of ample supply equipment and the proper and timely construction of all water stations to insure the train operation incident to the carrying out of the transportation program for which the Director General of Transportation was responsible. In other words, the Engineer of Water Supply was responsible not only for the correct locations and proper capacities of railroad water services, but also for providing for the services an adequate supply of good water at all times, but he could not determine the source of supply, the kind and size of supply equipment, procure the material or direct the construction of any part of the installation."

Method of Authorizing Work

Before work could be begun on either new or supplemental water stations, authority had to be had from the Commanding General, Service of Supply, G-4, U. S. A., and the French railroad on which the facility was located. A blanket approval was given by the Commanding General, Service of Supply, G-4, for all railroad water stations. The French railway companies had to be approached in either one of two methods—by official channels with consequent delays or by conferences with the French railway officials.

The official method was a roundabout course, involving complete working plans before anything could be started. The Engineer Water Supply would submit his plans to the Deputy Director General of Transportation at Paris. It then went to the Franco-American Mission for its approval, and thence to the French railway officials. With any suggested alterations, it was then returned to the point of origin through the same channels. The Engineer Water Supply through the Director General of Transportation then directed the Department of Construction and Forestry to begin construction. With this procedure, which might take a month, practically no progress could be made for obvious reasons. Knowledge of the available sources of supply and the details of the existing equipment were absolutely necessary before the spacing of the proposed water stations could be made. Detailed descriptions of the proposed equipment and method of placing it were demanded by the French railway officials before their consent could be given. Designs of distributing systems were required by the Department of Construction and Forestry in order that it might investigate the source of water and make requisitions for material for the supply works to be subsequently built by the Section Engineer.

In more ways than one this was getting "the cart before the horse". The Engineer of Water Supply was obliged to investigate sources of supply and all available materials before he could turn a wheel if he wished to provide for the train operation required. The elements involved would be:

1.—Inspection of existing water stations with their sources of supply.

2.—Inspection of proposed sites with their sources of supply. (The geology and contour of the country were important items.)

3.—Procurement of detail plans and other information for all French water stations on the different French railways included in the Lines of Communication.

4.—Translation from the French and tabulation of the results.

5.—Studies of these and other available water sources; computation of the drainage areas to determine whether the supply would be adequate. These were to be made after inspection on the ground with the help of such records of stream flow as were available.

6.—Determination of the best spacing of water stations to meet the proposed American operations and still to conform to locations where adequate sources of supply were available within reasonable distance.

7.—Determination of the quantities required at each water station for the constantly increasing transportation problem.

8.—Submission of this information to the Department of Construction and Forestry for its investigation. (French tanks were to be used where available.)

9.—Preparation of plans for both new and reinforced water stations.*

10.—Submission of these designs to the different French railways with all available information as to the probable mechanical equipment.

11.—Transmission of the approved plans to the Department of Construction and Forestry for construction.

12.—Following up all schemes of every nature not entirely completed.

13.—Special investigation of doubtful sources of supply.

14.—Preparation of priority construction programs in order to use the small amount of material available to the best advantage.

15.—Inspections to aid in expediting construction and procurement of construction material from America.

Inspections and Surveys

Inspections made during April and May, 1918, showed that on the First Line of Communication the intermediate water stations had several months' reserve capacity for the transportation program of 1 500 000 men. Therefore, the supplies for the new yards and terminals were given the priority for immediate study. The facilities to suit each scheme were then indicated on the large scale maps prepared by the Engineer of Construction and forwarded to the Department of Construction and Forestry for action.

Plans and detailed information for all existing water stations on the First, Second, and Third Lines of Communication (Fig. 2) were requested May 1, 1918, from the P.-O., P. L. M., and Est Railways. These data were translated and compiled, together with computed drainage areas from contour maps and estimates of capacities per minute of local pipe lines.

These studies revealed the fact that several points which would have been suitable as to spacing, did not have sufficient supplies for future requirements. The deficient stations were pointed out in conference with the Water Supply Section of the Department of Construction and Forestry, with requests for stream measurements in July, August, and September. The Water Supply Engineer of the Department of Military Engineering and Engineering Supplies was asked to furnish data on rainfall and run-off in France for estimating probable yields.

* The term, "reinforced water station", was applied to French water stations which did not have adequate velocity of flow at the water crane and had to be augmented to secure 2 500 gal. per min., usually by the addition of crane lines and water cranes.

Up to this time, nothing had been done to determine dry-weather flow. Where water was required for railroad use such information was of the greatest importance, as the maximum traffic was expected to coincide with the dry season. The following statement taken from a report of the Assistant Engineer of Water Supply very ably illustrated some of the difficulties:

"The line from Perigueux to Argenton-sur-Creuse may be taken as a typical section of the lines of communication on which doubtful sources of supply existed [see Fig. 2]. The drainage areas of streams adjacent to the French roadside water stations were drawn and studied in connection with the existing supplies and the locations of stations to be used as water stops for American trains were determined to use the best existing facilities as far as possible and conform to the desired spacing of from 20 to 25 miles. The water stations chosen were Perigueux, Thiviers, Nexon, Ambazac, La Souterraine, and water station for heavy south-bound trains climbing the grade from Argenton to La Souterraine. The average annual precipitation at these different water stations varied from 750 mm. at Celon to over 1 000 mm. at Ambazac, and Thiviers. La Souterraine, between Celon and Ambazac, and Nexon, half way between Ambazac and Thiviers, had annual rainfalls at 850 mm. Figures on the distribution of the rainfalls throughout the year were not obtained, but observation through the summer demonstrated that the rainfall during the dry period was much greater in the mountainous region of Ambazac than it was in the less mountainous areas near the other stations.

"Storage or new sources were, therefore, necessary to supply deficiencies at La Souterraine, Nexon and Celon, although the drainage areas at these points were nearly as large as that giving an ample supply at Ambazac. Accordingly, it was planned to build a dam on the stream below Celon to store water for the dry period of 1919, and to lay a pipe line to the existing dam of Etang du Chi, near La Souterraine, which had sufficient capacity and elevation to furnish the additional water requirements by gravity."

Water supply problems similar to the foregoing were found on all points of the line, and attention has been drawn to this one simply for the purpose of illustrating conditions, rather than to convey the impression that it was a particularly bad territory.

Number of Stations Projected

On the First Line of Communication (Fig. 1) from St. Nazaire and Bordeaux to the rail-heads there were ninety-two French water stations. All these stations were studied carefully and the results tabulated on data sheets similar to those already described. (See Fig. 2.)

The necessity for an early start being apparent, a preliminary list of forty-one water stations was sent to the Department of Construction and Forestry on April 19, 1918 (see Tables 1 and 2). This was some time before it was possible to secure and work out any detailed information, and after only one inspection trip had been made. Later studies caused only minor changes in six of these preliminary locations. The estimated quantities also varied but slightly.

The lines from Brest to Tours *via* Le Mans; from Rochefort and La Rochelle to Saumur and the so-called Second and Third Lines of Communication had ninety-two stations which were also tabulated and studied on receipt of the necessary information. (See Figs. 1 and 2.) Thus, there were

184 water stations covering 1 760 miles, which were studied in connection with the program in effect as early as April, 1918.

TABLE 1.—Water Facilities Required Between St. Nazaire and Neufchateau (*via* Cercy La Tour), France.

Stations and intervals (miles).	Mile posts.	Gallons per day.
St. Nazaire (6)	0	Some facilities
Montoir (14)	6	427 000
St. Etienne de Montluc	20	135 000

Marmagne sur Creusot (33)	364	700 000
Santenay (29)	397	700 000
Vougeot (12)	426	700 000
Is sur Tille (19)	438	1 561 000
Villeguisien (28)	457	780 000
Avrecourt (Chal.-Neuf) (19)	480	360 000
Bourmont (18)	499	360 000
Neufchateau	512	427 000
Vitrey-Vernoise (Chal.-Epinal) (21)	481	360 000
Conflans-Varigney (23)	502	360 000
Xertigny (12)	525	360 000
Epinal	537	427 000

By November 11, 1918, 260 stations had been tabulated and studied in detail as to their availability for American transportation. Of these, 105 were selected for reserve or entirely new stations to fit the transportation program. By that time plans had been prepared for all the distributing systems, most of which had been approved by the French and transmitted to the Department of Construction and Forestry, while the remainder were in the hands of the Franco-American Mission (Fig. 2).

TABLE 2.—Water Facilities Required Between Bassens and Pont Verte, France.

Stations and intervals (miles).	Mile posts (from Bordeaux).	Gallons per day.
Bassens (10)	2	470 000
St. Sulpice (18)	12	150 000
Coutras (26)	30	250 000
Mussidan (24)	56	250 000
Perigueux (23)	80	570 000
Thiviers (25)	103	390 000
Nexon (25)	128	390 000
Ambazac (25)	153	390 000
La Souterraine (23)	178	260 000
Celon (25)	201	260 000
Chateauroux (32)	226	390 000
St. Florent	258	260 000

Thus, at the time of the Armistice, 105 plans had been completed for 1 900 miles of railroad; studies were well under way for 1 000 miles more; and data had been assembled and plans made for 100 water stations on the 1 500 miles of railroad which would have been required to advance the rail-heads to the Rhine.

Spacing of Water Stations

A number of factors must be considered in spacing railroad water stations: First, the rate of evaporation at different locomotive speeds must be known; second, the capacity of the tenders; third, the profile to be traversed; and, fourth, the method or scheme of operating trains. The last factor can only be anticipated in view of many years of past experience.

The tanks of the American locomotives held 4 900 to 5 300 gal. of water. The rate of consumption was 70 to 120 gal. per mile with a locomotive having its full tonnage rating. The variation was caused by the rise and fall in the grade line. A locomotive running on a level track uses more water per mile than one with the same load on a profile having many changes from adverse to favoring grades, where the engine works at full throttle ascending, but can coast down the favoring grades without using steam. The maximum rate of consumption takes place on an adverse maximum grade involving possible engine delays, so that it would not be safe to have less than 1 000 gal. of water in the tender. For these reasons, a maximum span of 30 miles was adopted with an average of 20 to 25 miles. The small French water stations were located between these points and could be used in an emergency.

American Locomotive Used

The principal American locomotive was similar to one class of French locomotives. The statistics of the engine were about as follows:

Cylinders	21 by 28 in.
Steam pressure	190 lb.
Diameter of driving wheels	56 in.
Wheel-base of driving wheels	15 ft. 6 in.
Grate area	32.7 sq. ft.
Tractive power	35 600 lb.
Weight, in working order	166 400 lb.

A total of 3 490 standard-gauge Consolidation locomotives were purchased for overseas use. This is more than twice the total number operated by the Chicago and Northwestern Railway Company with 8 500 miles of line. Not all of them were delivered, however.

In all, 1 303 Consolidation locomotives were shipped for use by the A. E. F. In addition, 332 locomotives were en route to France or on docks in the United States awaiting shipment at the time of the Armistice. Also, 30 saddle-back switching locomotives were in use. Hence the undertaking to supply them with water was not a small one. On 1% grade, an engine would haul about 1 450 tons at the speed required under the circumstances.

General Plans

The roadside water stations having been selected, the French station plans were copied and the new facilities shown on them. These stations were of two general types (Fig. 4), one for trains with single engines, the other for helper engine districts.

The standard distributing equipment consisted of a 50 000-gal. wooden tank on a wooden tower located as close to a No. 11 Sheffield, 10-in. water crane as possible. The pipe line from the tank to the crane was of 10-in. threaded pipe with couplings. Existing French pipe lines were used, when available, by the addition of other lines to increase the capacity to that of the 10-in. line. Water cranes were placed, when possible, between the main track and passing sidings so that engines could take water without blocking the main line. They were designed to furnish water to American locomotives during 5-min. stops (Fig. 4).

At a few points, such as the Perigueux Engine Terminal, high ground was available for the concrete reservoirs, but this was rare. The prime requisites for watering a locomotive quickly are pipe lines of large volume and water at comparatively low heads, to avoid valve and pipe-line troubles from water ram due to sudden closing of large valves.

The quantity of water needed at each of these stations was calculated from the average daily tonnages necessary to supply the Army. It is obvious that military situations might have changed the whole conception of the matter and have required any one of the lines to be used at its full capacity. This was taken as 3 to 4 trains per hour in each direction for a 24-hour day.

At engine terminals, 5 000 gal. per engine entering was used. As the terminal spacings were the same as for the roadside stations, it was assumed that each engine would take 3 500 gal. of water when entering and 1 500 gal. would be needed for losses while standing idle. An allowance of 10 000 gal. per day was made for each switch engine and from 30 000 to 90 000 gal. per day for power plants, boiler washing, and miscellaneous uses.

Fortunately, the quality of water did not complicate the situation to any extent. Most of the water from the coast to the northeast part of France is what is called "light". It is not very hard until the Vosges territory is reached. At the sea coast, in 1918, considerable trouble was experienced with foaming. During the summer months, the reservoirs were pumped down so that seepage changed from the landward side to the seaward side. The salt water caused the trouble.

Organization Difficulties

The actual working history of an organization is usually dry reading. However, as similar situations may occur in any campaign, it seems advisable to give a brief outline of organization troubles that added immensely to the work without in themselves producing any water stations; and it was water stations that were required.

On January 5, 1918, preliminary plans, including water requirements at several engine terminals, were sent to the Chief Engineer Officer, Lines of

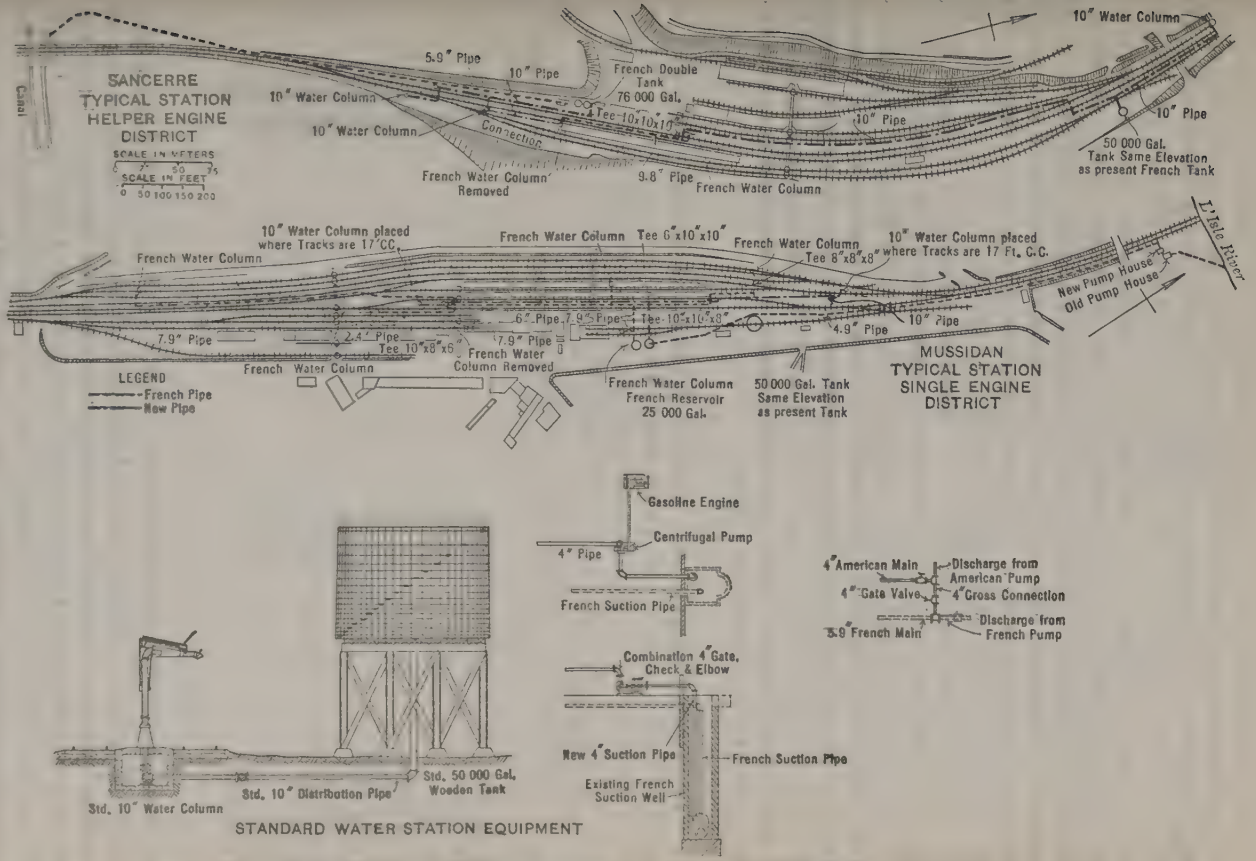

FIG. 4.—TYPICAL REINFORCED ROADSIDE WATER STATIONS AND STANDARD EQUIPMENT, TRANSPORTATION CORPS, A. E. F.

Communication (later Department of Construction and Forestry). On April 19, 1918, a set of tables of water requirements (Tables 1 and 2) was sent by letter to the Department of Construction and Forestry. On May 6, 1918, a list of seventeen engine terminals (Table 3) was sent to the same destination. It gave estimates of requirements for 500 000, 1 000 000, and 1 500 000 men. On May 25, 1918, a report was sent dealing with conditions between St. Nazaire and Saumur, pointing out the advisability of investigating ground-water conditions at Saumur, an engine terminal and very important point. By memorandum of June 6, 1918, notes of a trip between Perigueux and Chateauroux were sent to the same officer. No reply having been received prior to June 19, 1918, two letters were sent, requesting ground-water surveys at Saumur and St. Luce and stream measurements in different localities.

To add to the confusion, the P.-O. Railroad officials, on June 30, 1918, presented detailed descriptions of what they wanted done to nine water stations and requested immediate action. The available material in stock in the Engineer Depots was determined at a conference with the Department of Construction and Forestry and a modified plan produced to satisfy the French officials. This plan was furnished to the officials of the P.-O. Railroad on July 6, 1918, and the Department of Construction and Forestry was requested to furnish the equipment by letter of July 4, 1918.

TABLE 3.—WATER INSTALLATION NEEDED AT VARIOUS POINTS IN THE ORDER NAMED.

Yard and terminal locations.	Requirements, in Gallons per Day.		
	For 500 000 men.	For 1 000 000 men.	For 1 500 000 men.
St. Nazaire	50 000	100 000	150 000
Montoir	142 000	284 000	427 000
St. Luce	17 000	34 000	50 000
Saumur	176 000	352 000	527 000
Gievres	272 000	544 000	817 000
Cercy la Tour	391 000	782 000	1 173 000
Is sur Tille	520 000	1 040 000	1 561 000
Liffol le Grand	142 000	284 000	427 000
Villiers le Sec	.....	.....	750 000
Bassens	157 000	314 000	470 000
St. Sulpice	50 000	100 000	150 000
Perigueux	190 000	380 000	570 000
Ambazac	130 000	260 000	390 000
Nexon	130 000	260 000	390 000
Chateauroux	130 000	260 000	390 000
La Rochelle	125 000	125 000	125 000
Aigrefeuille	50 000	50 000	50 000

These negotiations with the officials of the P.-O. Railroad were but a forerunner of numerous conferences and illustrate the importance of having all information in the hands of any one entering such discussions. A letter was accordingly sent to the Department of Construction and Forestry on July 6, 1918, asking for joint reconnaissance surveys of proposed water stations by the representatives of the Engineer of Water Supply of the Transportation Service and Section Engineers of the Department of Construction and Forestry, with authority to agree on methods, etc. This letter was unanswered, and telephone

inquiry only resulted in the information that the Section Engineers were too busy to pay any attention to these details.

The next move (July 17, 1918) was to appeal to the Commanding General, Service of Supply, for an adjudication. His decision is found in a memorandum of July 23, 1918, forwarded to the Department of Construction and Forestry, stating in part:

"It would appear that there can be no objection to permitting representatives of the Transportation Department working jointly with the Construction and Forestry Departments in investigating sources of water supply at various water stations. However, the responsibility for supplying an ample supply of water where needed, rests squarely on the D. C. & F. Any information of sources of water which the T. D. has, should be turned over to the D. C. & F. The importance of this matter is so great that immediate attention must be given to this problem." (See Fig. 3.)

No one was able to explain just how much of this information was to be turned over. It consisted in part of mental conceptions resulting from many years of experience in similar matters, and could not be made into a neat package for delivery.

During the negotiations, the Water Supply Section of the Department of Construction and Forestry secured a geologist to go over the line from Perigueux to Celon. He was accompanied by a representative of Engineer Water Supply of the Transportation Department. This was the beginning, and by September 10, 1918, the first complete reports of the proposed methods of developing doubtful sources of supply were received.

Engineers are prone to make curves to illustrate their meaning with the idea that busy men will get the point without effort. This was tried in order to relieve the busy Section Engineers of labor. It worked like the well-known Australian boomerang; the information was used by the Section Engineer of the Department of Construction and Forestry as an argument against the reinforcement of certain stations. The small French stations had to be used between engine terminals until all the reinforced stations in the district had been completed. Hence the small actual consumption at the selected roadside water stations was compared with the requirements for any day taken from the curves and used as an argument against the immediate necessity of proceeding with construction.

Difficulties in Securing Material

The rapid increase in the size of the Army and the military activities due to the St. Mihiel Drive in September, 1918, produced such a density of traffic as to bring out forcibly the weak points. The roadside water stations had not been reinforced to deliver water rapidly, and all trains were stopping at the small French water stations to take water. Sometimes they obstructed the main track for 20 min., thus automatically limiting train movement to 2 trains per hour. Such conditions finally brought the problem of railroad water supply into the spotlight, and this resulted in accelerated construction which thereafter advanced as fast as material was received.

Lack of suitable material was the most serious factor in delaying construction. Requisitions had been made for material, but the shipping tonnage allotted the Transportation Department was so small that it was deemed necessary at first to utilize all of it for locomotives, cars, rails, etc. When the new Department of Engineer of Water Supply was formed, in April, 1918, it was discovered that no material for water service had arrived and none had been called for by the Department of Construction and Forestry during the previous two months, when the work had been under its jurisdiction. Consequently, the first shipment was requested on April 18, 1918, as a part of the tonnage quota of the Director General of Transportation. The same was true of May and June.

The Engineer Water Supply explored every possible channel for procuring tanks in Europe, but without success. The only ones found were several 25 000-gal. wooden tanks made by the construction forces at Gievres. These were excellent, but construction of them had been discontinued. Thus, it was necessary to depend entirely on shipments from the United States. When notice of the first shipment of tanks was received, a list of the points where they were most urgently needed was given to the Department of Construction and Forestry. This was done from time to time, but by October 17, 1918, it became apparent that only the tanks on the original requisition had arrived. (For that matter these were all that ever did reach France.) A hurry-up movement was then instituted to get shipments of tanks for the proposed drive to the Rhine, but this was stopped by the Armistice.

In conference with the officials of the P. L. M. Railway, it was found that they could use German war prisoners to build reinforced concrete tanks for American transportation by contract. This scheme was carried into effect at three different points before the cessation of hostilities, but, even then, American water cranes had to be used, for not even one was obtainable in France.

Paper Work and Construction

Quoting again from an official report:

"However, as the organization stood, a great deal of the work was only done on paper with a comparatively small accomplishment in actual construction. An excellent example of this may be seen in the case of the roadside water station reinforcement proposed at Thiviers. In all there were 46 letters, telegrams, and conferences extending over a period of six months, with which the Engineer of Water Supply was concerned, on this one project. And at the time the Armistice was signed, the construction had not started, although a shipment of 6-in. supply pipe had arrived a short time before." (See Fig. 3.)

By the careful assignment of available material to the new engine terminals, yards, and weakest roadside stations, it was possible for the American Lines of Communication to carry one-third of the total tonnage needed to supply 4 000 000 men. In November, 1918, water facilities had been installed sufficient for 1 300 000 men, which was nearly the size of the Army contemplated in July, 1918, for the campaign in 1919.

When the Armistice was signed, eighty of the projects were canceled, the remainder being used for the different movements needed for the return of

troops to the base ports, the maximum traffic being reached about the middle of December, 1918.

In addition to the principal duties in connection with train movement the Engineer of Water Supply, Transportation Department, was called on for various other odd jobs. Among these were fire protection at Bassens docks, water facilities on forestry sidings, supplying drinking water to train crews and to troops in transit, aid in the rehabilitation of the Lines of Communication through the fighting area into Germany after the Armistice was signed, and aid in operating the lines taken over after the St. Mihiel Drive. His advice and assistance in securing all kinds of approvals from the French were necessary before they could be carried out.

One of the problems that was carried to a conclusion was that of mending the damaged water supply at Couflans-Jarny (on the front north of Toul) on the section of railroad near the Luxembourg border, operated by the Americans. This terminal had been badly damaged by American artillery fire. The large distributing mains had been broken in six different places and the pumping machinery carried away by the Germans. The mending of the breaks and the installation of a steam pumping plant was carried out under the direction of the Department of Engineer of Water Supply and a report submitted recommending what was needed at other water stations on the section under American control.

At the time the Armistice was signed, the writer was investigating a very mysterious cause of foaming on the lines of the Woevre (near Thiaucourt). This was on a line that had been taken over after the St. Mihiel Drive. Engines foamed on Wednesdays and Thursdays. A voyage of inspection of several miles up the creek from which the water was taken disclosed a village with a large public laundry. The inhabitants washed their lingerie on Mondays and Tuesdays, the soda and soap reached the engines on Wednesdays and Thursdays; hence, the disturbance. It is the only case on record during years of experience, in which engine foaming conformed to the calendar. As it was impossible, with due regard to the *entente cordiale*, to sentence the population to wearing soiled shirts, nothing was done about it, except to protest.

Conclusions

The lessons to be drawn from all these experiences may be summarized briefly as follows:

The Engineer of Water Supply, Transportation Department, should have primary control of certain fundamentals with sufficient personnel to carry matters to a conclusion:

1.—All investigations necessary to determine the sources of water supply for transportation.
2.—Design of supply systems to the extent of specifying capacities of pipe lines to be installed and general location plans.
3. Control of essentially railroad water service material, such as tanks, water cranes, valves, piping, engines, and pumps.

4.—Installation of water tanks, water cranes, and connections for roadside water stations.

5.—Control of a maintenance force for their upkeep. When accidents happen, the enginemen must report it by wire to the dispatcher so that he can change his train movements accordingly. The repair forces should be within easy reach of this source of information.

There is no essential difference between engines, cars, coal, and water as parts of a transportation scheme, and they should be under the same general head. To assemble engines and cars is not far different from erecting water stations. It is believed that the supply of equipment for indefinite problems is best handled from one large depot and is, therefore, rightly under the Department of Construction and Forestry. This includes pumps and engines which can more readily be selected from a large stock.

The main object in work of this kind is to preserve the continuity of all operation. This has been accomplished under civilian control by the organization of "all line gangs". These are under the control of one official who can move them about into different divisional jurisdictions. Similar forces, completely equipped, could have simplified matters in France. The chief obstacle to be avoided in transportation is delay. As a chain is only as strong as its weakest link, so local delays may interfere with train movements perhaps hundreds of miles away.

It would not seem difficult under military organization to accomplish this by the creation of a separate unit. This unit would have absolute control over its own activities from the starting point, or investigation, to the conclusion—a completely equipped water station with sufficient supply to enable it to deliver water to locomotives at points best suited to the expediting of traffic.

DISCUSSION

CHARLES H. LEE,* M. AM. SOC. C. E. (by letter).—The author has vividly described the difficulties faced by the engineer officer in specialized service during the World War. His experience had its duplicate in all the combatant armies, but with the A. E. F. it was possibly intensified because of general unpreparedness for overseas duty and the speed with which organization and expansion were undertaken. To those who shared with the author in his experience there remain two lasting impressions: First, the display of ingenuity and energy on the part of officers drawn from civilian life in accomplishing results without the accustomed facilities; and, second, the tremendous loss of time and effort due to the lack of information, material, and appropriate equipment for specialized military engineering operations. The lesson to be learned is the need of a greater degree of preparedness in order that lost motion may be reduced to a minimum.

The writer was assigned to the Water Supply Service of the A. E. F. late in 1917, and during the following eighteen months was attached at various times to the Water Supply Sections of the Office of Chief Engineer, A. E. F., Office of Chief Engineer, First Corps, the Department of Military Engineering and Engineering Supplies, and the Office of Chief Engineer, First Army. His duties (as Captain) were related to the selection and development of water sources and the control of specialized equipment used in water development and transmission.

The organization diagram, Fig. 3, pertains entirely to the Service of Supply and the Advance Section. It does not include the Zone of the Armies, which is the field of operation of the combatant forces. The latter might be indicated on the diagram by extending the top line to the right and adding below it, "Commanding General First Army", "Commanding General Second Army", etc. Each Army had its Water Supply Service and Water Supply Officer, nominally consisting of one engineer regiment of water supply troops and its commanding officer.

The diagram might also be made more complete by the addition of "Water Supply Section", under the Chief Engineer Officer, A. E. F., Department of Military Engineering and Engineering Supplies. This office had technical supervision of all the water supply activities of the A. E. F., including the Water Supply Services of the First and Second Armies, the Service of Supply, Department of Construction and Forestry, and the Advance Section. F. F. Longley, M. Am. Soc. C. E., was placed in charge of this office in September, 1917, and continued throughout the war.

A quotation from Paragraph 2, General Orders No. 131, A. E. F., dated August 7, 1918, indicates the status of the Water Supply Service as a branch of the A. E. F.:

> "I.—1. Section VI, G. O. No. 34, G. H. Q., 1918, is hereby revoked and the following substituted therefor.
>
> "2. The responsibility for water supply work for the A. E. F. is divided as follows:

* Cons. Hydr. Engr., San Francisco, Calif.

"(*a*) In the army zones special engineer troops (Water Supply) assigned to armies shall be responsible for the supply of adequate quantities of water at 'water points' located as conveniently for the troops as service conditions will permit. This water will, if necessary, be purified by filtration or disinfection, or both, in such a manner as to insure the delivery of water of the best quality practicably obtainable under the conditions.

"(*b*) In all areas occupied by the American troops outside of army zones the Engineer Department will be responsible for the development, as required, of water supplies for the use of American troops and for American activities of every kind. This water will be given such treatment as the conditions demand and permit."

Its character and functions are also well shown by the following quotation:*

"A.—Organization of Water Supply Service

"I.—The Water Supply Service of the American E. F. is organized as a branch of the Engineer Department. It consists of certain officers and special engineer troops experienced in water supply work, including examinations, design and construction. Its duties are defined by Sec. I, G. O. No. 131, G. H. Q. A. E. F., 1918.

"For each army the water supply service will consist of Army Engineer troops (not to exceed one regimental headquarters and six companies), especially trained and equipped for water supply work and such additional officers as conditions may require.

"In general, the functions of the Army water supply organization will include the investigation of water resources, the development of water supply, and the construction and operation of such works as may be necessary to make water available at 'water points', including conveniences for watering animals, filling water carts, water-tank trains, buckets, canteens, and other containers. Tactical units will make provision for the transportation of water from 'water points' to the final point of consumption."

The Water Supply Service, as thus established, was modeled somewhat after that of the French and British Armies with modifications that experience had shown desirable. One water supply regiment, the 26th Engineers, was organized and functioned in scattered units in the Service of Supply, the Advance Section, and the Zone of the Armies. A number of detached officers with qualifying civilian experience were also assigned to water supply duty. Water supply systems were designed and built for all purposes throughout the area embraced within the American Lines of Communication. These scattered units and officers were attached to the various base sections and functioned under the direction of base section engineer officers. Companies of the 26th Engineers also saw active service in the Zone of the Armies supplying water to combatant troops. Watering stations for light railways were also established at many points in the Army Zone. In addition to design and construction, much work was done by specially qualified officers attached to the Water Supply Section, Department of Military Engineers and Engineer Supplies, in compiling general water resource and water requirement information

* *Bulletin No. 55*, A. E. F., dated August 8, 1918.

and recommending specific sources of supply for various hospitals, aviation fields, depots, base ports, railway points, etc.

The office of Engineer of Water Service under the Engineer of Construction, Transportation Service, was apparently not established as a part of the general Water Supply Service of the A. E. F., but as an independent unit within the Transportation Department. Its functions, as shown in Fig. 3, were limited, and were in conformity with the suggestion of the Director General of Transportation in his letter of January 5, 1918, quoted on page 207. The inter-departmental difficulties described by the author were incident to the building up of a utility organization under tremendous pressure for results, but without precedent and without previous information of requirements or of physical resources. Time would undoubtedly have dissolved these difficulties and proved the worth of the type of organizations as formed.

The relation of water resources to railway water supply is of great importance. Much depends on the choice of an adequate, dependable, and pure source of water supply. For military purposes, the time required for development and the type and amount of material required are also of greatest importance. The experience of the A. E. F. in France emphasizes the need of carefully compiled and analyzed water resource data as an element of preparedness both to aid in the choice of sources of water supply and in ordering equipment and material. The sources of data are so diverse and so scattered in the various countries of the world, that it is only in times of peace that they can be assembled and reduced to a condition of usefulness.

As a nucleus for the study of water resources of any region there should be available, as complete as possible, a collection of published data relating to the region; together with topographic and geologic maps, geologic sections, and maps showing forests, streams, lakes, and, if possible, springs and wells. With the A. E. F., in France, the Geologic Section, Office of Chief Engineer, and Meteorologic Division of the Signal Corps, co-operated with the Water Supply Section, Office of Chief Engineer, both in obtaining maps and data from French sources and in making mutually available all data secured. This procedure proved valuable to all concerned.

The precipitation and hydrologic data were obtained from time to time as the pressure of current work permitted, and, although available for reference, it was not possible to analyze and compile them for general use until just before the Armistice. The following summary is of more than passing interest, as it illustrates the general features of a water resource compilation for any country.

There are three distinct hydrologic types in France which serve to divide the country into districts useful in the selection of sources of water supply, study of water supply characteristics, determination of methods for development, and choice of construction material and equipment.

The first type is represented by elevated igneous rock masses flanked or partly overlaid by metamorphic rocks constituting much of the mountainous area of France, and receiving an average annual precipitation of from 35 to 60 in. Falling within this type are the following hydrologic provinces (see Fig. 5 for location): (1) The Brittany Peninsula; (2) the assembly of

ranges in Central France, known as the "Central Massif"; (3) the Ardenne; (4) the Vosges Mountains; (5) the Pyrenees Mountains; and (6) the main chain of the Alps. The igneous and metamorphic rocks are dense and unfissured except superficially, and have no stratification of porous and impervious formations characteristic of the more recent sedimentary formations. The principal source of water in these areas is direct run-off from precipitation. In the Brittany Peninsula and Central Massif the rainfall is relatively light and the run-off rapid. In the higher mountain districts (Areas Nos. 3 to 6), the stream flow is more regular due to the heavier precipitation with snow storage and forest litter. Important railway lines operated by the American forces traversed the Brittany Peninsula and Central Massif (Figs. 1, 2, and 5), and it was necessary to resort to artificial storage in these areas. Springs afforded minor supplies, which were of little value for railway purposes in any areas of the first type.

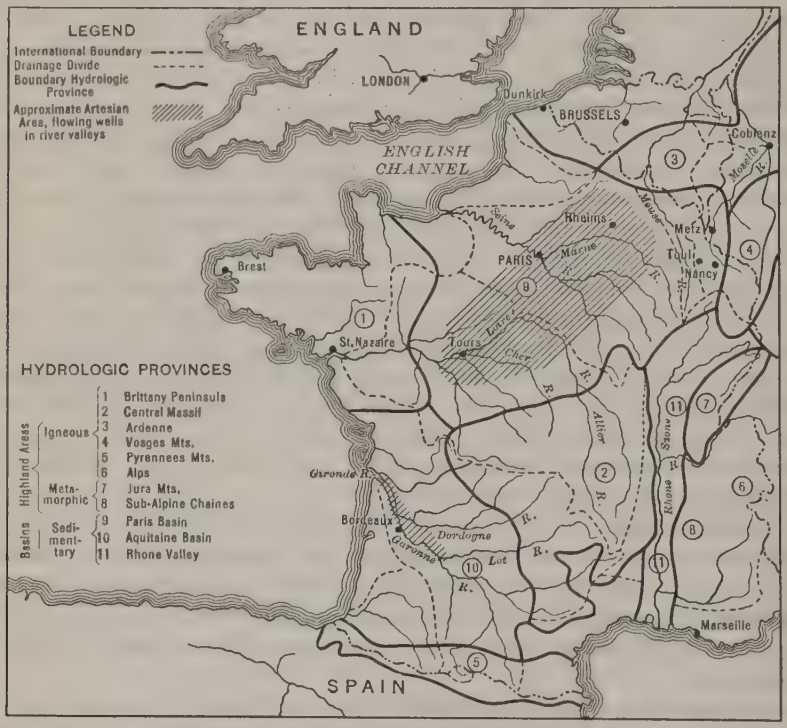

FIG. 5.—HYDROLOGIC MAP OF FRANCE.

The second type of hydrologic province is composed of elevated and highly tilted and folded sedimentary rocks receiving an annual precipitation of from 35 to 60 in. This type includes (7) the Jura Mountains, and (8) the Sub-Alpine Mountain chains bordering the Rhone Valley on the east. Rock formations in these areas are more or less fissured and sometimes cavernous, but seldom porous. The principal sources of water supply are flowing streams

fed by melting snow and ice. Some very large cavern springs occur in the limestone regions. The southern end of the railway, terminating at Marseilles, lay in the Sub-Alpine Province (Figs. 2 and 5).

The third type of hydrologic province comprises the great "structural basins" embracing the valley and plateau areas of France. The precipitation varies from 24 to 35 in. per year over these areas. Included in this type are: (9) The Paris Basin; (10) the Aquitaine Basin; and (11) the Rhone Valley. These basins are filled to a great depth with comparatively soft, regularly stratified, sedimentary rocks of the Secondary and Tertiary Series, and are bordered by the upturned and exposed edges of the various underlying strata. They contain the most highly developed agricultural and industrial areas of France, and are the regions of densest population. Local Quaternary deposits of unconsolidated gravel, sand, and silt occur in the various river valleys. This area also includes most of the territory traversed by the American Lines of Communication from base ports to rail-head (Figs. 1, 2, and 5), as well as the Zone of the Armies.

The sources of water supply are more varied than in the highland provinces. Numerous rivers with dependable flow have their sources in the mountain areas and traverse the basins, affording ample supply for railway purposes, except in the elevated limestone plateau districts and the flat clay and shale areas, such as the Woevre District in the Toul Sector and northward to Stenay. In the latter occur many shallow lakes ("etangs"), in which the water is more or less stagnant and often colored from vegetation, but can be easily clarified for use. Springs are common in the limestone districts, many with large and reasonably dependable flow. The "contact" type of spring is especially important in the northeastern part of the Paris Basin. These springs issue from fissured limestone, interbedded with layers of shale or clay, the latter serving as an impervious base on which the water absorbed from precipitation may accumulate in the fissures and crevices of the overlying rock. Such springs were the most generally used sources of water supply in the Argonne-Meuse Offensive, and also for small hospital and camp supplies in the Advance Section. They were occasionally of sufficient size for railway supply.

Water-bearing river deposits, consisting of porous sand and gravel transported from the highland areas, were deposited in shallow beds along river bottoms. These form an important source of supply where the stream traversing the valley has a permanent flow accessible to the gravels. The method of developing for military purposes was by use of small dug, driven, or drilled wells.

Shattered limestone at the margins of river valleys and in ravine bottoms with shallow water planes, sometimes yielded large quantities of water from shallow dug wells. The success of such a well is a matter of chance, however, due to the local occurrence of fissures. One of these wells at Sorcy Gare, the rail-head for the Tour Sector, produced considerable water.

Deep, water-bearing formations were also an important source in the basin provinces. These consist of porous water-bearing strata lying at various depths below the surface, exceeding 100 ft., from which water may be obtained

in considerable quantity from drilled cased wells, either by pumping or by artesian flow. The water-bearing formations have an outcrop along the margins of the basins and are fed by streams flowing from the adjacent highland areas. Water is encountered in drilling at depths of from 200 to 1 000 ft. The yield of a single well is often ample for extensive railway use. The time required for drilling wells precluded their use in the Army Zone, but they were practical for railway purposes. Several flowing artesian wells were drilled by the Water Supply Service at Bassens, the American rail terminal near Bordeaux, and gave an ample supply for railway, ship, and camp use.

These wells were drilled to recognized water-bearing strata. In other locations where wells were drilled without consideration of the geology and in unfavorable locations, either dry holes, or very poor yields, were obtained. The author expresses the opinion that the supply of equipment for indefinite problems is best handled from one large depot, and includes pumps and engines. The writer would also include well-drilling equipment. Obviously, the supply of such equipment must be limited in overseas military operations. The idea is quite commonly held among officers responsible for the location of camps, hospitals, aviation fields, depots, etc., that a water supply can be obtained anywhere by drilling, if sufficient depth is reached. Acting on this concept, requisitions for well-drilling rigs and tools received at Headquarters, soon far exceeded the supply. Investigation of the local geological formations by a trained representative of the Water Service or Geological Section often showed the utter impossibility of securing water by drilling, due to the local geological formation. With such information available, and a system of material control in effect, requisitions for well-drilling equipment could be filled in the order of probability of securing a water supply.

The writer does not agree with the author's first "Conclusion," as he believes that this work could be done more readily and with less duplication by a general office. The same is true of the second "Conclusion," although full co-operation should be maintained, and when only railway requirements are involved, the latter should be given the preference.

The writer wishes to emphasize the desirability of compiling and digesting complete geologic and water resource data for the various countries of the world as a peace-time activity of the General Staff.

William G. Atwood,* M. Am. Soc. C. E. (by letter).—This paper is a valuable addition to the record of the engineering activities of the American Expeditionary Forces and illustrates, as all thoughtful papers must, the woeful waste caused by unpreparedness. The lack of any plans for army organization, which included the engineering and transportation phases of the operations of an overseas army, made necessary the continual re-organization mentioned, until a satisfactory one was developed. The delays and losses of time resulting can be imagined, but must have been experienced to be fully appreciated. They were unavoidable under the conditions. Papers like this will put on record the experiences and needs of the multitudinous services

* Cons. Engr., New York, N. Y.

of a large army in such a way that similar experimenting will not have to be done in the face of an active enemy in the next emergency.

If it had not been for the inspired foresight of Col. Wilgus when he prepared the famous Requisition No. 6 only a short time after the 1st Division landed in France, conditions would have been much worse than they were. That a requisition could be prepared providing for automatic shipment of the enormous number of items required for the construction, operation, and maintenance of the army transportation net based on the number of men in the field was a wonderful piece of work. To have that requisition so complete that it was successfully made the basis for the supply of the transportation needs of the Army during the entire period of hostilities was still more wonderful.

It was unfortunate that the Water Supply Service of the Transportation Corps could not have been organized sooner, since it would have been very helpful had the Section Engineers known what would be needed in the way of roadside water stations; but this condition was no different from those pertaining to the facilities of any other branch of the Army.

The general water supply problem was one of the most serious among the many that had to be solved. There was always apparently water enough to make mud, but little for any other purpose. When the original plans for the development of the St. Nazaire-Montoir Area were submitted by the 17th Engineers (Railway) in October, 1917, the doubtful factor was the water supply.

The Montoir Yard, according to Table 1, would require a new supply of 427 000 gal. per day, but the city, camps, hospitals, and ships were estimated to require 2 500 000 gal. more, with an existing plant in the city furnishing a maximum of 375 000 gal. It was necessary to construct a number of reservoirs, some of them 25 miles away, to secure sufficient storage; and when the water had been impounded the problem of getting it to the point of use was still more serious in view of the lack of pipe and pumps. About 5 miles of 24-in., and 2 or 3 miles of 12-in., pipe were all that could be secured. The final pumping capacity, including boosters, was about 10 000 000 gal. per day. The railroad consumption at the Port of St. Nazaire and Montoir was roughly one-fifth of the total, and while the railroad use was of equal importance with the others it would have been "putting the cart before the horse" to have placed the design and construction of this plant in the hands of the Railroad Water Service, had it been organized at that time.

In the Montoir Area, roughly 2 by 6 miles, where all the construction was in virgin territory, the six railroad water tanks and engine house were supplied from the same mains that served the camps and the new wharf. In the other terminals in Base Section No. 1, Nantes-St. Luce, La Rochelle, La Pallice (later Base Section No. 5), and Saumur, the latter was the only point at which the railroad and other activities were so separated as to make the railroad water supply an individual problem and in that case the solution was simple.

All the roadside water stations were relatively small, but some of them were hard problems because of the difficulty of developing adequate supplies

with available equipment and material. Aside from the tanks and water columns they required no material or equipment not common to other water supply installations, and a number of railroad water tanks were used for other purposes.

The theory of army organization does not differ from that of any other well-organized activity. There is complete centralization of authority as to policy and complete decentralization as to execution, but always there is a clear line of authority and responsibility.

The author would change this procedure so far as the water supply organization is concerned, and in this the writer believes he is wrong. The purpose of all activities of an army is to defeat the enemy and the duty of each part of the organization is to carry out the plans of headquarters to this end; for that reason the line of authority and consequent responsibility must be clear. One of the greatest steps for the improvement of conditions relating to construction in the A. E. F. was made when the General Purchasing Board under General Dawes placed the different items of supply in the hands of some one branch of the Army and made it responsible.

The writer believes that the final organization of the construction and operating activities of the A. E. F. was good. The Transportation Corps, Medical Corps, Quartermaster Corps, Air Corps, and others presented their approved plans to the Director of Construction and Forestry, and they were passed along for execution to the Section Engineers, each in his respective Section. The Section Engineer controlled all available labor and supplies in his Section and allocated them in conformity with the priority schedules furnished him. Any other plan is bound to be wasteful of both material and labor, neither of which were or ever will be adequate.

The Engineer of Water Supply, Transportation Corps, should be a specialist and should have adequate assistance, but he, as well as most other specialists, should be Staff Officers. The Section Engineers should have, and did have as far as Base Section No. 1 was concerned, such corresponding staff specialists as were needed. The section organization knows local conditions and, with proper information as to requirements and general design, should be able to construct adequate facilities much more efficiently and with much less waste of labor and material than a number of small independent organizations.

No units were organized for base section work in the A. E. F., but the two most important Base Sections, Nos. 1 and 2, were continually supervised from August, 1917, to the Armistice by the 17th and 18th Engineers (Railway), respectively. The writer believes as a result of his experience as Section Engineer of Base Section No. 1 that organizations of this type are fully competent to supervise installations for all branches of the service once they are informed of the requirements, and that independent individual organizations of specialists are out of place, except as designers or, in Army parlance, staff departments. The use of separate construction organizations and sources of supply for various branches of the Service was tried in the A. E. F. and found wanting.

The writer, therefore, finds himself in disagreement with the author on most of his conclusions. He believes that the Engineer of Water Supply, Transportation Corps, should furnish a statement of the requirements in as much detail as possible. This will reach the Section Engineer with an indication of the desired priority and from that time on the Section Engineer is responsible for furnishing the necessary facilities at the proper time. He knows what labor and material he has or can make available, and it is his business to follow as closely as possible the plans furnished him. At the proper time he must furnish an operating unit that will perform the required service whether or not it conforms to the plans in all respects.

The writer agrees with the author's Conclusion 5, regarding the maintenance and operation of the water stations once they are completed.

The delays on account of the necessity of sending formal communications through channels are very real, but many of them can be avoided by informal conference and agreement. In the A. E. F., work was delayed on account of the necessity for securing approval from the French; but this was not an unreasonable requirement on their part, although it was very trying at times. The writer remembers one case when approval of the plans for an arch dam for a very badly needed hospital water supply was long delayed because of doubt in the minds of the French engineers as to the adequacy of the structure. When they finally authorized the work to go ahead it was with the expressed hope that the Americans would never find it necessary to fill the reservoir. At that very moment there was 10 ft. of water behind the dam and it was rapidly filling.

The matter of army engineering organization is one which all civilian engineers should study because it will be the case in the next war as in the last one that the Reserve Officers will have to furnish the largest proportion of the personnel, and they should have as complete a picture as possible of the requirements and difficulties. Railway water supply is an extremely important item, and this paper very fully and correctly shows its difficulties.

Paul M. LaBach,* M. Am. Soc. C. E. (by letter).—Mr. Lee's discussion contains much information, particularly with reference to a variety of activities concerning water supply for the A. E. F. in France. As he states, the water supply for railways was a special branch. However, he is mistaken in the idea that its activities extended only over the areas of the Service of Supply and Advance Sections. The last railway line taken over by the Transportation Corps before the Armistice, was above Sorcy in the Woevre (Second Army Area). Fig. 2 shows very clearly the areas finally covered. In warfare, rail transportation will always be extended just as far as possible into the combat areas, and, at times, facilities are destroyed. These facilities are linked with others farther back in a manner not always appreciated. The idea that the whole problem is a chain is not generally apparent except as regards track.

One of the plans followed by the writer was to consult French hydraulic engineers, located in Paris (as a rule), and much general information was

* Engr., Water Service, Rock Island Lines, Chicago, Ill.

acquired in that manner. Also, the writer made an extensive trip with a French Major in that line of work in civil life. By this method the Water Supply Department for Transportation kept itself sometimes several months ahead of the information furnished by other Departments in the A. E. F. This was due to the fact that they had nothing in common at many points, and no reason to make any investigations.

The situation as to the numerous different water supply bodies described by Mr. Lee, has no real application to this specific case. It is too general. There is the same situation in peace times. The United States is fairly well covered with hydraulic engineers and State organizations. Much work has been done along these lines, which is available in print or otherwise.

However, practically every large railway system has an engineer of water service and water service organizations on every division. In making investigations, the railway engineer of water service usually has all the published data and much information acquired in years of practice. He uses these just as one should do in an army if there is time to acquire it from co-related departments. In the end, however, he must make his own investigations and decisions, which are based on considerations of railroad operation.

A railway water service engineer does not have to go to the State Engineer of a given area to obtain help either in making investigations or in the construction of facilities. The State Engineer would nearly correspond to the Section Engineer as outlined in the A. E. F. No industry like a railway would dream of such a procedure, on account of the delay, even in time of peace when delay is less important than in time of war.

Organization diagrams are only an index of offices or utilities in their relation to each other. When once made they should not become sacrosanct. Mr. Lee's idea is that "time would undoubtedly have dissolved these difficulties and proved the worth of the type of organizations as formed". That may be true, but the time came only after all the work was finished and nothing was left of urgent importance. The war was over. The object of organization is to aid, particularly when things are beginning and time is of major importance. If, then, it is found that the organization hampers the work the thing to do is to change the former, if the work is efficiently managed.

Mr. Lee's discussion is interesting, but the Water Department of the Transportation Corps probably had a greater collection of general data than any other single organization. However, general information is only an index showing the probable direction for investigation. The writer has refrained from touching on such matters, as it is desired to confine the paper strictly to the subject assigned. The writer heartily concurs in Mr. Lee's statement in regard to wells. The idea is only too prevalent that a well can be put down anywhere.

Judging from his discussion, Mr. Atwood seems to have gained the impression that the writer wishes to change the entire structure of Army organization. The real purpose of the paper was to give a short account of successes and failures under a given set of circumstances. The suggestion of changes

in organization was not directed at any other activities than those in his own department.

The Construction Division was decentralized, that is, the Section Engineers were in charge of construction in a given area. This was a territorial sub-division and each sub-division was independent of its neighbor. The water supply for Army railways was under central control, as it could not be handled otherwise. It covered a small area in width, but extended from the Base Ports to the Rhine. In this area, construction, maintenance, and operation were being handled at the same time without a clear line of demarcation between them. To use a railway term, they were "interlocked". To open one line, another had to be closed. The writer's proposal is to put such an area in the same basis as a "Section". This would not change any fundamentals of organization in any manner, but would bring correlated and interlocked activities under one head. This would be similar to actual civil practice so successful for many years.

Armies are organized for combat service, and the attempt is usually made to adapt the same organization to constructive activities. Its very virtues in combat sometimes are hindrances under other circumstances. The question of rank and the authority which goes with it have some bearing. When a new military unit is invented, or borrowed from civil life, it is usual to put somebody, perhaps an expert, in a staff position to take charge of its activities. If it is a large staff, and he desires to get anything done, he must devote much of his energy to getting priorities. Having had many years' experience, the chief of staff will naturally lean toward and favor activities with which he has had personal knowledge. New schemes from civil life, while old subjects to the proponent, are new to him, and so the new staff officer starts with a handicap. In the A. E. F., these debates were called the "Battles of Chaumont, Paris, Tours, Toul", etc.

For this the writer would wish to substitute direct action in the case under discussion. Make the responsibility for results and the authority necessary to secure them co-extensive. It was practically impossible to hold meetings with a scattered organization except at wide intervals. To convince those present of the importance of the work under debate was not always possible. Everybody told a similar tale of woe to the Section Engineers.

As an illustration of the workings of the system the writer recalls two communications of the same day about three weeks before the Armistice. One stated that, because of the failure of a small French water station and the fact that the new station had not been completed, 5 miles of trains loaded with ammunition and other supplies were unable to proceed. The other was from a Section Engineer and contained an argument against doing any work on the reinforcement of a water station because the work would never be needed. The benefit of the experience of one was lost in so far as the other was concerned, although both water stations were integral parts of the same machine.

Observation in two wars and several revolutions makes the writer somewhat skeptical on the subject of staff jobs as a cure for troubles. In the World

War practically every peace-time staff had to be re-organized after hostilities had begun. The French General Staff, while it had wide control of the railways, did not interfere with actual operation, which was conducted by the railway organization from start to finish. These organizations could not expand to help the American Army as they were already short of both men and material. Most of the personnel had had Army service before the war. When it came to a critical situation at one time it was found that results on the P.-L.-M. Railway could be obtained more quickly through its organization and the use of German war prisoners than through any military channels. This was due to the centralized organization in direct contact with daily operations.

Decentralized organizations were much more useful in former times than at present. They grew up out of necessity due to slow methods of communication. At present, with the telegraph, telephone, radio, and aeroplane, the same reason does not exist.

In water supply for military railways, the writer's plea, in railroad parlance, is for grade separation as distinguished from interlocking.

Paper No. 1661

THE SHANDAKEN TUNNEL*

By R. W. Gausmann,† M. Am. Soc. C. E.

With Discussion by Messrs. W. W. Brush and Charles Goodman.

Synopsis

The Shandaken Tunnel, extending between Prattsville and Shandaken (mostly in Greene County), N. Y., is about 18 miles in length, the longest yet built. It connects two water-sheds, making the run-off of Schoharie Creek as impounded by the Gilboa Dam on the north available to the Esopus water-shed on the south, already serving the City of New York.

The paper recounts the development of this project and the geology of the region. The actual construction work is covered in detail, both construction shafts and tunnel proper. Drilling, dynamiting, mucking, timbering, and concrete lining operations are described; also mechanical equipment, progress, and costs.

Some special features, such as the use of the concrete gun, organization problems for efficient progress, and transportation, are treated incidentally. Actually, the construction was under way from November, 1917, to October, 1924.

General

The Shandaken Tunnel forms a part of the Catskill Water Supply System of New York City. Its function is to carry water from Schoharie Creek to Esopus Creek, from which the flow is to the Ashokan Reservoir (Fig. 1). The tunnel is 18.1 miles long, being the longest continuous tunnel in the world for any purpose. It is horseshoe-shaped and concrete-lined, with inside dimen-

sions of 11 ft. 6 in. in height by 10 ft. 3 in. width, and has a uniform slope of 4.4 ft. per mile, except for the northerly 3½ miles which is depressed, making that portion a pressure tunnel. Its capacity, computed as a grade tunnel, is 650 000 000 gal. daily.

The intake is located about 3½ miles north of Prattsville, N. Y. From this point the tunnel extends in a general southeasterly direction to just south of Allaben, N. Y., where it discharges into Esopus Creek. An intake shaft and seven intermediate shafts are provided, the aggregate depth of the shafts being 3 238 lin. ft., the maximum depth of a single shaft being 630 ft. The minimum distance between shafts is 1.3 miles, and the maximum, 2.7 miles. All shafts are circular with a diameter of 14 ft. inside the concrete lining. The upper portion of the intake shaft is so constructed that it will act as a Venturi meter, the building over this shaft containing the control gates and keeper's residence; discussion of the intake and outlet structures is not included in this paper.

Historical

Apparently, the first mention of a tunnel carrying water from Schoharie Creek to Esopus Creek was made in a paper published in the *Scientific American*, of September 4, 1886. Years later, in 1903, a survey was made for such a tunnel by the Commission on Additional Water Supply for New York City (William H. Burr, M. Am. Soc. C. E., the late Rudolph Hering, M. Am. Soc. C. E., and John R. Freeman, Past-President, Am. Soc. C. E.). The first engineering work on this project by the Board of Water Supply of New York City was done in 1907 when a line of levels was run. The surveys from which the final alignment of the tunnel was made, were run in 1916. The contract for construction was let on November 10, 1917, to the Degnon Contracting Company, and all work was completed on October 22, 1924. Thus, a period of 38 years elapsed from the time of the original published proposal to the final completion of the work.

Geology

In the region penetrated by the tunnel the rock was gray sandstone and red and gray shale (red predominating) lying in nearly horizontal layers, the dip being from 2½ to 2° in a southerly direction. The shales drilled easily, broke well to line, and would sometimes stand for a limited time, but they had a marked tendency to disintegrate when exposed to the atmosphere. Of slightly coarser texture, but often difficult to distinguish from the shales, were the red sandstones. Almost invariably the two were more or less mixed, and, when penetrated in the roof of the tunnel, needed support. The gray and blue sandstones, being the hardest and coarsest grained rocks in the vicinity, were more difficult to drill and shoot, but had an advantage in that they required little sealing and generally stood well without support when not too thinly bedded.

During driving the temperature in different parts of the tunnel remained almost constant at 59° Fahr. despite the variation in cover from 200 to 2 200 ft. This constant temperature may have been due to the system of ventila-

FIG. 1.

tion. Several crush zones were encountered between Shafts 3 and 4 (Fig. 1). At one of these a horizontal clay seam surmounted by a badly broken-up bedding of shales caused a maximum inflow of water of 170 gal. per min., which decreased in a few days to 65 gal. per min. A mud seam, varying in thickness from 5 to 7 ft., also crossed the tunnel line. Another crushed zone yielded an initial flow of 130 gal. per min., which rapidly dropped to less than 30 gal. This water was highly saline and smelled and tasted of sulfur. Apparently, it was of Devonic origin. In general, the tunnel was remarkably dry, the largest quantity pumped at any one shaft being 170 gal. per min.

Between Shafts 4 and 5 the phenomenon of "popping rock" was observed. This rock was coarse-grained gray sandstone and appeared to be sound and of the best texture. "Popping" usually occurred shortly after the tunnel had been excavated; it ceased in from one to two weeks. A loud report would be heard, followed by the falling of a slab from the roof or the shooting of a rock fragment across the tunnel.

Small quantities of inflammable gas were encountered in the vicinity of Shafts 3 and 4 and occasionally minute quantities of carbonized organic matter were found.

Brachiopods and other forms of shell fossils were found in two strata 30 ft. apart. These strata were encountered on Stevens Mountain above the Gilboa Dam; back of the intake chamber, at the Bearkill Falls; and in the tunnel between Shafts 1 and 2. Fossil twigs and branches were also found, as well as a small stump similar to the fossil stumps found at Gilboa, which have been named *Eospermatopteris* (dawn of seed-bearing fern). Geologists assert that they are the oldest trees in history.

Preliminary sub-surface investigations disclosed pre-glacial gorges at each of the valleys crossing the line of the tunnel. This made it advisable to depress the tunnel below the hydraulic gradient between the intake and a point between Shafts 1 and 2 (Fig. 1) in order to provide sufficient natural rock cover under the Bear Kill Gorge.

From preliminary studies it was thought that comparatively little timber would be required; the conditions actually encountered, however, made it necessary to timber about 50% of the tunnel. In general, this included all the shales that disintegrated on being exposed to air and the areas in which popping rock occurred. The crushed zones required special types of timbering.

Construction Shafts

While the construction of the Shandaken Tunnel was done under a single contract, the sinking and lining of the shafts, being specialized work, were handled by a separate organization under a sub-contract. The shaft subway equipment was used for this operation only. Active work was started in June, 1918. By October 15, 1919, all the shafts except the intake were completed and lined; the headings were turned; and the tunnel was driven for about 35 ft. on either side of the shafts. An interim of several months occurred at each shaft before tunnel driving, using regular tunnel equipment, was started.

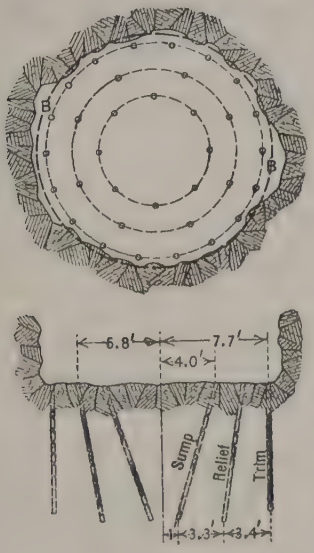
In general, the method of sinking the shafts was to excavate the earth cover by hand, using a derrick. When this part had been timbered (in some cases,

concreted), a light temporary head-frame was set up and the remainder of the shaft was sunk and lined.

In all, 24 521 cu. yd. of rock and 1 066 cu. yd. of earth were excavated for shafts. The actual volume of excavation in rock per linear foot of shaft was 7.65 cu. yd.; and the payment volume, 8.01 cu. yd.

The general method of drilling and shooting is shown in Fig. 2 and Tables 1 and 2. At some of the shafts the relief holes were omitted; this reduced the amount of drilling, also of powder, and gave equally good results.

There was a considerable variation at the different shafts in the number of holes drilled per round, in the depth of holes, and in the quantity of powder used. These variations were frequently due more to the superintendent than to the character of the rock. In general, the number of holes varied from 30 to 38, the linear foot of hole per cubic yard of excavation from 5.3 to 6.5, and the powder from 1.3 to 3.2 lb. per cu. yd. The "pull" per round was between 5 and 8 ft.



DRILLS USED

MAKE	DIAM. OF STEEL	DIAM. OF BIT	LENGTH	REMARKS
Ingersoll Jack Hammer Drills	7/8"	1 3/4"	2' to 3'	Starters
	7/8"	1 1/2"	5'	
	7/8"	1 1/4"	8' to 10"	

Note:- 60% dynamite was used in sticks 8" x 1" diam., weighing 1/2 lb.

All holes drilled before any shooting or mucking done.

See Tables 1, 2 and 3 for added data.

SHANDAKEN TUNNEL
SHAFT EXCAVATION IN ROCK
METHOD OF DRILLING & SHOOTING

FIG. 2.

Supplementing the other data, Table 3 gives a more detailed analysis of excavation at Shafts 4 and 5. The variable in these two shafts was the percentage of shale. The shale drilled more easily and broke better, otherwise conditions at both shafts were about the same, and the difference in progress may be attributed to the difference in plant, that at Shaft 5 being much better than that at Shaft 4.

When any appreciable quantity of water was encountered in sinking the shafts, holes were drilled and grouted to shut off the flow. For example, while drilling a round of holes between Elevation 1 254 and 1 247 at Shaft 4, the flow of water, which had been no greater than 3 gal. per min., suddenly in-

creased to 18 gal. per min. The sump was thoroughly cleaned and eleven equally spaced holes, as near the outer side of the excavation as possible, were drilled 9 ft. deep, pointing outward so that the lower ends were 3 ft. outside the ordinary limits of excavation. Pipes were wedged tightly into the holes and 68 cu. ft. of liquid grout, in the proportion of 9 gal. of water to 1 bag of cement, was forced in by means of a Canniff tank under a pressure of 70 lb. The flow practically stopped for the time being, but it broke out after mucking had reached Elevation 1 236. Five horizontal holes were then drilled 3 ft. deep in a seam at Elevation 1 244. Through these, 14 cu. ft. of grout was forced at 70 lb. pressure. This effectually stopped the leak.

* Not obtained at first shooting, it generally being necessary to blow out butts, reload, and fire a second time. This accounts for excessive use of powder.

† When drilling is finished before end of shift, drillers complete shift as muckers.

After the shaft had been excavated to a depth of from 100 to 300 ft., depending on the character of the rock, it was lined with concrete starting

from the bottom and working up. Simple, metal-covered, wooden forms were used, 5 ft. high in four 90° sections, with a key. Concrete was mixed at the top of the shaft, lowered in a bucket, and dumped on a platform from which it was shoveled into the forms.

This mix was in the proportion 1:2.33:4.67, a bag of cement being estimated as 0.905 cu. ft., and no correction being made for swell in the aggregate due to moisture. The cement factor for concrete placed in the shafts averaged 1.57 bbl. per cu. yd. Fine aggregate came from local pits or crusher screenings; coarse aggregate was either crushed sandstone from the excavation or crushed field stone from neighboring stone walls. Grout was forced behind the lining at all water-bearing seams, by the method already explained.

* When drilling is finished before end of shift, drillers complete shift as muckers.

The average progress for all shafts was 1.1 ft. per shift; and for lining, 6.1 ft. The average progress for sinking and lining was 8.3 ft. per week.

The plant at each shaft included a compressor with a capacity of from 275 to 528 cu. ft. of free air per min.; three to six jack-hammer drills; a hoisting engine; a crushing and screening plant; a boiler or boilers aggregating from 50 to 100 h.p.; a ½-yd. concrete mixer; a generator of from 2 to 3¾ kw.; and trucks and teams.

Small camps were built at each shaft and enlarged before tunnel driving started; these will be described later.

* Only one set of relief holes was drilled. This round consisted of 8 holes, each 8 ft. deep; 80 sticks of dynamite were used.

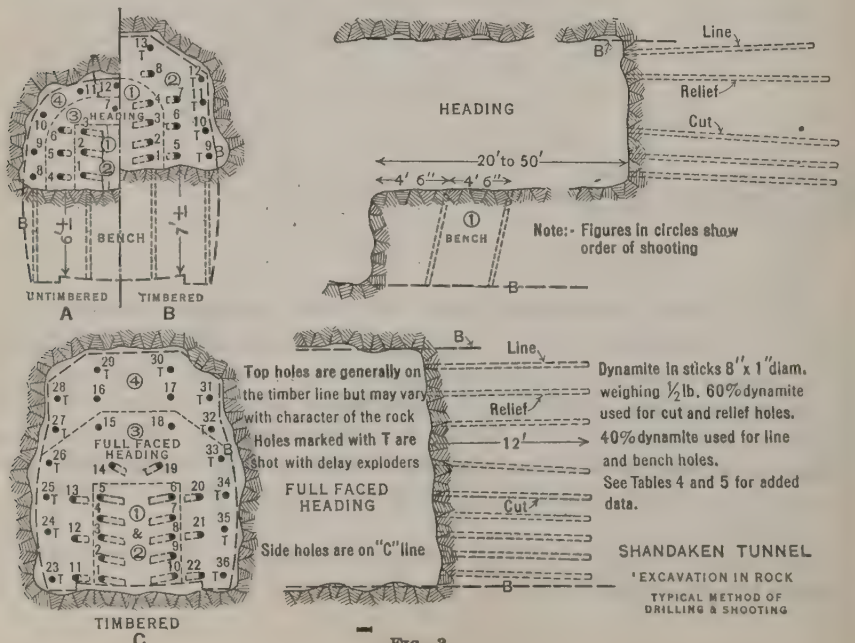

Fig. 3.

Tunnel Construction

The tunnel was driven both ways from all shafts except Shaft 2 (Fig. 1). A short length of tunnel was driven from the outlet, in earth, but none from the intake.

In general, three methods of driving were used: The top heading, the full-face heading, and the bottom heading. In sound rock most of the tunnel was driven with a top heading with a bench from 40 to 50 ft. long. In the earlier stages of the work the bottom heading was used, but this was abandoned later, when the work encountered unsound rock, which seemed better adapted to the full-face heading. In unsound rock, where support was required up to the face, the full-face heading, combined with a mechanical mucker, permitted the most satisfactory progress.

Details of the average methods used in these two types of driving are shown on Fig. 3 and in Tables 4 and 5. Vertical columns for supporting the drills were used in both methods.

Drills.—In the headings Ingersoll-Rand water Leyner drills No. 248 were used, and on the bench, Jap drills, B. C. R. No. 430. After numerous tests the six-point, or rose, bit was adopted. This bit has a flat taper for a short distance back from the face, which prevents the points from breaking. After each round the drill steel was sharpened with a special machine. The drills were carried back from the heading, taken apart, cleaned and greased, and made ready for the next round. As it was found difficult to make the drillers keep their machines oiled, a 1-gal. oil cup was placed on the air-line and regulated in such a manner that a predetermined quantity of oil would be fed to the drills with the air. An expert drill man spent his entire time going from shaft to shaft, inspecting and repairing the drills so that they might be kept at maximum efficiency.

Scaling was done after each shot and at regular intervals throughout the length of the untimbered tunnel. Except for that done immediately after blasting, little was necessary.

Trimming.—Once a week the trimming was determined and marked. In general, the tunnel was kept trimmed at all times well toward the heading and down to 1 ft. above the invert grade.

Muck.—In the top-heading method, muck was shoveled into wheel-barrows, wheeled along a runway supported on pipes extending across the tunnel, and dumped into muck cars—Sanford end dumpers—holding about 1 cu. yd. of solid rock. Trains of six or seven cars were hauled to the shaft; cars were taken up singly to the tipple and dumped into Western 4-yd. dump cars, which were pushed to the dump by electric locomotives. Each shaft was equipped with two cages so that when a full car was going up an empty one was going down.

The tunnel locomotives were of the storage battery type, the greater number being General Electric, 4-ton capacity, 30-in. gauge, with a drawbar pull of 1 000 lb., a speed of 5 to 6 miles per hour, and a voltage of 85 to 125. The batteries were readily detachable, extra ones being kept in the tunnel, where they were charged.

* Where mucking machine is in operation only two muckers and one mucker machine operator are employed.

For the full-face heading a Myers-Whaley mucking machine was used to load the cars. This lifted the muck on to a traveling belt which emptied into the muck car. As each car was loaded it was placed on a near-by siding until the whole train was loaded.

Support.—It was a difficult matter to decide, in advance of excavation, the type of timbering that would best suit the conditions. In general, the ground did not develop heavy pressure, as evidenced by the rather wide (7½-ft.) spacing of arch ribs; yet when allowed to stand for a considerable period, the rock frequently disintegrated and "reeded". The use of temporary timber at such a place would have necessitated considerable additional excavation preparatory to placing concrete. This work is slow and expensive; and interferes greatly with lining operations. It was the rule to place permanent timber wherever the roof was in soft red shale, or in thinly bedded sandstones, or where "popping rock" occurred. Where support was needed merely to protect men from the small thin slabs that fell, temporary timber was placed. About 570 cu. yd. of rock, or an average of 0.1 cu. yd. per lin. ft., was removed with the temporary timber. This was not evenly distributed; where the temporary support was replaced with a permanent one the amount was greatly in excess of this average.

The usual type of support was a three-piece arch rib of 10 by 10-in. timbers, spaced 7½ ft., center to center, with 3 or 4-in. lagging. It was supported on each side on a short 3-in. plate resting on three 1¼-in. steel pins, 24 in. long, set 18 in. in the rock. From four to seven 2 by 10-in. planks (known as "lacing") were spiked to the under side of the arch ribs to provide lateral support. Extra lacing was placed near the heading to protect the timber.

The same type of construction was used for both temporary and permanent timber (Fig. 4), the permanent timber being placed above the normal concrete lining while the temporary timber was lower. The space between the permanent timber and the roof of the tunnel was packed with rock. Ordinarily, temporary timber was left without packing, but in case of high breakage cordwood was used.

Lumber for crown pieces, lagging, and lacing was cut to dimensions in the Allaben Yard. A special device made it possible to measure the length of legs accurately in the tunnel and then cut them on top, thus saving labor and transportation. The timber used was miscellaneous hard and soft woods. All varieties showed a marked tendency to decay; and much of it that had been in place for two or three years was punky and lifeless. Due to this, some bents fell and others had to have supplementary supports for the lagging. At other places the lagging failed. In all, thirty-one bents were replaced or supplemented. While this is a very minute percentage of the total number of bents, it certainly shows that it is not safe to rely on timber support for too long a time.

Progress of Timbering.—Approximately 3 083 000 ft. B. M. of lumber was placed in the permanent support and 363 000 ft. B. M. in the temporary support. About 6 700 lin. ft., or 7% of the length of the tunnel, was driven with the temporary support. Approximately 1 000 lin. ft. of this was later replaced

with permanent timber; this, with the 38 950 lin. ft. driven as a permanently supported type, gave a total length of 45 650 lin. ft. of timbered tunnel, or 47.7% of the total length.

The force on the timbering included 1 carpenter and 2 laborers cutting on top of the shaft; and 1 foreman, 3 carpenters, and 4 laborers erecting in the tunnel. This gang could make an average progress of 20 lin. ft. completely erected and dry-packed in 8 hours.

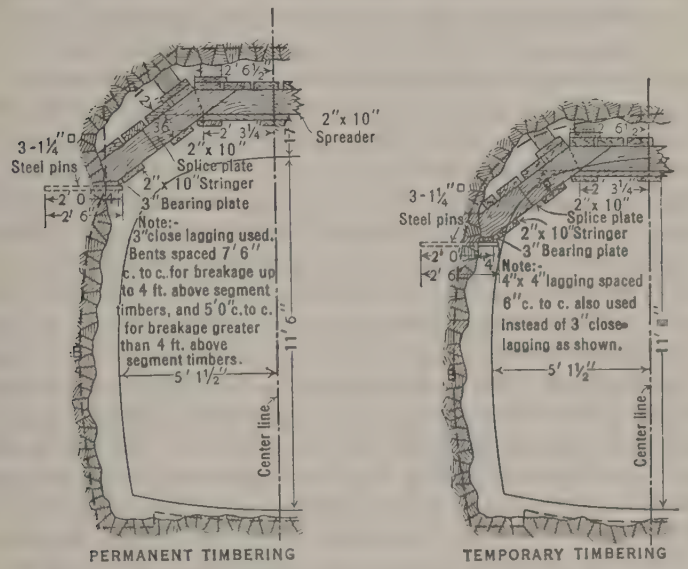

FIG. 4.—STANDARD TIMBER ROOF SUPPORT, SHANDAKEN TUNNEL.

Explosives.—Various well-known brands of explosives were tried. Finally, Dupont gelatine low-freezing dynamite was adopted, as this appeared to give the smallest amount of objectionable fumes. A special wrapper, developed by the powder manufacturer for use on this job, was very effective in reducing objectionable fumes. A saving was effected by using 60% dynamite for cut holes and 40% for all others. A slight saving was also effected by having the size of the sticks slightly reduced, as the loader measured his charge by the number of sticks and not by weight. In general, cut holes had to be fired more than once and occasionally three times on account of the depth.

Dupont electric blasting caps (No. 8) fired from a switch on the electric circuit, were used for exploders. First delay exploders were used for line holes. Some second delay exploders were tried, but for various reasons were finally discarded. A small amount of shooting was done with a fuse, using No. 6 fuse caps for exploders. This burned at the rate of 1 ft. per min. Two men lit the fuse, one on each side of the face. Two reasons for not using fuse more generally were the lack of experienced men and the improvement of delay exploders.

Tamping material consisted of crusher screenings or natural sand put up in paper bags 12 in. long and $1\frac{1}{4}$ in. in diameter. Brass or copper pipe was used to blow out holes that had once been loaded.

Storage for 400 to 10 000 lb. of explosives was provided at each shaft in specially constructed magazines, built to conform to the rules of the State Industrial Code. There was also a small magazine near the shaft head for storage between loading periods.

Power.—Electric power was purchased from outside sources. This involved the construction of 48 miles of line. Wooden poles, 35 to 50 ft. long, spaced 150 ft. apart, having two wooden cross-arms with three bare 7-strand, No. 1 copper wires, were used to carry the current to the nearest shaft. A similar construction but with No. 4 wire was used along the tunnel line. Every fifth pole was grounded with 7-strand, galvanized, messenger wire. The current was 60-cycle, 3-phase, 33 000 volts. At each working point it was stepped down to 440, 220, and 110 volts.

The power consumption during 1922, when both driving and lining was in progress, was about 11 700 000 kw-hr., including line loss. During January, February, and March of that year, when driving only was in progress in all twelve headings, the power consumption was 2 758 000 kw-hr., or 2 554 kw-hr. per heading per day. During this period 95 000 cu. yd. of rock were excavated at about 30 kw-hr. per cu. yd., not including line loss. The mucking machine required about 1 kw-hr. to load a car, taking about 3 min.

A 71-hour power test made during this period showed an average power consumption of 1 328 kw. per hour, with a maximum of 1 840 and a minimum of 960 kw. Drilling and shooting were in progress in eleven headings about 5% of the time, in six headings about 50% of the time, and in one heading about 90% of the time. This test showed that from 22.2 to 36.8 kw-hr. was required for each cubic yard of rock taken from the tunnel, with an average of 27.3 kw-hr.

Ventilation.—The plenum process was used. A Connersville blower with a capacity of 2.77 cu. ft. of free air per rev., was driven by an electric motor at speeds sufficient to supply from 900 to 1 200 cu. ft. of compressed air at from 7 to 10 lb. pressure. The air was conveyed down the shaft by an 8-in. pipe and through the tunnel in a 6-in. steel well-casing about $\frac{1}{4}$ in. thick, weighing 11.65 lb. per ft. and supported on rods driven into the sides of the tunnel about 5 ft. above the invert.

The pipe was made with Dresser joints. This joint is flexible, requires no threading, and permits the use of comparatively thin pipe; it is quickly and easily repaired or replaced. During the shooting period, and for a short time afterward, the 4-in. air-line used for drilling, was opened at the heading. This helped to clear the heading rapidly and drive the smoke cloud toward the shaft. Generally speaking, the ventilation was satisfactory except that smoke clouds occasionally interfered with alignment work in the longer headings.

Compressed Air.—Two compressors, each rated at 750 cu. ft. of free air per min., and electric-driven, furnished air for the drills. A 4-in. steel well-

casing, weighing 6.06 lb. per ft., and suspended on rods driven in the side of the tunnel, carried the air to the heading. This pipe was also made with Dresser joints. Air was furnished to the drills at about 90 lb., varying with the length of the tunnel. A manifold at the end of the line served the drills. There was always sufficient compressed air.

Pumpage.—Water was either drained by gravity or was pumped by air or electricity to a sump at the foot of the shaft, whence it was pumped to the surface. A typical installation for this was a Gould triplex, 5 by 8-in. pump, rated at 120 gal. per min., driven by an electric motor delivering water to the sump; and a Cameron pump with a 5-in. water cylinder, 10-in. air cylinder by 13-in. stroke, rated at 125 gal. per min., raising it to the surface. At the top of the shaft the water was measured over a V-notch weir equipped with an automatic recording gauge. The inflow of water was never great enough to influence progress, the maximum in any heading being 170 gal., and the minimum, 7 gal., per min. The total pay pumpage was 162 545 000 000 ft.-gal.

Illumination.—A 220-volt current was used for lighting the shaft and tunnel, the spoil area, and parts of the camp. The current was carried into the tunnel by three No. 0000-gauge cables supported on pins driven in the side of the tunnel about 8 ft. above the track. Attached to these cables from 40 to 50 ft. apart were 50-watt lamps. Within a few hundred feet of the heading the voltage was reduced to 110 by a small portable transformer; a portable cable, No. 12 gauge, carried current for lights in the heading.

Progress.—In general, some work was in progress throughout the 24 hours. Two methods were used. In one, the drilling and mucking shifts overlapped four hours and two advances were made in a heading each day; in the other, known as the swing shift, two advances were made in the north heading and one in the south on one day, and one advance was made in the north heading and two in the south on the next day. A law preventing men from working more than 8 hours per day was in force until May 25, 1923.

In all, 613 668 cu. yd. of rock were excavated in the tunnel. The quantities of excavation, in cubic yards per linear foot, for the two principal types of tunnel, were, as given in Table 6.

TABLE 6.

Quantities.	Unsupported.	Supported.
Theoretical	5.71	6.61
Actual	6.09	6.91

The unsettled condition affecting the country generally, as a result of the World War, had its effect on the progress of the work and the cost to the contractor. On November 11, 1920, the Degnon Contracting Company made an assignment to the Shandaken Tunnel Corporation for which the active agent was the Ulen Contracting Corporation. At the time the contract was assigned the work was approximately a year behind schedule. The job, however, had been well equipped by the Degnon Contracting Company.

With new capital and efficient management the new organization succeeded in overcoming the time handicap and completed the underground work four months ahead of schedule. This is shown effectively on Fig. 5, which indicates the rates of progress for the principal items. The excavation by years is given in Table 7.

The average monthly progress of excavation per heading, including the time when, for various reasons, work was not in progress, was 280 ft. In headings, where work was more nearly continuous, the average progress with two drilling and two mucking shifts was about 417 ft. per month, with a maximum of 612 ft. The average "pull" per round in the various headings varied from 7.5 to 10 ft.

Bonus.—During 1921 the contractor worked out a bonus system which was successful in reducing costs and increasing progress. A bonus was given the superintendent and walking bosses at each shaft, provided the costs per cubic yard of excavation were decreased below a fixed figure. Likewise for each shaft, the drilling foreman whose gang made the highest average "pull" per shot for the week received a bonus, while a similar bonus was distributed to the gang in proportion to their pay.

TABLE 7.—Progress in Excavating Shandaken Tunnel.

Year.	Progress, in linear feet.	Remarks.
1919.....	1 095	Shaft sinking completed and tunnel excavation started October 27 at one point.
1920.....	12 041	Contract assigned November 11.
1921.....	47 863	Steady acceleration of progress.
1922.....	33 485	All but one heading "holed through" during year.
1923.....	1 134	Finished excavation February 13.

The effect of this bonus on progress was very marked. Before installing the system the average "pull" was 7.5 ft. Three weeks after the bonus had gone into effect the average "pull" had increased to 8.18 ft. and within five months it had reached 9.34 lin. ft.

Earth Tunnel.—At the south end the roof of the tunnel for 534 lin. ft. was in earth. At the junction with the rock the earth was a compact mass of clay, sand, and boulders, with little or no water. No difficulty was experienced in driving this part of the tunnel.

The support for the earth part of the tunnel driven from Shaft 7 was a 5-bar arch, 5 ft. on centers, supported on wall-plates. The methods of excavation were similar to those used in rock including, to some extent, the use of light charges of explosives. The advance was made with a top heading kept from 10 to 70 ft. ahead of the bench. About 240 ft. was successfully driven in this manner. However, as the heading advanced pockets of blue clay were encountered and, later, the material changed to a saturated mixture of clay, sand, and gravel of the consistency of wet concrete. Driving became difficult and the full heading was abandoned; wall-plate drifts, or a center drift, or a combination of both, were substituted. The spacing of bents was

SHANDAKEN TUNNEL
PROGRESS BY HEADINGS

FIG 5

reduced to 3 ft. and then to 2 and 1½ ft. Breasting was necessary for the full drift section. After a fair trial this method was abandoned on account of small progress.

Following the cessation of driving from Shaft 7 an attempt was made to drive the tunnel from the portal. A small shaft was sunk and a drift started, but this soon failed due to insufficient breasting. A new shaft, 16 by 16 ft., was then sunk and a 9 by 8-ft. center drift, with its base at the wall-plate, was started. The cap of this drift was in line with the crown of the completed three-piece rib section driven from the portal. This drift was advanced continuously with a consistent progress of about 25 ft. per week until it joined with the tunnel driven from Shaft 7.

Operations were carried on systematically, as the ground was very treacherous. The face was always breasted. In some places the ground was so bad that only 6 or 8 in. could be opened at a time; however, no ground was lost and only a small portion of the timber settled, the maximum being 4½ in. All open spaces outside the lagging were carefully packed with salt hay or excelsior. Where clay was encountered in the roof the poling boards were spaced from ¼ in. to 2 in. apart, so that the clay might swell without breaking the boards or caps.

After this drift had connected with the completed tunnel it was widened out to the full section down to the wall-plate, working south, and, later, the full excavation was completed, working in the same direction. The photographs and diagram, Figs. 6, 7, and 8, give some of the details of this work.

The force working from the portal was on a three-shift basis. It included a superintendent and, on each shift, 2 to 3 miners, 2 to 3 helpers, 1 hoist engineer, and 1 pump man. Four shifts were required for one complete 5-ft. advance of the top drift. Of the top drift 220 ft. was completed in 65 days, while 52 ft. of re-drifting (in making the connection through the last advances made from the north) took 21 days. Enlarging the top drift to full size took 68 days. Removing 299 ft. of bench and completing the tunnel to full size took 114 days. The advance of all work, including drifting, widening, and taking out bench, was approximately 1 ft. per day.

In all, 3 669 cu. yd. of earth were removed from the tunnel, an average section containing 8.57 cu. yd. per lin. ft.

Concrete.—The tunnel was lined with concrete throughout, placed from Shafts 1, 3, 4, 5, and 7. It was mixed on the surface, poured through a pipe into cars at the foot of the shaft, and hauled to the forms. The invert and side-walls were placed by hand, while the arch was placed with a "concrete gun". The general methods and sequence of operations are shown on Fig. 9.

The work progressed away from the shaft. Operations 1 and 2, and 3 and 4, (Fig. 9) were later combined by suspending the forms for the footing course and concreting the half invert and footing in one operation. On part of the work, 150 ft. of side-wall and arch forms were used. Templates for the half invert were set about 15 ft. apart. After the concrete had been screeded and rolled these templates were removed, and the empty space was filled with

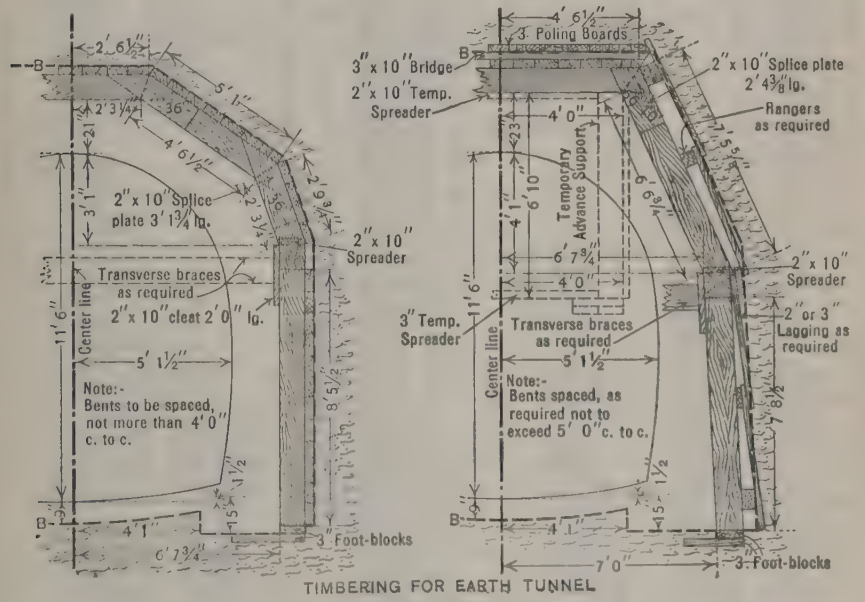
FIG. 6.—EARTH TUNNEL, 9 BY 8-FOOT CENTER DRIFT, THREE-BAR TYPE.

FIG. 7.—EARTH TUNNEL, COMPLETED TIMBER LINING, FIVE-BAR TYPE.

concrete. Pipes were set in the invert about 50 ft. apart to provide a vent for the relief of any pressures that might accumulate.

The fine aggregate consisted entirely of particles of crushed rock, as there was no acceptable natural sand in the vicinity. Part of this material came from the crusher, but most of it was made with sand rolls. The material proved satisfactory except that it caused difficulty in securing a smooth invert. The average fineness modulus was about 3.2. The amount passing the 100 sieve varied from 5 to 11 per cent. The coarse aggregate came from sandstone taken from the tunnel and from quarries opened up near the shafts. Shale was not used.

The concrete mix was 1 : 2⅓ : 4⅔ by volume, 1 bag of cement being assumed as 0.905 cu. ft. Measurement was made in pyramid-shaped hoppers, all materials being measured loose without correction for moisture. During cold weather the sand and stone were thawed out by placing steam pipes in the bins, approximately 100 sq. ft. of radiation being supplied to each bin. The water was heated with live steam. The cement factor was 1.48 bbl. per cu. yd. of concrete. Empty cement bags were shaken by machine, with a recovery of 1 bag of cement to every 170 bags shaken. In general, sufficient water was added to make a plastic mix. The average compressive strength determined from twenty-eight representative cylinders was 1 484 lb. per sq. in. at the age of 28 days.



TIMBERING FOR EARTH TUNNEL

FIG. 8.

The concrete gun (Fig. 9) proved an efficient tool for placing concrete in the arch. A short section of arch was placed by hand; later, holes were drilled through the crown, and the depth was tested. By comparison it was found that 76% of the depth was filled by the hand method while 89% was

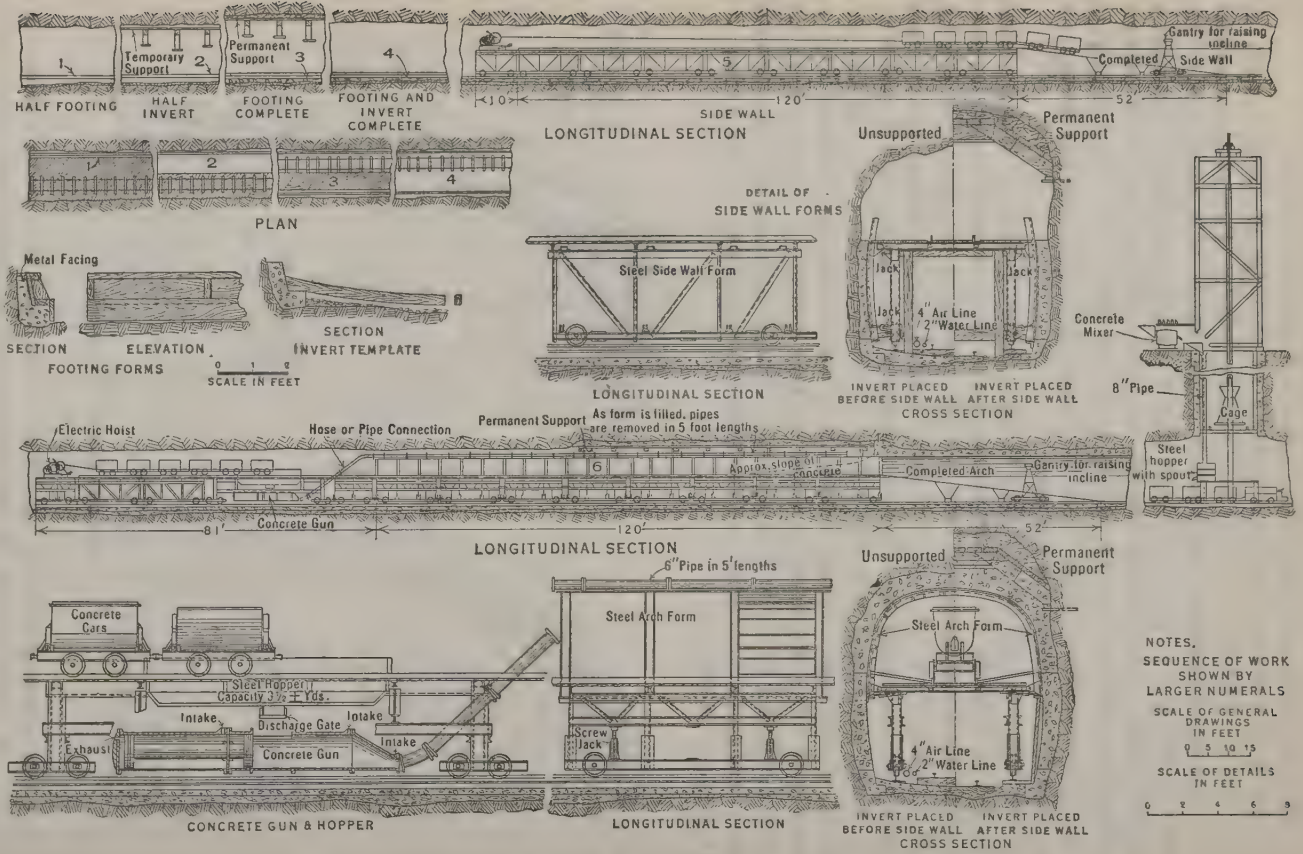


FIG. 9.—SECTIONS SHOWING CONCRETING OPERATIONS, SHANDAKEN TUNNEL.

filled with the gun. The latter product was of good quality, with few honeycomb spots and a dense, smooth surface. It flowed on an average slope of 1 on 13. When working at a distance from the shaft the gun required about 1 200 to 1 500 cu. ft. of air to operate it. It was possible to shoot a 6-car load, or 5½ cu. yd. of concrete, in 10 min.

The force placing concrete included:

7 men transporting materials on the surface;
1 foreman and 7 men operating mixer;
4 motormen and 1 signalman in tunnel transporting concrete;
1 foreman and 10 men placing concrete invert or footings*;
1 foreman and 11 men placing concrete side-wall*;
1 foreman and 9 men placing concrete arch*; and
1 foreman and 4 to 6 laborers on forms.

Using two side-wall forms and two arch forms in the tunnel between Shafts 5 and 6, 120 ft. of lining was completed in 24 hours with three shifts. The average progress from Shaft 4 to Shaft 5 was 58.7 lin. ft. per day; and from Shaft 5 to Shaft 6, 59.4 lin. ft. This is a fair average for the entire job. In general, the rate of progress was limited by transportation.

In the lining, 212 677 cu. yd. of concrete were placed. The quantity per linear foot varied from 2.109 to 3.378 cu. yd. The quantity of pay concrete was only 183 564 cu. yd., because the contractor preferred driving a slightly enlarged tunnel to trimming. He was paid a nominal sum for the excess concrete plus the cost of the extra cement.

Grouting.—Liquid grout under low pressure was placed between the lining and the rock throughout the supported tunnel, and in all but 21 942 lin. ft. of the unsupported tunnel. The purpose of the grout was to bind the lining solidly to the rock, all voids being filled. The lining thus forms an air-tight cover around the permanent timber to arrest decay.

During the placing of the permanent timber, 2-in. pipes were set, extending through the lagging approximately to the roof of the tunnel. These pipes were near the center line, approximately 50 ft. apart. Before placing the concrete, 1½-in. pipes, extending down to the forms, were telescoped inside these pipes, and securely wedged. In addition, grout pipes were placed aproximately 50 ft. apart on either side of the tunnel extended through the lagging near the lower limits of the dry packing. The lower end of each pipe was fitted with a coupling that was kept about ½ in. from the forms, by means of a screw-plug, or what was more successful, by means of a bit of oily waste, which aided in locating the hole after the removal of the forms.

In the untimbered part of the tunnel pipes were placed along the axis at intervals of about 40 ft. and also at points of especially high breakage. These pipes were held in place by being screwed to a special flange attached to the key-plate. In special types of timber with tight lagging behind the plumb-posts, grout pipes were placed through the lagging.

Where water was encountered the leaks were caulked, or, if they extended over a considerable area, they were covered with tin. In either case the

* Only one of these three operations was carried on at a time.

water was collected and led into the tunnel through a pipe usually placed on top of the side-wall. No attempt was made to shut off this leakage as the water was of good quality; but, in general, most of the leakage was stopped by grouting.

Grout was placed either with Canniff machines or with the concrete gun. After a sufficient trial it was found that the gun was not sufficiently mobile, and it was abandoned. In the early operations materials were mixed inside the tunnel with the Canniff machine. As grout could not be made in the gun it was mixed on the surface and transported to the gun. Although the gun was abandoned, the practice of mixing on the surface was continued, either 5 or 10-bag batches being made in the Ransome mixer in the proportions of 1 bag of cement, 1 bag of sand (90 lb. net), and from 5.5 to 7 gal. of water, with an average liquid volume of 1.92 cu. ft. per bag.

The mixture was poured down an 8-in. pipe into concrete cars at the foot of the shaft. The cars were hauled in trains of from three to six cars to the Canniff machines. The grout was then pumped to a small tank from which it flowed by gravity into the Canniff tanks. During the pumping, the material in the cars was agitated continuously. The tanks forced the grout out at a pressure of from 30 to 75 lb. in rock; and at less than 20 lb. in earth. The grout traveled a maximum distance of 700 ft. in the timbered tunnel with an average of 200 ft. In the untimbered tunnel, the maximum travel was 470 ft., and the average, 50 ft. Connection was usually made to a low hole, and when a good flow of grout appeared in an adjacent high hole, that hole was plugged.

A natural fine sand, obtained from local pits, was used for grouting. When screened to remove the coarse particles this sand had a fineness modulus of about 1.6. Only about 18% was coarser than the No. 30 sieve, and 60% coarser than the No. 50. It was all finer than the No. 8 sieve.

Contraction cracks were found in the tunnel from 15 to 30 ft. apart, extending across the arch and down the side-wall. They were very noticeable when grouting was in progress, as were the horizontal and vertical construction joints. It is thought that all these cracks were effectually closed by grouting.

The force for a single shift was 12 men on the surface and from 9 to 12 men inside the tunnel. At some shafts the outside force mixed grout for two headings. Grouting was done on a 1, 2, and 3-shift basis. A single shift placed on an average thirty-five 10-bag batches per 12 hours in unsupported tunnel. In supported tunnel a single shift averaged about ninety 10-bag batches in 10 hours. In the Allaben Division, where most of the grout was placed, the maximum linear feet of tunnel grouted per week was 4 000 in unsupported tunnel and 2 400 in supported tunnel; the average was 1 500 and 1 000. An average of 13.4 cu. ft. of liquid grout per linear foot of tunnel was placed in the supported, and 2.8 cu. ft. in the unsupported, type. The maximum quantity of liquid grout placed from one connection was 9 650 cu. ft. A total of 23 449 cu. yd. of grout was placed, at 3.5 bbl. of cement per cu. yd.

Cleaning

After grouting was completed the tunnel was cleaned. The first operation, working against the flow, was to remove the lumber, forms, clay, and muck that had accumulated on the invert. This allowed a fairly free passage for the flow of water. The side-walls were then scraped, using long-handled chisels with a 3-in. blade. Lips formed by the junction of forms were removed and the very few places that were honeycombed were cut out and patched.

The arch was then scraped from a high platform placed on a flat car, with the same tool used for the side-walls. Plugs were removed from grout pipes and the ends of the pipes were packed with mortar. Finally, the rails and ties were removed, and the invert was given a final scraping and brooming, working with the flow. The pipes left at 50-ft. intervals in the invert were cleaned out, or, when these could not be found, holes were drilled through the invert.

In the shafts all cage timbers, pipes, etc., were removed, all bolt holes plugged with mortar, and the sides scraped, after which the head-frame was removed. A concrete cover with a metal grating was then placed over the shaft.

Two shifts of about 10 men each, working 10 hours per day, made an average progress of 125 lin. ft. of finished cleaning in the tunnel (including all operations) per day.

Intake and Outlet

The intake is an open channel through rock to a down-take shaft equipped with gates for controlling the flow, and a vertical Venturi meter. The outlet is through short lengths of standard and pressure aqueduct to a water-seal, thence through an open channel to Esopus Creek. Both are specialized structures, beyond the scope of this paper.

Force and Housing

A maximum force of nearly 1 500 men was employed on this work; for a year and seven months the number exceeded 1 000. Except for a small percentage of local labor, this force had to be imported and housed near the various shafts. Generally, men were housed in 28-man barracks, two men to a room, heated with stoves and lighted by electricity. The men were furnished with iron spring cots, mattresses, and blankets, which were regularly cleaned. They were fed in large mess halls, the food being ample and good.

Dry houses were built at each shaft, but, in general, were not used, probably owing to the dryness of the tunnels. Wash-houses were equipped with hot and cold water, shower baths, and facilities for washing clothes. Toilet facilities consisted of Kaustine units in buildings on the surface and portable Kaustine closets in the tunnel. An ample supply of wholesome water was piped from near-by springs or pumps. This supply was analyzed from time to time and was carefully guarded. Smaller houses were supplied for married men, and bungalows for superintendents and executives.

Due to the general unrest, the isolated location of the camps, and other conditions, the labor turn-over was high, frequently as much as 700% in a year.

Supplies and Transportation

Materials were brought by railroad to the Allaben Yard, or to a siding at Grand Gorge, and taken to the shafts by motor truck. The road from Shandaken to Lexington was of dirt—at some times fairly good, but, at others, nearly impassable. The contractor did considerable work on this road to keep it usable. In the winter, he kept the entire road along the tunnel line open, using snow plows attached to trucks or tractors. At times, it became necessary to shovel parts of the roads to keep them open. As an example of the amount of material handled, 609 carloads of cement and 387 carloads of other freight were hauled from the Allaben Yard alone in 1922.

Costs

The following are the contract costs to the city: The entire tunnel, including the Venturi meter and sluice-gates, cost $12 292 411, at the rate of about $128 per ft., or $679 000 per mile. The surface work at the intake, including the superstructure and sluice-gates, cost $382 444. The sub-surface work, including the Venturi meter, cost $99 868. The outlet cost $132 448.

The shafts, excluding the intake, cost $367.52 per lin. ft., as follows:

Surface work	9%	=	$33.08—
Sinking	79.97%	=	293.91—
Lining	10.87%	=	39.95—
Grouting	0.16%	=	0.59+
Total		=	$367.52

The entire length of tunnel alone cost $109.21 per lin. ft., made up as follows:

Driving	65.71%	=	$71.76+
Timbering	2.51%	=	2.74+
Dry packing	0.47%	=	0.51+
Concrete lining	28.15%	=	30.74+
Grouting	3.16%	=	3.45+
Total		=	$109.21

The normal unsupported type of tunnel cost per linear foot:

To drive	$66.91
With temporary timber	72.63
To drive and line with concrete	96.30
With temporary timber	102.02
To drive and line with concrete and grout	98.09
With temporary timber	103.81

The normal supported type of tunnel cost per linear foot:

To drive	$77.05
With permanent timber	82.55
With permanent timber and concrete lining	115.31
With permanent timber, concrete lining, and grout	122.22

Conclusions

From the experience gained on this work, it seems desirable that in tunnels of this size the shafts should be much farther apart. As will be noted from Fig. 5, consistent progress was maintained from Shaft 1 toward Shaft 3, even when the distance was greater than 2½ miles. This would indicate that shafts might be placed from 5 to 6 miles apart.

Progress in tunnel driving was limited by the removal of muck from the heading. A somewhat larger section permitting the use of an air-operated shovel might have been constructed more quickly and cheaply. To a considerable extent the progress of driving and concreting depended on the condition of the single track. Derailed trains caused by poor track retarded progress greatly. Well-kept double track might be economically sound for a long tunnel.

DISCUSSION

W. W. BRUSH,* M. AM. SOC. C. E.—The speaker cannot add any information as to the construction work for the Shandaken Tunnel., For the last twenty-two years the City of New York has carried on its water supply work under two separate organizations. The Board of Water Supply has designed and constructed the works for additional water supply, and the Department of Water Supply, Gas, and Electricity has taken over the completed works and maintained and operated them.

The tunnel was indirectly responsible in part for the Ashokan Reservoir being at a very low level on two separate occasions. This statement is not a charge against the tunnel because some of the men in the Department of Water Supply, Gas, and Electricity were directly responsible. The first low level was in 1923, when, to avoid unnecessary pumping, the Department tried to utilize the maximum quantity of water that might be drawn from the Catskill System, with enough left over to take care of the needs of the City until the supply came from the Schoharie through the Shandaken Tunnel. The run-off was low during that year, so that in the fall of 1923 the Ashokan Reservoir was down to about 16 000 000 000 gal. capacity as against 130 000 000 000 gal. when full.

By June, 1924, with the aid of the tunnel, the reservoir was nearly full. In 1926 a low level was again recorded due, once more, to the engineering desire to avoid the expense of unnecessary pumping. This low level resulted in a very sensational newspaper story about leakage from the Ashokan Reservoir. It was stated that the water was going out through the bottom as fast as it came in, and that was the reason why the reservoir was low in the fall of 1926. At present (June, 1927) it is nearly full, containing more water than at any time since the spring of 1917, and no evidence of a leak has ever been found.

From an engineering viewpoint the story of the leak was absurd, but from the viewpoint of the consumer in the city, who pays very little attention to his or her water supply, except when that supply is interrupted for any cause, it made an unfortunate impression which remains in the minds of many to-day.

It is not an engineering question, but a very human one, whether it was wise to try to save hundreds of thousands of dollars by avoiding unnecessary pumping through lowering the level of the water in the Ashokan Reservoir, thus unintentionally creating in the minds of many a feeling that the system had not been functioning successfully, or whether it would have been wise to spend the money to pump the water and let it go over the dam in the spring of 1927. Apparently, the people of New York would be perfectly satisfied to pay the bill and not save hundreds of thousands of dollars, simply so that they could see plenty of water in the reservoir.

The probabilities are that, with the tunnel and the reservoir completed, and with the consumption in the city increased, it will not be safe to take the reservoir level down to as low a point as it was taken in the fall of 1926.

* Chf. Engr., Bureau of Water Supply, Dept. of Water Supply, Gas and Electricity, New York, N. Y.

The speaker believes that the people in the city would rather pay the cost of pumping some water that would go over the dam rather than save their money, have a low reservoir level, and be asked to conserve water. Although the Department only requested care in use of water, the public thought the Department was trying to develop a water famine for the purpose of accelerating action on an additional water supply system for the city. With water flowing over the Croton Dam yearly, it is impossible to convey to the average citizen of New York the idea that the city needs to go farther afield to get additional water supply. That seems to be a thought that cannot be brought home.

It would manifestly appeal to engineers that if several sources of water supply are available, the obvious thing to do is to operate the system so as to minimize the cost; and, yet, when an engineer tries to serve the several million people in New York City, and to utilize the water-works in the most efficient and economical manner, it seems almost impossible to obtain the public support. When the people are told that they will need additional sources of supply made available ten years hence, many think that this is an exaggerated statement made for the purpose of enabling the engineer to plan and carry out additional works at the cost of the tax-payer.

The people of New York are very proud of their water supply system, and justly so, but they seem to be very suspicious of the need of developing additional sources of supply. The Shandaken Tunnel, prior to the completion of the Schoharie Reservoir in the fall of 1926, furnished an average of 170 000 000 gal. per day for about two and one-half years. It was a great aid in enabling the Department to meet the requirements of the city without installing additional pumping equipment to raise the Croton water to a higher level.

With the completion of the tunnel, the normal available yield of the Catskill System will be about 600 000 000 gal. per day. Just what the maximum dependable yield will be is necessarily uncertain. The stream-flow record in the Catskills is only for twenty odd years, and that is not long enough to determine what water supply is available; but water supply operations will be on the basis of 600 000 000 per day.

The Catskill Aqueduct will deliver about 630 000 000 gal. per day. It did deliver about 660 000 000 gal. per day in 1925, but with the higher water level now maintained and with the resultant growths on the sides, which have interfered with the flow, the daily capacity is now about 630 000 000 gal. The present delivery capacity is being raised by the use of chlorine to destroy the growths on the inside surface of the aqueduct.

The maximum delivery of the tunnel has been practically 650 000 000 gal. per day (the figure set by the designer), and the normal dependable supply that will be obtained by the combined use of the tunnel and the reservoir will be about 300 000 000 gal. per day.

The Schoharie Reservoir has once been virtually full and then emptied since the fall of 1926, and it is now (June, 1927) about half full. It will probably be emptied rather rapidly later in the year. Usually, the Schoharie Reservoir will be at a low level for the purpose of holding the flood flows, because the

reservoir is small compared with the capacity of the water-shed. The reservoir has a capacity of only 20 000 000 000 gal.

The work that the Board of Water Supply has done on the Catskill System has been designed and carried out in such a manner that it has met every promise made for it, and all the parts have functioned, from the operating viewpoint, in an exceptionally efficient manner.

CHARLES GOODMAN,* M. AM. SOC. C. E.—The trimming of a rock tunnel is made necessary where a minimum dimensioned cross-section is called for; usually it is needed for a timber or concrete structure. This trimming is best done immediately back of the heading before the track, the pump, the air-pipe lines, and the electric light and power lines are laid; otherwise, these must be moved out of the way of the blasting for trimming, thereby incurring additional expense and a loss of time.

Careful setting of line and grade plugs for directing tunnel alignment results in saving rock-trimming work. One plug set to correct line every 50 ft. is better than incorrect plugs every 25 ft.

In driving a heading, the rim line to guide in locating drill holes has to be painted. The question arises as to whether this line shall be painted at the minimum section or 3 to 6 in. wider than the minimum section, in order to avoid subsequent trimming work. If the rock is hard, usually it will blast out in an approximate straight line between the drill holes; and in softer rock, back of the drill holes. The deviation of a straight line between drill holes 30 in. apart from a curved rim of 5 ft. radius is more than 2 in.

In pointing a drill hole, a driller must have some leeway and allowance for the space occupied by the drill; thus, where a tight roof exists, the drill hole must be started possibly 3 in. inside the rim line, and the hole must be pointed carefully to insure that the bottom will not be wide. Experience shows that considerable trimming has to be done when drill holes are placed on the neat line. If they are placed 6 in. wider than the neat line, the additional cost per square foot of tunnel surface for the extra ½ cu. ft. of rock removed, would be about 5 cents; and for the ½ cu. ft. of excess concrete, about 20 cents; or a total of about 25 cents per sq. ft. The speaker believes that trimming costs would be much more than this and, therefore, recommends that drill holes be located 6 in. back of the neat lines.

The next step is to arrange carefully, so that drilling can be properly done to line. Place the column, whether horizontal or vertical, at a certain regular distance from the rock face to be drilled. The column arms supporting the drills should also be placed at studied locations. Thus, the drill can be easily brought to its correct position from which the hole will be bored in its intended location. Drill holes located straight in or straight down aid in speeding up work and simplify the alignment. Downward bench holes should end at the proper heights, measurements being taken from the column and column arms.

The spacing, depth of holes, and quantity of dynamite charge needed in each hole to break the rock can be best ascertained by results which, in turn, will indicate how the holes should be drilled to eliminate trimming. It is

believed that rock miners will not object to using methods which would result in eliminating subsequent trimming, especially if simple mechanical devices for pointing drill holes are used.

Figs. 10 and 11 (with Table 8) show methods used in driving a tunnel 250 ft. long around a curve at 54th Street and Eighth Avenue, New York, N. Y. The heading rim was painted 6 in. back of a minimum cross-section, and subsequent trimming was not necessary. The average breakage of the heading was 8 in. back of this paint line, or 14 in. back of the minimum line. The down-hole bench drilling was only partly successful, as the bottom broke out in a horseshoe shape, notwithstanding that a number of bottom horizontal holes were used. However, subsequent trimming of the bottom half was not necessary. The average bottom breakage was 17 in. back of the neat line.

Straight holes, nearly perpendicular to the face, were used for driving the heading of the last half of this tunnel. The cut holes extended at least 1 ft.

beyond the expected advance of the round. This cut was placed at the top of the bench. A long 4-in. horizontal bar was attached to two 4-in. vertical columns; 6-ft. arms attached to the columns and to the horizontal bar enabled

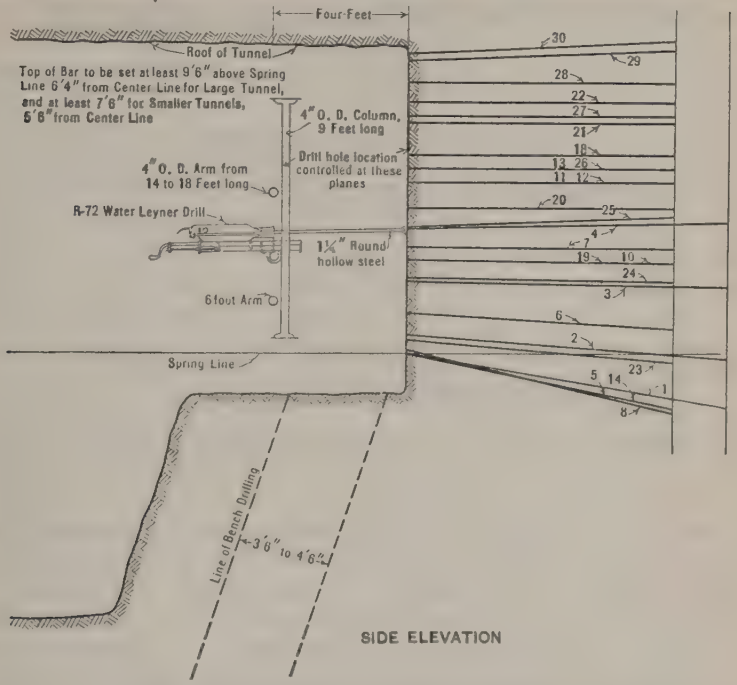

FIG. 11.—TUNNEL AT 54TH STREET AND EIGHTH AVENUE, NEW YORK, N. Y. ELEVATIONS SHOWING DRILL HOLES.

the drills to be placed close to the rim, so that a straight, almost perpendicular, hole could be drilled. This supporting system made a rigid frame on which six or eight drills could be mounted.

Paper No. 1662

THE EYE-BAR CABLE SUSPENSION BRIDGE AT FLORIANOPOLIS, BRAZIL*

By D. B. Steinman† and William G. Grove,‡ Members, Am. Soc. C. E.

With Discussion by Messrs. J. A. L. Waddell, Spencer Miller, Lloyd G. Frost, C. G. Emil Larsson, Clyde T. Morris, V. R. Covell, T. J. Wilkerson, and A. D. Nutter, Frederick C. Carstarphen, A. de H. Hoadley, F. N. Menefee, T. Kuo, Leon S. Moisseiff, R. McC. Beanfield, Charles F. Stowell, Hardy Cross, and D. B. Steinman and William G. Grove.

Synopsis

The recently completed Florianopolis Suspension Bridge, with a main span of 1 113 ft. 9 in., is the longest span bridge in South America and the longest eye-bar suspension span in the world. The bridge was constructed for the Brazilian State of Santa Catharina, and spans the waters of a strait of the Atlantic Ocean. It is to carry a highway, electric railway, and water-supply main to Florianopolis, the island capital of that State.

The structure is of interest to bridge engineers as the first executed example of a new form of suspension stiffening construction, whereby greatly increased rigidity and economy of material are secured simultaneously. The distinctive feature of this construction is the utilization of the cable to replace a part of the top chord of the stiffening truss, and the consequent change from the conventional parallel chord truss to a stiffening truss of more effective outline.

Another departure from customary practice is the use of rocker towers, yielding advantages in economy of material. The Florianopolis Bridge is the first suspension bridge in the Americas to be built with rocker towers.

* Presented at the Meeting of the Structural Division, New York, N. Y., January 21, 1926.
† Cons. Engr. (Robinson & Steinman), New York, N. Y.
‡ Asst. Engr., Am. Bridge Co., New York, N. Y.

The bridge is of further interest to engineers as the first application of an important new structural material. Instead of wire for the cables, eye-bars are used; and these are made of the newly developed, high-tension, heat-treated carbon steel, having a yield point exceeding 75 000 lb. per sq. in., and intended to be used with a working stress of 50 000 lb. per sq. in. The bid price for this type reduced the total cost to the lowest estimated cost with wire cables.

Originally the suspension type, of conventional design, was adopted for this bridge in economic competition with cantilever designs. Subsequent modifications yielded further economies in favor of the suspension type.

In the foundation work for the main piers, novel construction methods were devised to overcome unusual difficulties. The concrete anchorages are of special design, U-form in plan, for maximum efficiency. One anchorage is founded on rock, the other on piles.

Finally, an entirely new method was developed for the erection of the eye-bar cable and suspension span stiffening trusses, using an overhead trolley, thus eliminating wooden falsework and working platforms. The entire field operations extending over a period of one year were conducted without loss of human life.

This paper describes the methods by which the bridge was designed, fabricated, transported, and successfully erected.

History of the Project

The City of Florianopolis is the capital of Santa Catharina (Fig. 1), one of the twenty-one States of Brazil. The site is on the Island of Santa Catharina, separated from the mainland by a narrow strait. The city lies on the strait side of the island about midway from the ends. There, because of peninsulas extending out from both the mainland and island, the strait is only about 1 500 ft. wide. The water is too shallow for large vessels so that most ocean-going ships anchor at the northern end of the island, passengers and cargo being transferred to the city by tugs and lighters.

A few years ago the late Governor of Santa Catharina, Señor Hercilio Luz, conceived the idea of developing the Port of Florianopolis and the whole east central portion of the State of Santa Catharina in order to provide a means of outlet for the products of the interior part of the State direct to ocean-going steamships for shipment to the United States and Europe. The entire project had a fourfold objective:

First.—To improve the harbor at the northern end of the island.

Second.—To build an electric car line about 12 miles long from the new port to the City of Florianopolis.

Third.—To construct a bridge connecting the island with the mainland.

Fourth.—To build about 100 miles of railroad direct into the interior connecting with the railroad extending from São Paulo, Brazil, to Montevideo, Uruguay.

Prior to 1920, various competitive designs had been submitted by American and European contractors and engineers for the proposed bridge at Florianopolis. Finally, the general contract was awarded to Byington and Sundstrom, Contracting Engineers, of São Paulo, Brazil, on the basis of a cantilever design. The bids on this design exceeded the appropriation and the general contractors wrote to H. D. Robinson, M. Am. Soc. C. E., about the advisability of preparing an alternative suspension design. Mr. Robinson in collaboration with one of the writers, Mr. Steinman, prepared a preliminary wire cable design.

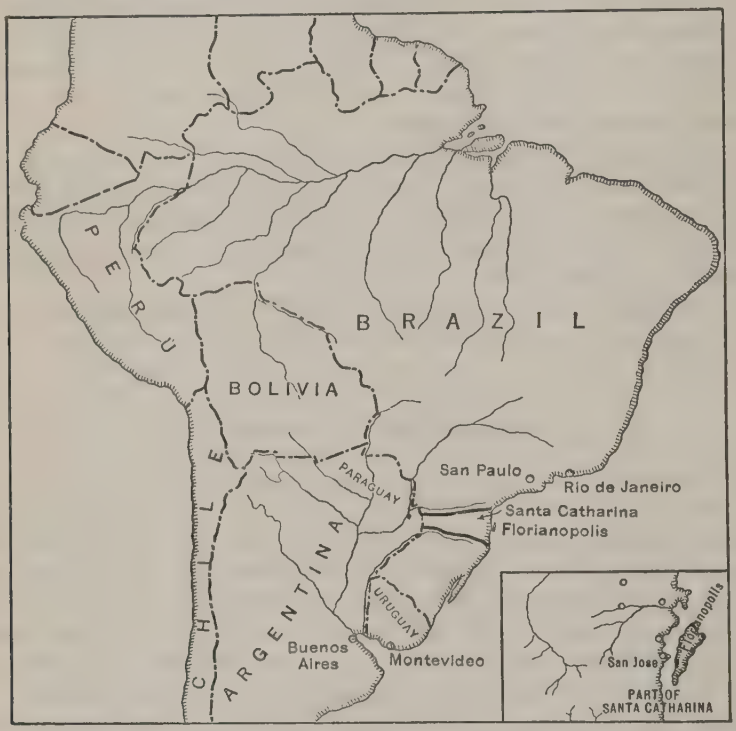

FIG. 1.—MAP OF SOUTH AMERICA, SHOWING POSITION OF FLORIANOPOLIS.

In 1920, A. Y. Sundstrom, M. Am. Soc. C. E., came to New York, N. Y., and, acting for his firm, engaged Messrs. Robinson and Steinman to develop the suspension design for the Florianopolis Bridge. At the same time, he arranged with the American Bridge Company, through the United States Steel Products Company, to revise the cantilever design, and to submit price quotations on both types. On the basis of the respective unit prices quoted by the Steel Company, the suspension design lost out by a small margin. Consequently, when they secured from the State of Santa Catharina the general contract for the construction of the bridge, Byington and Sundstrom adopted the revised cantilever design, Fig. 2 (*c*). Before any work was commenced, the entire project was suspended by the failure of the

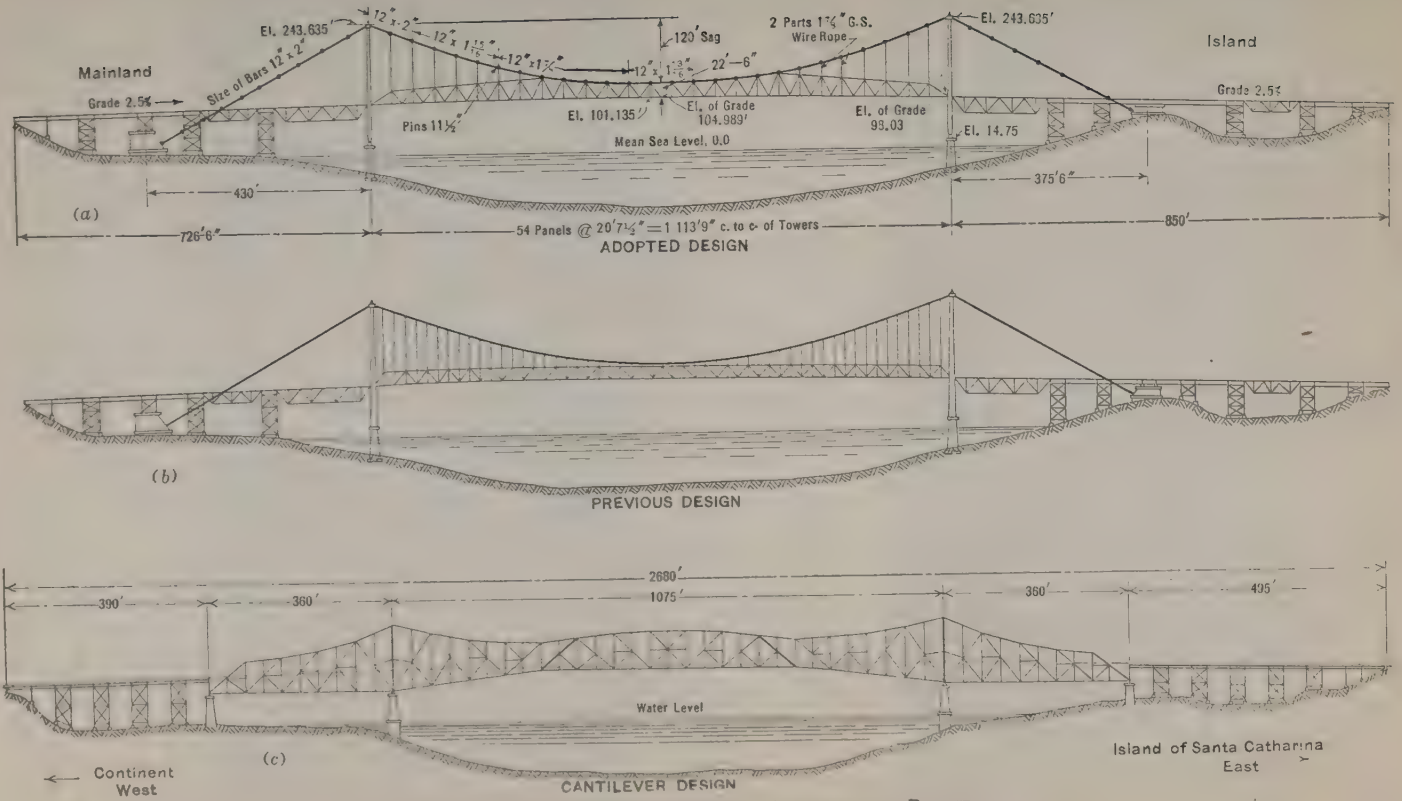

FIG. 2.—COMPARISON OF DESIGNS OF FLORIANOPOLIS BRIDGE.

New York banking firm that held the bridge funds, as proceeds of a bond issue.

In 1922 interest was revived by the availability of new funds, and the question of suspension *versus* cantilever design was re-opened by Byington and Sundstrom. The designs were slightly revised and new price quotations were secured from steel firms.

During this two-year interval the American Bridge Company had independently investigated several suspension designs and its engineers had reached the conclusion that this type was more economical than the cantilever. This was borne out when the bids were received as the suspension design was found to be more economical by a substantial margin, and, therefore, was adopted by the general contractors.

In fulfillment of the previous obligation, Byington and Sundstrom entered into a new contract with the United States Steel Products Company to furnish the fabricated steel, after satisfactory adjustments had been made in the unit prices. The general contractors, with the professional assistance of Messrs. Gross, Robinson, and Steinman, planned to handle the entire erection.

Messrs. Robinson and Steinman then proceeded with the completion of the plans. Alternative designs were made for the cables, using parallel wire and twisted wire-rope strands, respectively. Fig. 2 (*b*) shows the latter design. Bids were secured on both materials from steel wire firms in the United States and abroad, the lowest quotation being received from an English firm.

As Mr. Sundstrom was about to cable acceptance, one of the writers, Mr. Grove, of the American Bridge Company, recommended the use of its new high-tension, heat-treated eye-bars as a substitute for wire cables. The United States Steel Products Company supported this recommendation by a proposal to furnish and erect the eye-bars for a sum that proved to be less than the general contractor's estimate for the wire cables in place. Upon satisfactory price adjustment, the new material was accepted, and a sub-contract for its fabrication and erection was added to the previous contract for furnishing the other fabricated steel. To save duplication of erection equipment and organization, the remainder of the steel erection (towers, stiffening trusses, approach viaducts, etc.) was then added to the contract, relieving the general contractors of the entire superstructure.

The adoption of the eye-bars as a substitute for the wire cables suggested to Messrs. Robinson and Steinman a change of design from the parallel-chord type of stiffening truss to some form that would utilize the availability of the eye-bar cables for greater efficiency of the stiffening construction. After several studies made with this object in view, a curved chord design utilizing the cable to replace the middle half of the top chord, Fig. 2 (*a*), was selected. Upon the evidence of a material economy in its favor, the change in design was approved by Mr. Sundstrom and was accepted by the Steel Company. A photograph of the completed structure is shown in **Fig. 3.**

FIG. 3.—VIEW OF FLORIANOPOLIS BRIDGE, COMPLETED, 1926.

FIG. 4.—VIEW OF CROSSING DURING CONSTRUCTION OF MAIN PIERS, FLORIANOPOLIS BRIDGE.

Location of the Bridge

The location of the crossing is shown in Figs. 4 and 5. The east, or island, end of the bridge (background, Fig. 4) was determined by a rocky promontory pointing toward the continent, and by a high rocky knoll a short distance back affording an ideal anchorage site. The west, or continent, end of the bridge (foreground, Fig. 4) was at a point where soundings indicated shallow depth for main pier foundations, and where the steep abutting topography provided a practical approach for the electric railway connection. To facilitate this connection, a curve was introduced in the west end of the approach viaduct.

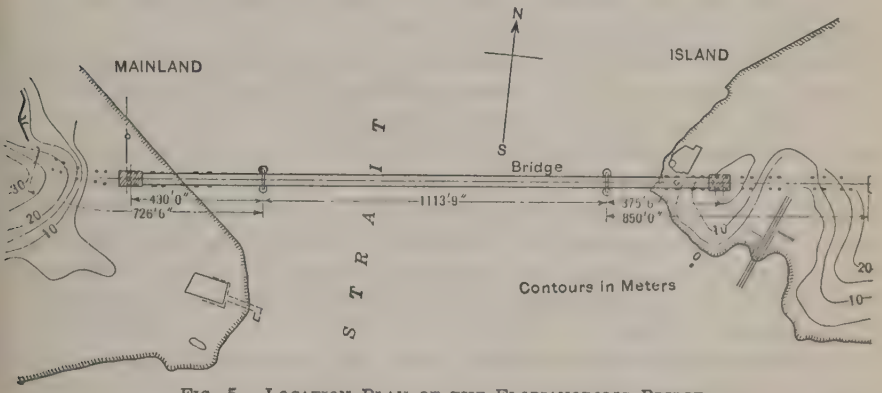

Fig. 5.—Location Plan of the Florianopolis Bridge.

The Government contract specified a main span of 340 m. for either a cantilever or a suspension bridge. This span length was based on the preliminary soundings and layouts, and was retained (with slight changes for English units and uniform panel lengths) in the final design.

Considerations of the profile, anchorage sites, highway crossings, and duplication of spans determined the span lengths and arrangement of the towers and spans of the two viaduct approaches.

New Type of Stiffening Truss

The form of stiffening construction adopted for the Florianopolis Bridge is an innovation. A comparison of the adopted design with other conventional layouts which it superseded (Fig. 2), shows the distinctive characteristics of the new type.

Utilization of the Cable as Truss Chord.—In the central portion of the conventional form of suspension construction, the cable, sustaining the dominant tensile stress, closely follows the upper chord of the stiffening truss, which has compression for its governing stress. Such juxtaposition of two principal members carrying opposing stresses represents a waste of material or, rather, a neglected opportunity for economizing. By combining the two opposing structural elements, one member is made to take the place of two;

the result is a subtraction of stresses instead of an addition of sections. This effects a partial neutralization of the maximum tension in the middle portion of the cable, and the omission of a corresponding portion of the upper chord of the truss.

This utilization of the cable as the upper chord of the stiffening truss should preferably be limited to the central half of the span. To extend this construction to the ends of the span would not be economical, because the saving of the top chord in the outer quarters would be offset by the increase in the length of the web members in a region where the stiffening truss has its maximum shears. Moreover, beyond the quarter-points there would be an addition instead of a subtraction of stresses, since the condition of loading that produces maximum tension in those top chords is one that produces nearly maximum tension in the cable.

Variation of Truss Profile.—Another neglected opportunity for increasing economy and efficiency in the conventional form of suspension construction is in the use of parallel-chord stiffening trusses. For maximum economy the truss should have a profile conforming to the variation of maximum bending moments along the span, a principle that is recognized in designing other structures, as simple trusses, cantilevers, continuous trusses, and arches. Since the economic depth at any section is a function of the governing bending moment, a truss should have its greatest depth at the points of greatest bending moment, and should be made shallow where the bending moments are comparatively small.

In a suspension-bridge stiffening truss, the greatest bending moments occur near the quarter-points of the span; consequently, the economic profile of a stiffening truss is one having maximum depth near the quarter-points and mimimum depth at mid-span and at the ends. This conclusion is strengthened by the fact that the shears in a stiffening truss are a minimum near the quarter-points and attain maximum values at the middle and ends of the span. Thus, a truss profile with maximum depth near the quarter-points also gives economy in web members since it provides the shallowest depth in the regions where the web stresses are greatest. Such a profile yields the additional advantage of greater uniformity of required chord sections throughout the span as a wide range of variation usually involves a waste of material in those chord members requiring minimum sections.

Another consideration governing truss depth is that of efficiency in reducing deflections. The most serious deflection of a stiffening truss, as measured by the resulting deflection gradients, is produced under the condition of live load covering approximately one-half the span. Half-span loading produces a downward deflection of the loaded segment and a smaller upward deflection of the unloaded segment, with a maximum deflection gradient at the loaded end. The magnitude of this deformation depends on the truss depth at and near the quarter-points. Calculations show that to limit the deflection gradient to 1%, a truss depth of about one-forty-fifth of the span is required. A parallel chord stiffening truss of such depth (as illustrated by the Williamsburgh Bridge, New York, N. Y.) would render the structure unsightly. To secure the requisite stiffness without resorting to a stiffening

truss of clumsy proportions, it is necessary to depart from the parallel-chord type and to adopt an outline providing the extreme depth only where it is needed, namely, in the vicinity of the quarter-points of the span.

Two Features Combined.—From the foregoing considerations the two logical means for improving conventional suspension design for increased economy and efficiency are:

1.—Utilization of the cable to replace a portion of the top chord of the stiffening truss (preferably limited to the middle half of the span).

2.—Variation of the truss profile to give maximum depth near the quarter-points of the span.

Fortunately, compliance with the first of these requirements automatically helps with the second. The result is the form of suspension construction adopted for the Florianopolis Bridge.

Originality of the Type

Although the Florianopolis Bridge is the first executed example of this new type of suspension construction, the idea appears to have been anticipated by others. The following prior proposals of designs embody the same or similar ideas.

In 1895, Landsberg described a similar design proposed for a bridge over the Rhine, at Bonn, Germany.* L. S. Moisseiff, M. Am. Soc. C. E., reported† a design embodying similar features which he had prepared in 1907 for a proposed 1 200-ft. span, with 600-ft. side spans. In 1911, R. Sontag published‡ a paper suggesting similar ideas for suspension designs.

The Revision of Design

The bridge had already been designed along conventional lines, when the decision to substitute eye-bar cables for wire cables prompted consideration of the revised truss design and facilitated its application. In the parallel-chord design, the stiffening truss was 25 ft. deep throughout; the revised lay-out, utilizing part of the chain as the top chord, provides a truss with depth varying from 22.5 to 42.5 ft.

In the first plans for the new design, the upper chord in the outer quarters of the span was made curved so as to produce an effect of symmetry about the quarter-points. Straight chords were substituted, however, at the decision of the purchaser, in order to minimize fabrication costs. Minimum cost was the outstanding requirement governing the entire design. The question of relative appearance of straight and curved chords in the outer quarters of the span is a matter of individual preference.

Although the revision from the conventional design was prompted and facilitated by the adoption of eye-bar cables for the principal suspension elements, the new form of stiffening construction can also be used in con-

* Described in *Zentralblatt der Bauverwaltung* and proposed by the Maschinenfabrik Esslingen; see discussion in *Die Bautechnik*, March 13, 1925; also *Der Bauingenieur*, No. 35, December, 1925.

junction with wire cables.* Approved details of the necessary connections between truss members and wire cables have been developed by Messrs. Robinson and Steinman for designs of this type.†

Economy of the Adopted Design

Comparative cost estimates of the two designs shown in Fig. 1 (*a*) and (*b*) demonstrate a material saving in favor of the adopted design. In addition to the major elements of economy inherent in the salient features of the new form of construction, a number of incidental savings arise from the change in design:

1.—Saving the material represented by the middle half of the top chord of each stiffening truss.

2.—A general saving in the remaining chord material resulting from the use of an economic truss profile conforming to the variation of bending moments along the span; and, in particular, a material reduction in the maximum chord sections near the quarter-points.

3.—A saving in details and in minimum sections resulting from the greater uniformity of required chord sections throughout the span.

4.—A saving in web material on account of the reduced truss depth in the regions of maximum shear.

5.—The omission, in the middle half of the span, of the sub-verticals previously required to shorten the compression chord members, now replaced by tension members.

6.—The omission of the intermediate top laterals previously required to stay these shortened compression chord members in a horizontal plane.

7.—As a result of these savings, a reduction of about one-third in the total weight of the stiffening truss, and a consequent further saving in all parts affected by the dead load of the truss.

8.—A saving in cable sections resulting from the reduced dead load of the truss and from the consequent reduced dead load of the cable.

9.—The omission of the suspenders in the middle half of the span and a reduction in length of the remaining suspenders.

10.—A combined saving in the towers resulting in part from the reduction (6.5 ft. in the case of the Florianopolis Bridge) in the total height in consequence of the reduced distance between the cable and lower chord at the center.

11.—A material saving in the anchorages resulting from the reduced dead load of the truss and cable and the reduced elevation of the back-stays.

In the case of the Florianopolis Bridge, much of this economy was not capitalized but was turned back into the structure in the form of a general reduction of unit stresses to provide a greater margin of safety for future load increases. Thus, the design stress for the stiffening truss was lowered from 20 000 to 18 500 lb. per sq. in. (actually 14 500 lb. as calculated by the

* Used in the suspension design by Messrs. Robinson and Steinman for the Sydney Harbor Bridge.

† *Engineering and Contracting*, June 24, 1925, pp. 1377–1386; *Die Bautechnik*, 1925, No. 33, pp. 451–452, and 1925, No. 44, p. 630.

exact method); and the unit stress in the cable was reduced from 50 000 to 46 500 lb. per sq. in.

Designs have been proposed, in the past, in which the cable would be utilized as the top chord of an overhead bracing system. G. Lindenthal, M. Am. Soc. C. E., advocated for the Manhattan Bridge and for the Quebec Bridge, eye-bar cable designs with bracing systems having the maximum depth near the quarter-points of the span. In those designs, however, the stiffening system would have to leave the roadway level to follow the line of the cable in the outer quarters of the span.

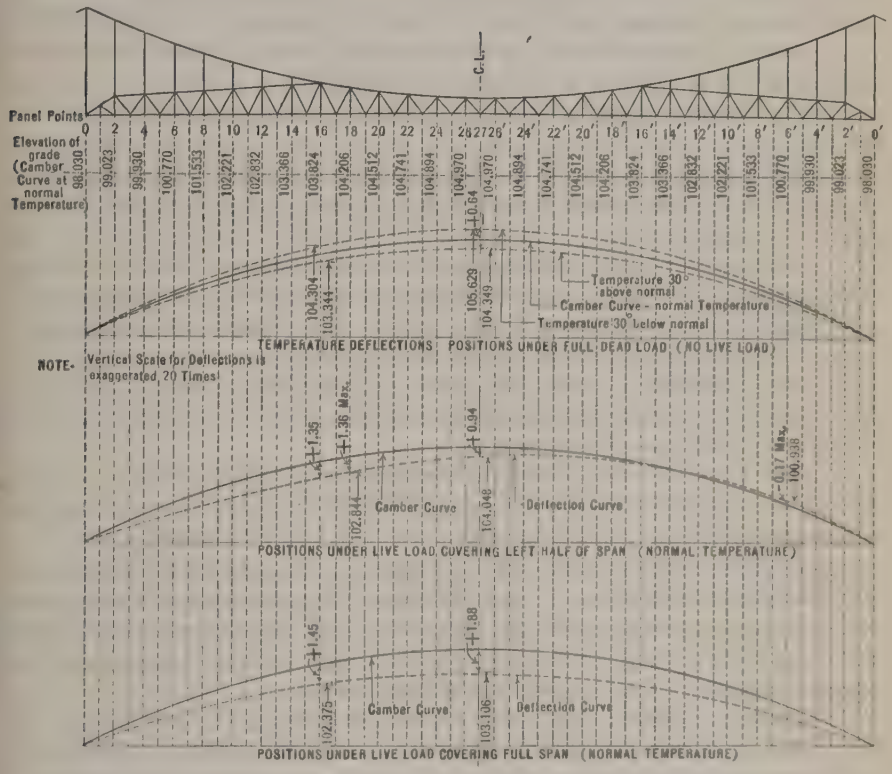

FIG. 6.—CALCULATED DEFLECTION GRAPHS FOR THE FLORIANOPOLIS BRIDGE.

The design of the Florianopolis Bridge secures the desired advantages while retaining a stiffening truss at the roadway level from tower to tower. The use of an overhead trussing system (departing from the roadway level) would necessitate separate wind chords for lateral stiffening.

GAIN IN RIGIDITY

Although the governing consideration in the change of design was that of economy, the change yielded greatly increased rigidity (300%) as an incidental advantage.

According to the deflection graphs calculated for the adopted design (Fig. 6), the maximum deflection under full-span loading is only 1.88 ft., or

$\frac{1}{352}$ of the span; and the maximum deflection under half-span loading is only 1.36 ft., or $\frac{1}{820}$ of the span, with uplift in the unloaded half practically eliminated. The actual deflections will be about 30% less than these calculated values, since the deflection calculations were based on the elastic, or "approximate", method and since no allowance was made for the stiffening effect of details. These deflections are approximately one-fourth of the corresponding values for the previous (conventional) design. As the Florianopolis Bridge is designed to carry a railway as its principal element of live load, this reduction of the governing deflections is of practical significance.

An increase in rigidity of about 25% may be attributed to the substitution of eye-bars for wire cables; the remaining 275% increase is the direct consequence of the new form of stiffening construction.

The following elements of the new design contribute to this increase in rigidity:

1.—The revised truss profile is more efficient in resisting deflections, since it provides a greater average depth, with maximum depth in the regions of greatest bending moment.

2.—The depth at the quarter-points has been made nearly twice as great as in the previous design, and the stiffness in the vicinity of the quarter-points is the principal factor in determining the rigidity of a suspension bridge under the critical condition of half-span loading.

3.—The functioning of the full section of the cable as the top chord of the stiffening truss in the middle half of the span greatly increases the moment of inertia in that part of the span.

4.—The fact that the live load introduces tension in the middle half of the top chord (by virtue of its forming part of the cable) further reduces mid-span deflections.

As a result of these various factors, the change of design yields greater stiffness with less material in the structure. In approximate figures, the design is four times as rigid with only two-thirds as much material in the stiffening truss. Thus, greater efficiency has been secured through a more scientific design of the suspension stiffening system.

In addition to the marked increase in vertical rigidity yielded by the new design, the lateral stiffness is improved by the large cable sections functioning as wind chords in the middle half of the span; and ideal longitudinal rigidity is secured by the direct connection of the truss to the cables. Longitudinal or braking forces are carried directly into the cable.

The net result of the change in design as applied to the Florianopolis Bridge is a reduction in cost (through actual saving in material), an increase in safety and longevity (through lowered unit stresses), and an increase in efficiency (as measured by resistance to deflections).

Rigidity in Suspension Bridge Design

There are differences of opinion among bridge engineers as to the desirability of rigidity in suspension designs. Those who advocate maximum stiffness as a desideratum are applying to suspension systems con-

siderations borrowed from other types of bridge construction. In those other types, rigidity, strength, safety, and longevity are intimately related.

In the suspension type, on the other hand, strength, safety, and longevity are not dependent on the degree of rigidity. A suspension bridge has greater safety and longevity than other types, even when its deflections are many times greater; and its strength is not measured by its rigidity.

Long-span suspension bridges of recent design or construction have been intentionally proportioned to permit maximum deflections of as much as 15 or 20 ft., without impairing the safety or permanence of the structure. A certain amount of flexibility is an advantage in a structure, providing, as it does, resilience to resist the effects of impact and shock. Nevertheless, for practical reasons, proper methods must be available for restricting or minimizing suspension-bridge deflections. One of these reasons is the requirements of railway traffic. For such loading, the permissible deflection gradients are limited; and the "traveling wave", involving the upward deflection of the unloaded part of the span, is cited as an objection. A design of the Florianopolis type permits the deflection gradients to be restricted adequately, and the "traveling wave" to be eliminated.

Another reason is a prejudice among laymen and others, against the suspension type on the score of its flexibility. Adverse impressions derived from flimsy, improperly designed, suspension spans are that the suspension type is necessarily light and shaky. To meet these conditions, it is most desirable to be able to limit and control the deflections of suspension designs.

Suspension Bridges Can Be Designed to Have Any Desired Degree of Rigidity

In the Sydney, Australia, Harbor Bridge competition, the suspension type was officially excluded on the score of alleged excessive flexibility; the engineer in charge declared that the deflection of the 1 600-ft. span under the heavy railroad traffic would amount to 11 ft. in a suspension design. As a challenge to this objection, a design submitted by Messrs. Robinson and Steinman embodied an extension of the principles of the Florianopolis type, the stiffening trusses being extended as a continuous structure through the towers to the anchorages. The calculated maximum deflection under the full live load of 12 000 lb. per lin. ft. was only 1.28 ft.; and the calculated maximum deflection under half-span loading was only 0.83 ft., or $\frac{1}{1\,930}$ of the span, with only an imperceptible uplift (a fraction of an inch) in the unloaded half of the span.

The Florianopolis type, by supplying great depth and stiffness at the quarter-points, minimizes the critical half-span deflections. The tendency toward upward deflection in the unloaded half-span is thus reduced and its value just about balances the downward tendency from the deflection of the span as a whole; consequently, there is no upward movement, or practically none, of the unloaded half of the span. In this manner, the "traveling wave" under an advancing train load may be completely eliminated with such design.

With the parallel-chord stiffening truss, flexibility is reducible by deepening the stiffening truss, usually at a sacrifice of both economy and appearance. With the Florianopolis type of construction, greatly increased rigidity may be secured without resorting to clumsy proportions and with a reduction, instead of an increase, in the weight of steel required.

Esthetic Considerations

Discussions of comparative æsthetic values in structural design are generally unsatisfying on account of the existing differences of individual taste. Any attempt to compare the Florianopolis design with the conventional suspension design must suffer from that limitation. At first comparison with the conventional type, the new design is under a certain disadvantage on account of the subconscious prejudice against novelty of form in favor of that which is familiar through custom.

Nevertheless, the new outline has certain æsthetic values to commend it:

1.—It produces an impression of sturdiness and strength in contrast with the apparent lightness and inadequacy of the usual suspension design.

2.—It relieves the effect of a long straight stiffening truss by introducing a curvilinear variation in depth of truss; this variation is particularly pleasing when the top chord in the outer quarters of the span is also made curved in symmetry.

3.—It contributes certain pleasing values through the more harmonious adjustment of chord outline to curve of cable.

4.—It produces a sense of a stronger functional relationship between truss and cable.

5.—The reduction of lines and members to a minimum enhances the effect of sturdy simplicity.

Finally, the new design has a certain æsthetic value on account of its obvious efficiency. Conflicting and redundant lines have been eliminated, and adjustment of form to function has been emphasized. The harmonious expression of efficiency and strength is, after all, the essence of structural æsthetics.

Heat-Treated Eye-Bars

In the Florianopolis Bridge a new material, in the form of high-tension, heat-treated, carbon-steel eye-bars, found its first application. This material, intended to be used with a working stress of 50 000 lb. per sq. in., was developed through experimental research by the American Bridge Company. It is furnished under guaranty of minimum elastic limit of 75 000 and minimum ultimate strength of 105 000 lb. per sq. in., and minimum elongation of 5% in 18 ft.

Heat treatment of steel has been known and used for some time, but it is only within the last decade that its application has been made to structural steel bridges. Carbon steel is the material used, but the amount of carbon is higher than in the ordinary structural grade with an ultimate strength of 55 000 to 65 000 lb. per sq. in.

After the steel is manufactured and rolled in the eye-bar sizes, the eye-bars are upset in the usual manner, except that the heads are made $\frac{1}{8}$ in. thicker than the body of the bar. The bars are then placed in the heat-treating or annealing furnaces and subjected to temperatures necessary to produce elastic limits and ultimate strengths of the desired amounts. After quenching, the bars are re-heated and then cooled slowly. Each bar is treated separately.

On account of the nature of the work of heat-treating, the Steel Company felt obliged to place restrictions around the inspection. There were more than 400 bars on the bridge to be heat-treated separately, each operation taking from 4 to 5 hours. All bars were 12 in. wide and varied from $1\frac{3}{8}$ to 2 in. in thickness. The 12 by $1\frac{3}{8}$-in. bars were about 20 ft. long, all others being 40 ft., or more. Thus, all bars except the 20-ft. bars exceeded in length the limits for the testing machine. Cutting and re-heading of test pieces selected from bars exceeding 40 ft. in length meant that these bars would have to be re-treated as the heating necessary for re-heading the bars would destroy the effect of the previous heat treatment. It was decided therefore to test two short and ten long bars. The two additional short bars were added to the thirty-two short bars needed and the entire group of thirty-four were headed and heat-treated. The inspector then selected two of the finished bars for Test Pieces Nos. 1 and 2.

Enough additional material was ordered from the mill for two bars, 12 by $1\frac{3}{8}$ in.; two bars, 12 by $1\frac{1}{4}$ in.; two bars, 12 by $1\frac{1}{8}$ in.; and four bars, 12 by 2 in. Before the remainder of the bars were made, the inspector selected from the mill material ten bars of the sizes mentioned. These ten pieces were cut to lengths to fit the testing machine, headed, and heat-treated for Test Bars Nos. 3 to 12, inclusive.

The policy of secrecy covering the material and processes of heat-treatment was unsatisfactory to the consulting engineers, but the Steel Company took the position that its contractual obligation was to furnish bars with stated properties, and that if the full-sized test bars satisfied these requirements, the processes giving these results were not open to the inspector but were to be considered as private. Under those circumstances, the consulting engineers declined to assume any responsibility for the strength and safety of the eye-bars furnished for the structure; and the matter was left with the understanding that the Steel Company assumed sole responsibility for that material.

In nine full-sized tests made during the period of experimental development, prior to the offering of the material for the Florianopolis Bridge, the physical properties ranged as shown in Table 1.

Of the twelve full-sized tests made during the fabrication of the eye-bars for Florianopolis, only one eye-bar, No. 12, failed to meet all the specified requirements, passing the elastic limit and ultimate strength requirements, but having an elongation of only 3.8 instead of 5 per cent. A new eye-bar, No. 13, was made up for "re-test" and passed the requirements with an elongation of 8.1 per cent. The complete physical properties for the thirteen test bars are given in Table 2.

It is possible to check the uniformity and reliability of this material by Brinell tests supplementing the strength tests. A comparison of the Brinell hardness numbers secured at different points of the finished eye-bar furnishes an index of the uniformity of treatment and physical qualities over the length of the bar.

TABLE 1.—PROPERTIES OF HEAT-TREATED STEEL.

	Maximum.	Minimum.	Average.
Elastic limit, in pounds per square inch	89 000	78 500	83 920

Percentage of contraction of area	39.2	16.5	24.6

USE OF ROCKER TOWERS

The Florianopolis Bridge is believed to be the first American suspension bridge built with rocker towers. The only large bridges previously built with this feature are the Elizabeth Bridge at Budapest, Hungary (1903), and the bridge over the Rhine at Cologne, Germany (1915).

Minimum requirements				75 000	105 000	5.0 in 18 ft.	

The evolution of suspension-bridge tower design has been marked by three successive types. First came the rigid form of tower, typified by the masonry towers of the Brooklyn Bridge. The principle of rigid-tower construction persisted for some time after steel replaced masonry, as illustrated in the towers of the Williamsburgh Bridge (New York City). When engineers realized that the rollers on the tower tops were usually inoperative and could not be relied on to provide the necessary movement of the cable saddles, the

flexible type of tower was introduced. In that type, the saddles are fixed on the tops of the towers, and the horizontal movement necessitated by unbalanced cable pull is provided by flexure of the slender, fixed-base towers. First used in the Manhattan Bridge (also in New York City), the flexible type of tower has been applied in the more recent structures, such as the Rondout (at Kingston, N. Y.), Bear Mountain (over the Hudson River), and Philadelphia-Camden Bridges. As a further step toward the reduction and simplification of tower stresses, the rocker type of tower has been developed.

The rocker type offers the most economical and scientific design for suspension bridge towers. It eliminates the bending stresses from unbalanced cable pull, thereby yielding a saving in tower material, and it obviates the difficulties of the necessary erection operation of pulling back the tops of the towers prior to stringing the cables.

In the case of the Florianopolis Bridge, the change was made from fixed bases after comparative estimates showed a net saving of about 20% in the weight of the towers in favor of the rocker type. There is a substantial reduction in the main sections by the elimination of the bending stresses. Another important advantage is the elimination of bending stress from the piers, permitting their size and reinforcement to be reduced.

Details of the Tower Design

As shown in Fig. 7, the towers are approximately 230 ft. high. The legs are battered, from a top width of 33 ft. 6 in. to a width of 55 ft. 6 in. at the base. The width at the top corresponds to the spacing, center to center, of trusses, the cables hanging in vertical planes. This form of tower design, introduced into suspension bridge construction by Mr. Robinson, has for its chief advantage the facility of running the truss and roadway construction through the tower portal without interference from the tower legs; an additional advantage is the increased transverse stability, of particular importance for narrow bridges.

The two legs of the Florianopolis tower design are braced together with rigid diagonal and transverse bracing members, the latter including a transverse distributing girder at the tower top, a transverse reaction girder (Fig. 8) supporting the stiffening truss and approach truss bearings, and a transverse portal girder (Fig. 9) immediately above the stiffening truss portal.

The reaction girder (Fig. 8) has a box section and supports the roller expansion bearings of the approach span and the pin-connected rocker supports of the main span stiffening truss. These rockers take care of the vertical reactions (both positive and negative) while permitting the necessary longitudinal expansion movements.

Each tower leg or column is made up of a double box section (Fig. 7), having a maximum longitudinal width of 8 ft. and a constant transverse width of 3 ft. 6½ in. The 8-ft. width tapers to 4 ft. 6 in. at the top, and to 5 ft. 0 in. at the base. Transverse stiffening diaphragms are provided at intervals, two in each column section.

The tower is designed for a maximum horizontal component of 3 860 000 lb. in each cable, resulting in a maximum vertical reaction of 3 790 000 lb. per column; this is supplemented by the vertical reactions of the stiffening

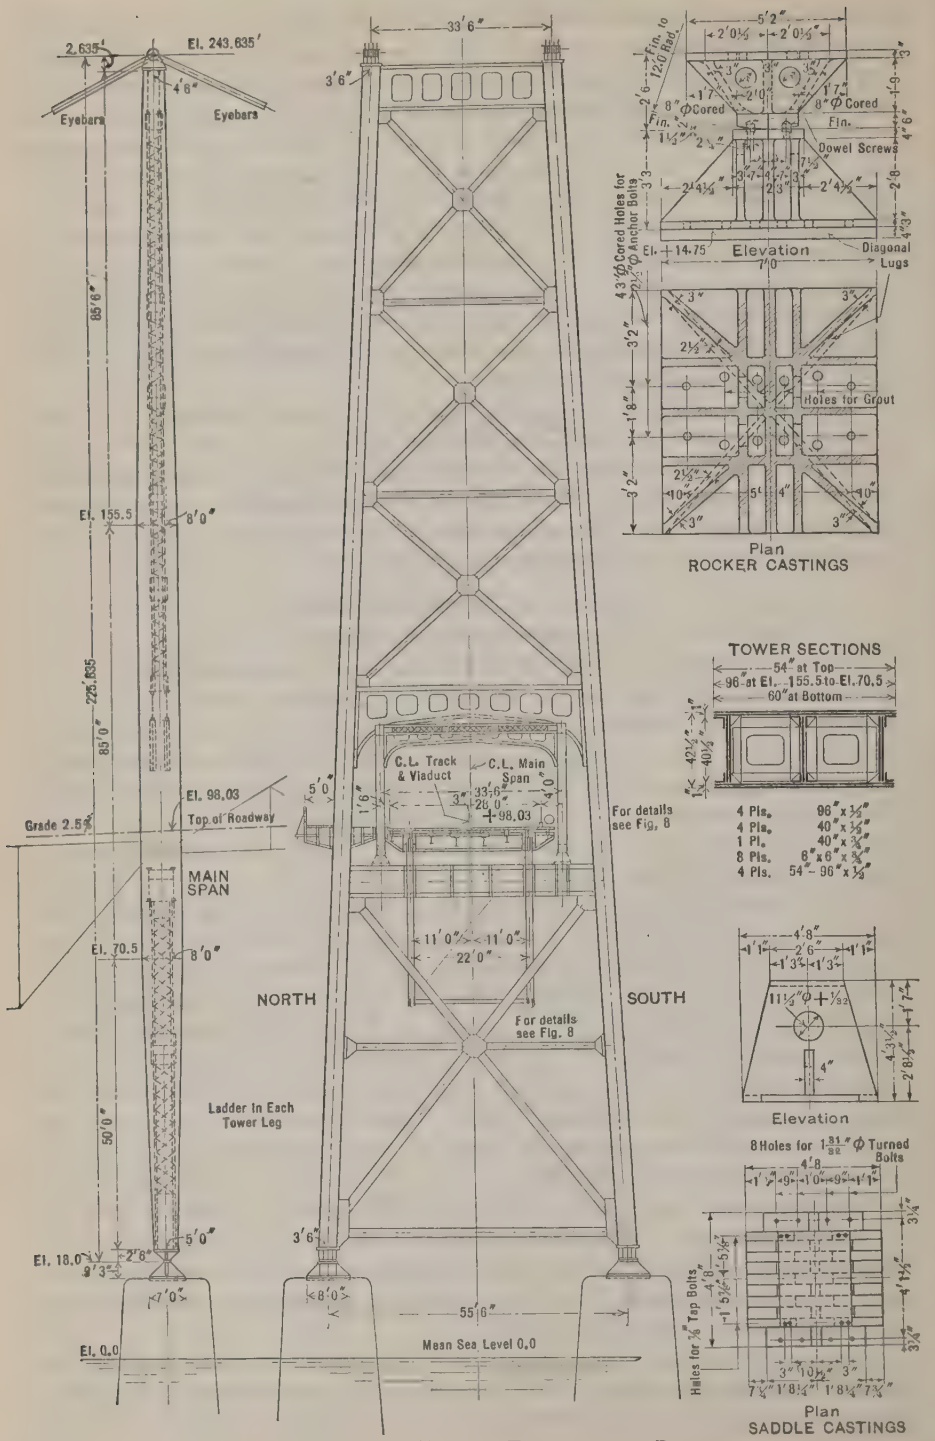

FIG. 7.—DETAILS OF TOWERS, FLORIANOPOLIS BRIDGE.

truss (240 000 lb.) and approach span (300 000 lb.), which reactions, however, affect only the lower sections of the tower. In addition, the tower top is subjected to a maximum lateral pull of 75 000 lb. per tower from wind forces transmitted through the cables; and, at the lower level, the tower receives the lateral reactions (190 000 lb.) from the trusses. All these forces are taken into account in proportioning the tower columns and the transverse bracing. Unbalanced cable pull at the top of the towers, which would otherwise materially affect the column sections, is eliminated by the rocker feature.

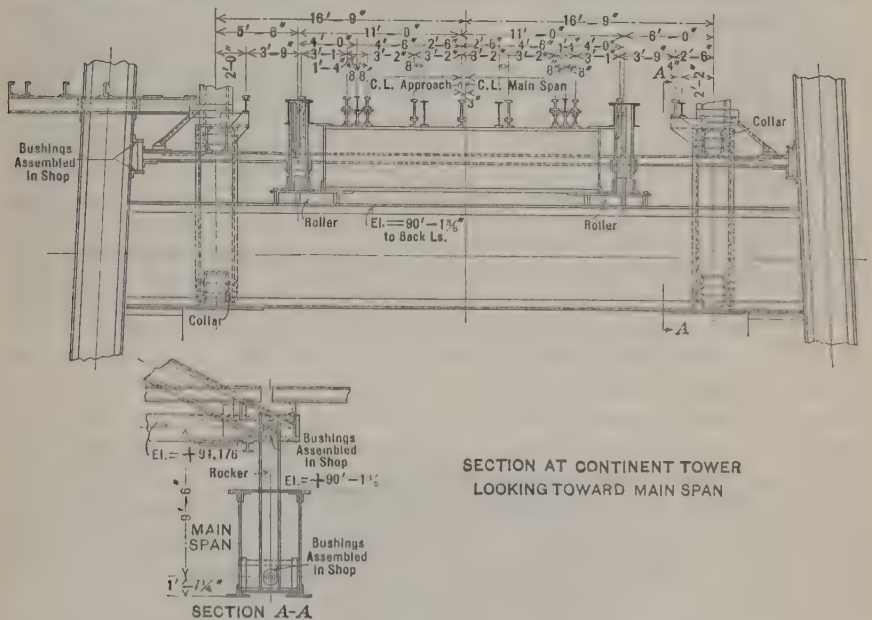

FIG. 8.—ASSEMBLY DIAGRAM OF TRANSVERSE REACTION GIRDER IN TOWERS OF FLORIANOPOLIS BRIDGE.

The tower column has a maximum cross-section of 370 sq. in., tapering to a minimum of 285.5 sq. in. at the top and 297.5 sq. in. at the base. This variation in cross-section (and in moment of inertia), similar to that provided in derrick booms, is calculated to take care of the varying flexural stress produced by the long column action.

The rocker base details are shown in Figs. 7 and 10. The pedestal or base casting, which rests on the concrete piers, is finished to a plane top surface, 27 by 45 in. The rocker casting, which is affixed to the column base, is finished on its lower or bearing surface to a radius of 12 ft. The line of contact is 45 in. long. For security against any possibility of creeping displacement, four screw dowels, 3 in. in diameter, are provided (Fig. 7). The rocking of the upper casting on the lower was tested in the shop with the dowels temporarily in place. In the bottom face of the pedestal casting are two full-length diagonal lugs which engage corresponding grooves in the masonry to prevent any possible sliding of the casting. The maximum vertical reaction on each rocker bearing is 2 420 tons. Details of the saddle casting are also shown in Figs. 7 and 10.

Design and Construction of the Anchorages

The design of the island anchorage is shown in Fig. 11. Both anchorages are U-form in plan, for maximum efficiency.

The east anchorage (Fig. 11) is on rock. The anchor cables and reaction girders are embedded in concrete in two stepped trenches excavated in the solid rock; the sides of these trenches were given a negative batter to increase the vertical resistance. On this construction is superimposed the buttressed concrete anchorage structure.

The west anchorage (Fig. 12) is on lower ground on the mainland. The excavation did not reveal rock as anticipated, and a pile foundation had to be used; about 25% of the piles (located under the forward portion of the anchorage) are battered in the direction of the resultant pressure.

Each anchor cable, consisting of heat-treated eye-bars, divides into two branches for connection to the anchor girders (Figs. 11 and 13). Each anchor girder, 16 ft. long, consists of five built-up girders reinforced with pin-plates and connected together by tie-plates. At the Y-point of each anchor chain, a built-up pin seat was provided to hold the pin in accurate position during the placing of the concrete around the anchor girder and the connecting eye-bars; these temporary pin seats were burned off after the girders and the lower eye-bars were securely concreted. (See Fig. 13.) Above these points, the anchor cables were boxed in during the completion of the concreting in order to prevent adhesion of the concrete before full dead load strain was in the cables. When the anchorage erection was completed, the boxing was removed; the tunnels were left around each anchor cable until the steel superstructure was erected and the full dead load stress was in the cables. Then the eye-bars were covered with a protective coating of minwax and the tunnels filled with concrete.

Construction of the Main Piers

The four main piers of the Florianopolis Bridge are cylindrical concrete shafts, 16 ft. in diameter, with coping 17 ft. in diameter. (See Fig. 16.) The base of each pier is 30 ft. square. The unusually small size of the pier shafts was made possible by the adoption of rocker towers, eliminating the pier bending stresses due to tower flexure. A separate pier cylinder is provided under each tower leg.

Construction was commenced in the spring of 1923. Huge, irregular boulders in the ocean bed were found to make the rock soundings quite misleading, the presence of these boulders and the slope of the bed-rock surface complicating the foundation work.

An open square coffer-dam of steel sheet-piles was driven for each of the four main pier foundations. The sheet-piles, ordered to the length found from previous soundings, went down to a maximum of 38 ft. below mean water level, while the rock lay at depths from 30 to 60 ft. below water.

A novel procedure was adopted in the case of the north mainland pier. After excavation within the 30-ft. square coffer-dam was carried down nearly to the bottom of the sheet-piles, a central test pit, 8 by 8 ft., was sunk within

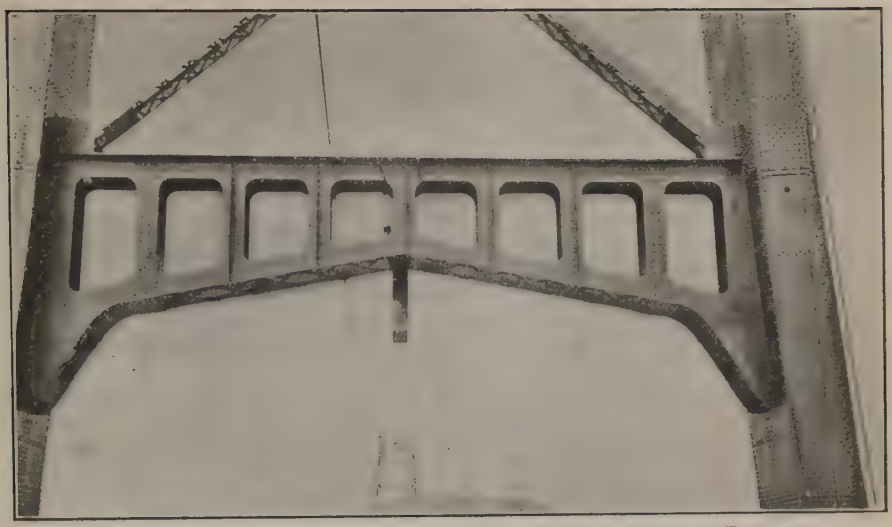

Fig. 9.—Transverse Portal Girder in Tower, Florianopolis Bridge.

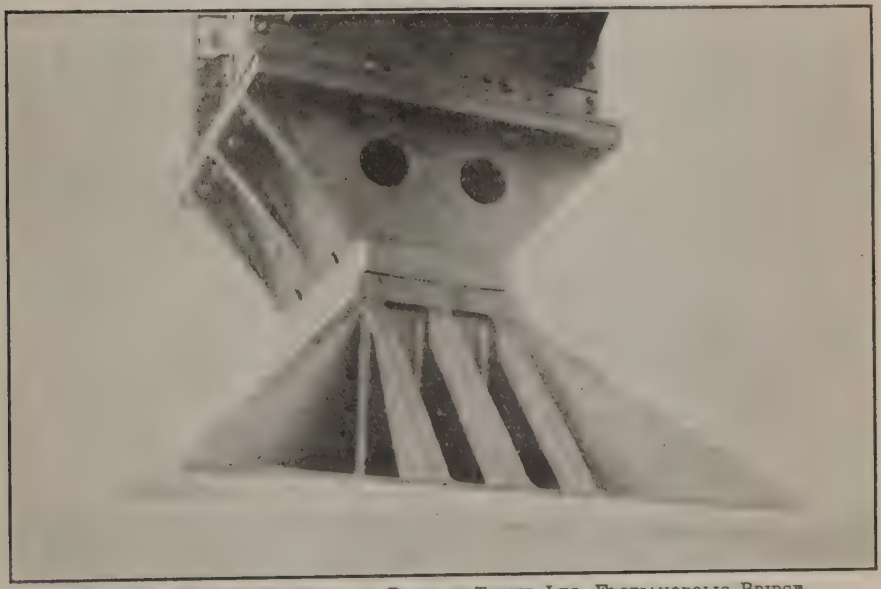

Fig. 10.—Rocker Castings at Base of Tower Leg, Florianopolis Bridge.

the coffer-dam to bed-rock at Elevation —59. This test pit was concreted, and then adjoining sections were similarly excavated and concreted, in succession, until the entire area within the coffer-dam had thus been underpinned down to bed-rock. On the concrete footing thus obtained, the square pier was built up, and stepped off at different levels, terminating in the cylindrical shaft.

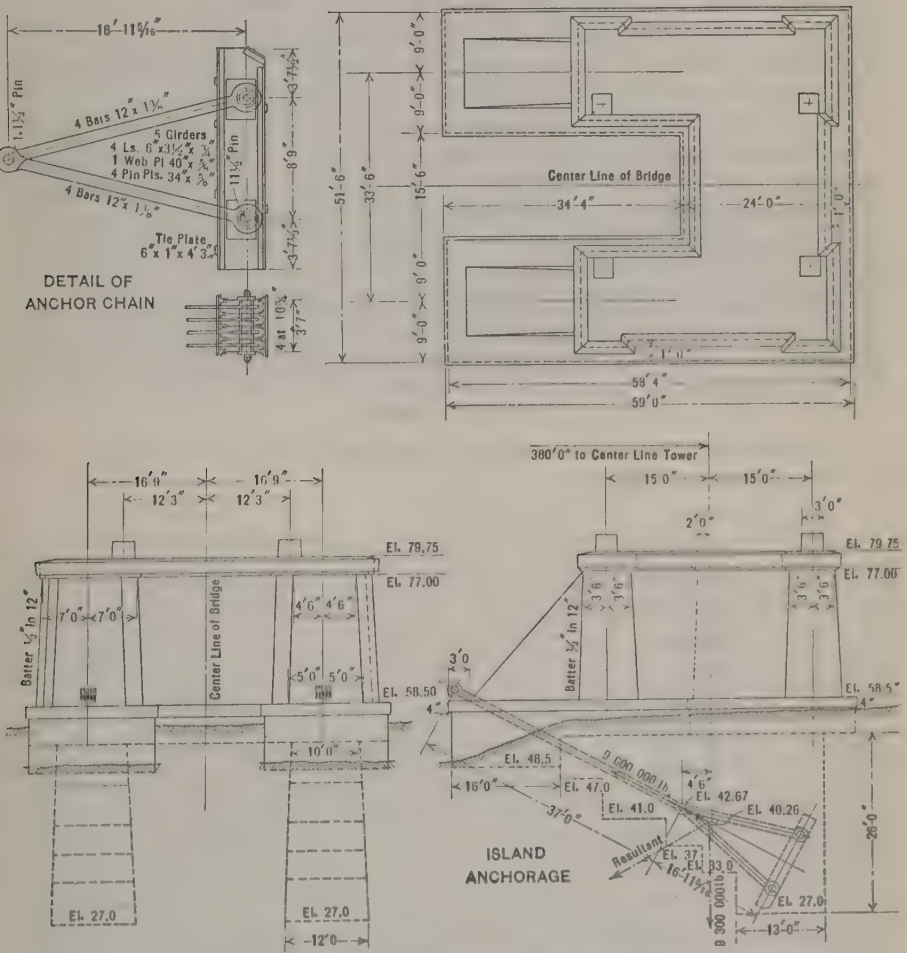

Fig. 11.—Final Design for Anchorages of Florianopolis Bridge.

In the adjacent (south) coffer-dam, rock was found at Elevation —32 over the greater part of the area, falling off sharply to Elevation —60 at one corner. Only this corner had to be sheeted down below the coffer-dam piling. The two island main piers reached rock at Elevations —37 and —50, respectively. The entire substructure work, including the concrete piers and anchorages, was completed in June, 1924.

Cross-Section of the Bridge

The Florianopolis Bridge was specified to carry a 28-ft. roadway, a meter-gauge electric railway, a 24-in. water main, and a 9-ft. sidewalk. The arrangement of cross-section finally adopted is shown in Fig. 14 (*a*); that of the approach viaducts is given in Fig. 14 (*b*). The sidewalk is carried on an outside bracket along the north truss; and the water main is located just inside the south truss, to help equalize the loads. The railway track is near the middle of the roadway, the trackway being covered with planking to provide a continuous surface. This planking is so detailed as to facilitate fitting the steel rails whenever the railway connections are completed.

In an earlier design, the trusses were spaced 31½ ft., center to center, with the water main located on an outside bracket. Careful studies showed that the small resulting increase in weight of steel was at the expense of other savings, such as simplified shopwork and erection. The necessary revision increased the width to 33 ft. 6 in., center to center of trusses, or practically one-thirty-third of the span length.

On account of the inherent stability of the suspension construction, sway-bracing is unnecessary. Adequate systems of lateral bracing have been provided.

Design Loads

The dead load used in the design of the main span totaled 4 370 lb. per lin. ft., made up as follows:

Cables	750 lb.
Suspenders	20 "
Stringers	340 "
Floor-beams	300 "
Brackets	40 "
Trusses	1300 "
Bracing	230 "
Flooring	900 "
Railings	50 "
Rails	40 "
Water main	400 "
Total	4370 lb.

The live load was taken at 2 000 lb. per lin. ft., plus 10% for impact, or a total of 2 200 lb. per lin. ft., for the design of the stiffening trusses. For the design of the cables, which require full-span loading (and extreme temperature) for maximum stress, the live load was taken at 1 850 lb. per lin. ft.

The floor was proportioned for the following moving loads:

Railway Loading.—A 50-ton electric locomotive followed by 2 000 lb. per lin. ft., plus 50% impact (Fig. 14).

Highway Loading.—A 6-ton motor truck, or 60 lb. per sq. ft., with 25% impact (Fig. 14).

Sidewalk Loading.—60 lb. per sq. ft.

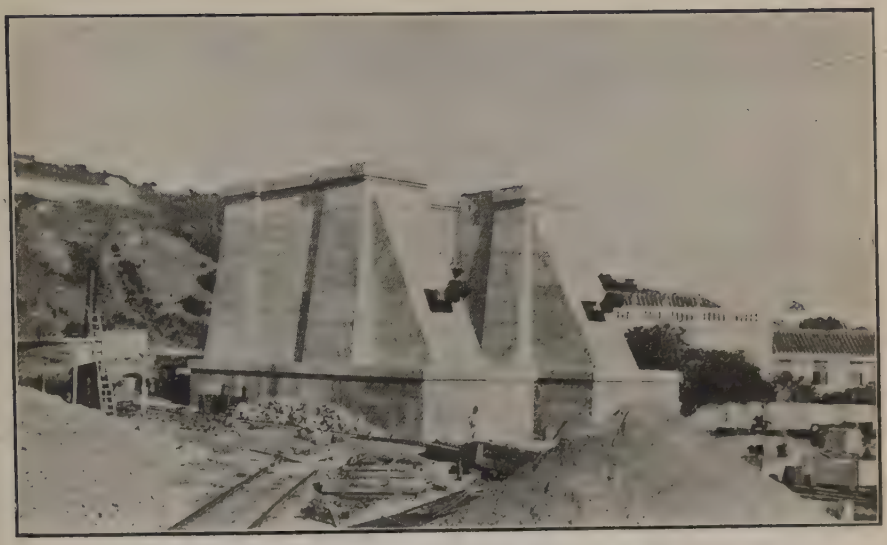

FIG. 12.—CONTINENT ANCHORAGE, COMPLETED, FLORIANOPOLIS BRIDGE.

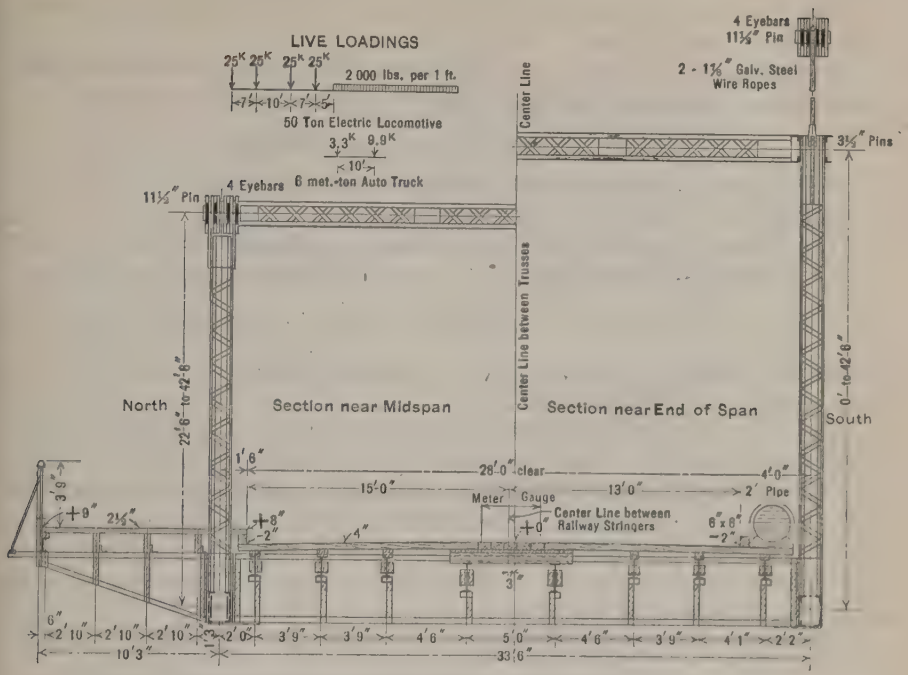
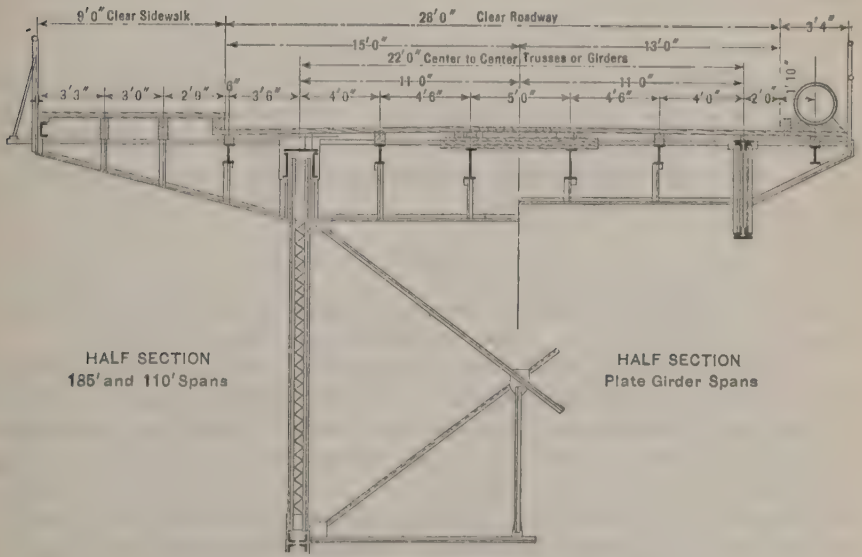
FIG. 13.—ANCHOR GIRDERS AND EYE-BARS IN PLACE BEFORE CONCRETING, FLORIANOPOLIS BRIDGE.



(*a*) CROSS-SECTION OF MAIN SPAN, FLORIANOPOLIS BRIDGE.



(*b*) CROSS-SECTION OF APPROACH VIADUCTS.

FIG. 14

The wind load was taken at 25 lb. per sq. ft. on the main span, and 30 lb. per sq. ft. on the viaduct.

The temperature variation was assumed as 30° Fahr., since the extreme temperatures reported for the locality are 30° and 90° Fahr., respectively.

Stresses by Method of Elastic Weights

The stresses in the main span of the Florianopolis Bridge were first calculated by the method of "elastic weights."

The first step is to calculate the stresses, u, produced in all the members of the unloaded structure by $H = 1$. For each truss member, that stress is given by $u = \frac{y}{r}$, in which, r equals the lever arm of the member about its center of moments; and y equals the vertical ordinate representing the respective effective lever arm of H.

The ordinate, y, is always measured along the vertical through the center of moments, and it is always measured from the closing chord of the cable. For the cable chord members, y is measured to the actual center of moments; for all other chord members, y is measured to the point of the chain directly above the actual center of moments; for the diagonals, y is measured from the closing chord of the cable to the prolongation of the cable member above the diagonal.

The strains, Δs, producible by the stresses, u, in the individual members are given by $\Delta s = \frac{u s}{E A}$, in which, s and A are the length and gross section of the member.

The next step is to calculate, for each truss member, the elastic weight, w, given by,

$$w = \frac{\Delta s}{r} = \frac{u s}{E A r} = \frac{y s}{E A r^2}$$

The calculations of the elastic weights, w, are recorded in Table 3. Each of these weights is considered as applied at the center of moments of the respective member, except that, in the case of a diagonal, the elastic weight, w, is resolved into two parallel opposing components, P and Q, applied at the respective ends of the diagonal:

$$P = -q \frac{w}{a}; \text{ and } Q = p \frac{w}{a}$$

in which, p and q, differing by the panel length, a, are the respective distances of P and Q from w. These calculations are recorded in Table 4.

These elastic weights, w, for the chord members, and the component elastic weights, P and Q, for the diagonals, are combined and treated as applied simultaneously on the span. The resulting moment diagram or equilibrium polygon is the "elastic curve". It is the influence line for H, if all ordinates are divided by a constant N, given by $N = \Sigma (u \Delta s)$, in which, the summation extends over all members of the structure that are affected by H, including anchorage steel, towers, back-stays, cables, suspenders, and truss members. This calculation is recorded in Table 5.

For diagonals, $\Sigma \Delta l =$								54.7718×10^{-8}
For chords, $\Sigma \Delta l =$								$1\,051.4886 \times 10^{-8}$
Total, $\delta =$								$1\,188.7069 \times 10^{-8}$

It is to be noted that the foregoing procedure is equivalent to constructing the H-curve to satisfy the influence-line equation,

$$H = \frac{\Sigma\,(Z\,\Delta\,s)}{\Sigma\,(u\,\Delta\,s)}$$

in which, Z equals the stress producible in each truss member by a unit concentrated load traversing the span, if the span were a simple truss without a cable. The elastic weight, w, for any member can be defined as that imaginary concentrated weight which must be placed on the span to yield a simple-beam moment diagram identical with the influence line for $Z\,\Delta\,s$ for that member. The equilibrium polygon for all the elastic weights, w, combined is the summation of the individual influence lines for $Z\,\Delta\,s$ and is, therefore, the influence line for $\Sigma\,(Z\,\Delta\,s)$, the numerator of the H-equation.

On the elastic curve, or H-curve, constructed as described (see Table 6), the simple-span straight-line influence diagrams for the various truss members (drawn to corresponding scale) are superimposed, and the intercepted areas are the required influence areas for the respective members.

The influence diagrams obtained in this manner for the chord members are reproduced in Fig. 15. Similar influence diagrams for the diagonals were drawn, but are not reproduced here. The influence diagrams for the upper chord members in the middle part of the span clearly show the stresses reduced as a result of the cable combination.

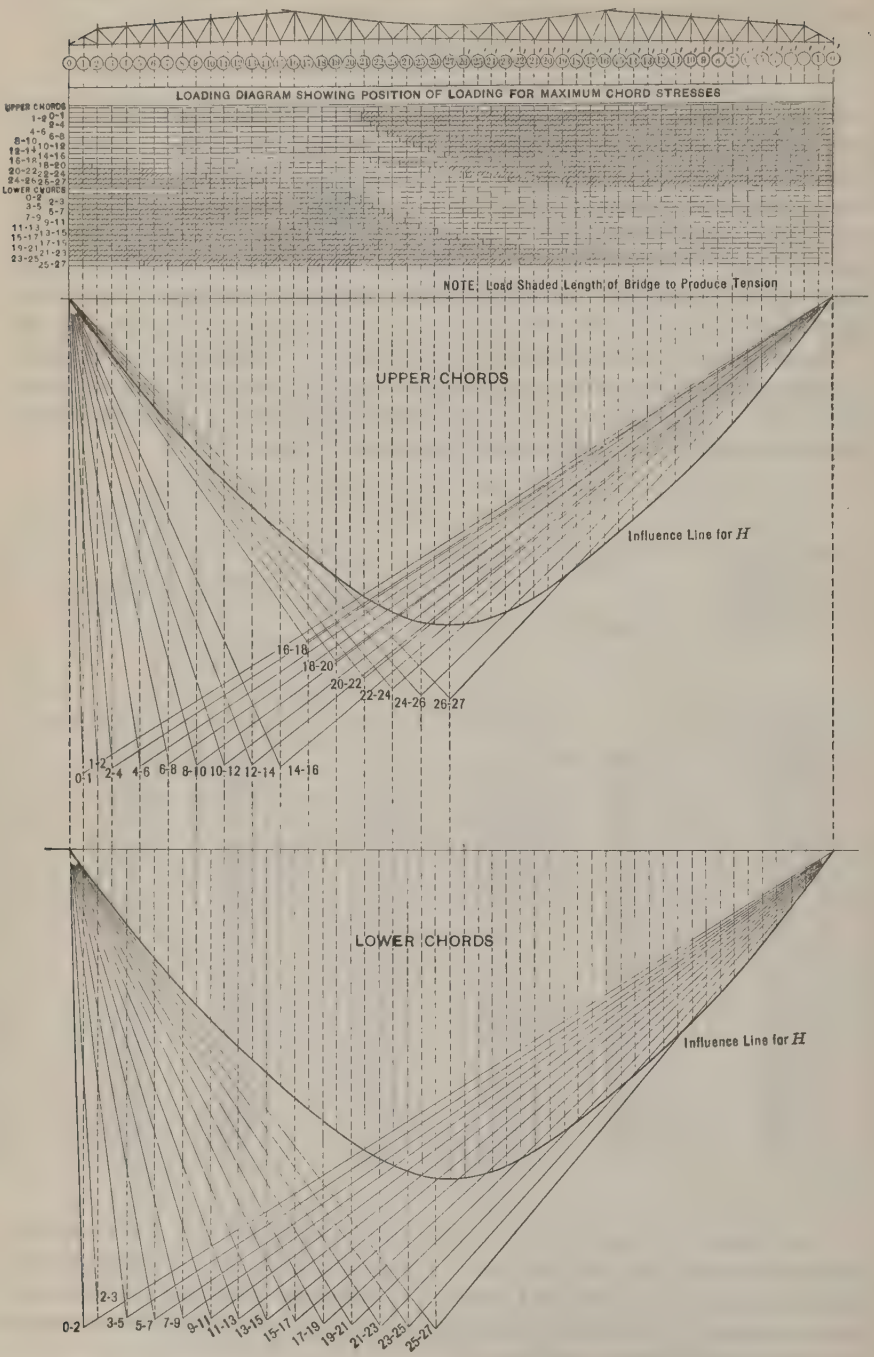

FIG. 15.—INFLUENCE DIAGRAMS FOR CHORD MEMBERS, FLORIANOPOLIS BRIDGE.

Stresses by the Deflection Theory

Following the calculation of the stiffening truss stresses by the Method of Elastic Weights, a re-calculation was made by the "More Exact" Method, or Deflection Theory.* The methods of analysis that do not make correction for the deformed configuration of the suspension system are only approximate; the resulting values of the stresses are too high, satisfying safety but not economy. The application of the deflection theory to the Florianopolis Bridge yielded a material reduction in the values of the stresses previously calculated by the less exact method.

Thus, for the quarter-points of the span, the deflection theory showed a maximum bending moment of 24 367 000 ft-lb. (with load extending from one end over 0.450 of the span), as compared with a bending moment of 30 300 000 ft-lb. obtained by the approximate method—a reduction of 20 per cent. For the middle or half-point of the span, the corresponding moments were 16 929 000 ft-lb. (with load covering the middle 0.460 of the span), as compared with 26 800 000 ft-lb. obtained by the approximate method—a reduction of 37 per cent.

In more flexible suspension spans, greater reductions of calculated stress are found by application of the "more exact" method. In the Philadelphia-Camden Bridge, these were 34 and 38%, respectively.

The final values of the maximum stresses in the Florianopolis stiffening truss, by the "more exact" theory, are about 14 500 lb. per sq. in. for the assumed loading. Since a working stress of 18 500 lb., or even 20 000 lb., is amply safe for stiffening truss members, the Florianopolis Bridge has a capacity for concentrated loads considerably in excess of that specified.

Unit Stresses Used in Design

In consideration of the comparatively generous assumptions of loading and impact, the unit stresses used in the design were as given in Table 7.

TABLE 7.—Assumed Unit Stresses.

Floor system	Tension	17 000 lb. per sq. in.
	Compression	$17\,000 - 80\,\frac{l}{r}$
Stiffening truss, towers, etc.	Tension	18 500 lb. per sq. in.
	Compression	$18\,500 - 85\,\frac{l}{r}$
	For combination of $D + L + I$ and $T + W$, increase, unit stresses, 25%.	
Suspenders	Tension	55 000 lb. per sq. in.
Chains	Tension	46 500 lb. per sq. in.

The towers and trusses, originally designed for a unit stress of 20 000 lb. per sq. in., were revised to reduce the maximum stress to 18 500 lb. per sq. in. (14 500 lb. by the "more exact" method). These unit stresses are increased 25% in computing any additional section required for temperature (T), and wind load (W), Table 8.

Sections of Truss Members

The sections used for the members of the stiffening trusses are shown in Table 8.

The top chord sections are composed of two built-up channels, 24½ in. high and 17¼ in. apart, with flanges turned out. The bottom chord sections are composed of two built-up channels, 20½ in. high by 16¼ in. wide, with flanges turned in. The diagonals are made up of two 12 or 15-in. channels, with flanges turned in. All verticals (functioning only as hangers) are four-angled sections, with single plane of lacing, providing a net section of 8.8 sq. in. to carry a maximum tension of 93 000 lb.

The details of one of the top chord members (*U*-14-*U*-16 which connects to the chain at *U*-16) are shown in Fig. 17.

Sections of Eye-Bars

Each eye-bar cable consisted of four similar members of 12-in. depth and of widths varying from 2 to 1⅛ in. The methods of compilation have already been described. For convenience, the details of stresses and sections have been listed in Table 9.

The Approach Viaducts

The cross-section of the two viaduct approaches is shown in Fig. 14 (*b*). Immediately flanking the main suspension span are 185-ft. deck trusses, spanning from each main tower to the near-by shore. These deck spans were used for tying in and holding the main rocker towers during erection. Symmetry terminates with the 30-ft. tower spans flanking the 185-ft. deck spans. Each approach also contains a 110-ft. deck-truss span, over existing highways.

The remainder of each viaduct is made up, as far as practicable, of 60-ft. girder spans and 30-ft. tower spans; each anchorage serves to support one of the latter. An odd 45-ft. girder span also occurs in each viaduct,

adjoining the anchorage on the island side and adjoining a bent on the continent side.

A length of 135 ft. near the east end of the continent viaduct is laid out to a curved center line of 150-m. radius (Fig. 5), for easement of the electric railway connections.

The total length of viaduct construction is 850 ft. on the island approach and 726 ft. 6 in. on the continent approach. Adding the main-span length of 1 113 ft. 9 in., the total length of structure from abutment to abutment is 2 690 ft. 3 in.

The grade is 2½% on each approach, the main span being cambered to a parabolic curve between these tangent gradients.

Development of Design of Viaducts and Towers

The design of the viaducts was normal for that class of work and no special problems developed in the preparation of the detail plans except where the tower columns were tied in to the adjoining 185-ft. spans during the erection of the towers.

On account of the hinged bases the main columns had to be supported during erection until such time as they were held definitely in position by the eye-bar cables. On account of shipping and erection requirements the weight of each column section was limited to about 15 gross tons, or 34 000 lb. There were, therefore, ten column sections ranging in length from 20 to 25 ft., with an average length of 22 ft. for each of the four main columns, the elevation of the top of the fourth section being somewhat higher than the viaduct floor level. Provision was made to connect the top of the second column section back to the end bottom chord, Point L-1, of the 185-ft. span, with a temporary strut until the third and fourth column sections were placed; then to connect the top of the fourth column section back to the corresponding U-1 point with a second temporary strut and to remove the first. Several of the permanent bottom laterals of the suspension span were used for these temporary struts. The second or upper temporary struts were to be removed after the eye-bar chains were swung.

Rivets 1 in. in diameter for both shop and field work were used in the main columns. To insure the tower members fitting together easily in the field, each tower was assembled complete in the yards of the Elmira Plant and the field connections were reamed and match-marked.

Development of Design of Eye-Bars and Pins

The suspension span was designed so that the entire dead load was carried by the eye-bar cables. This dead load was not uniform either along the cable or along the horizontal so that the pins connecting the eye-bars lay neither in a catenary nor in a parabola. The position of the eye-bar cable in space was an equilibrium polygon passing through three fixed points, the top of each tower and a point at the center of the span having a sag of 120 ft.

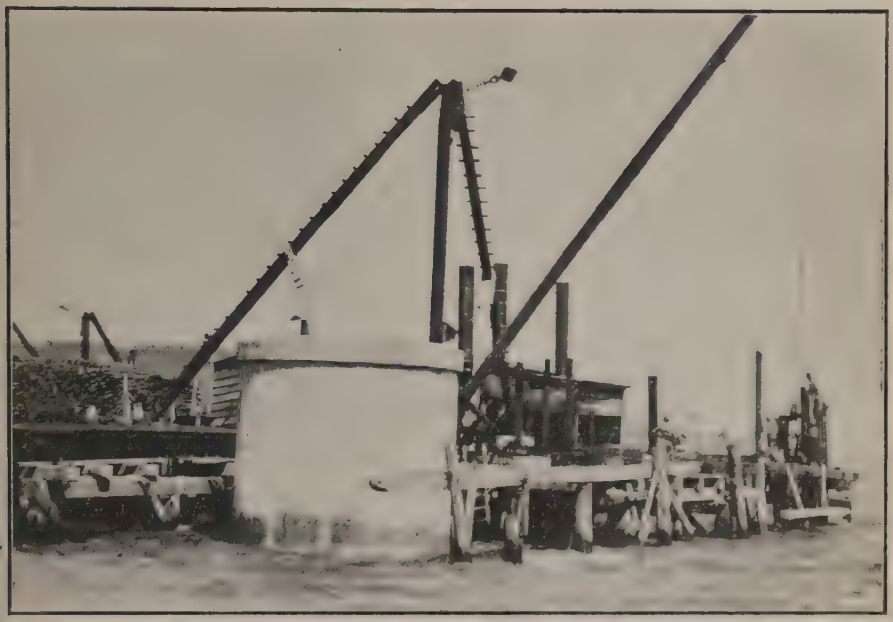

FIG. 16.—VIEW OF ONE OF THE MAIN PIERS, COMPLETED, FLORIANOPOLIS BRIDGE.

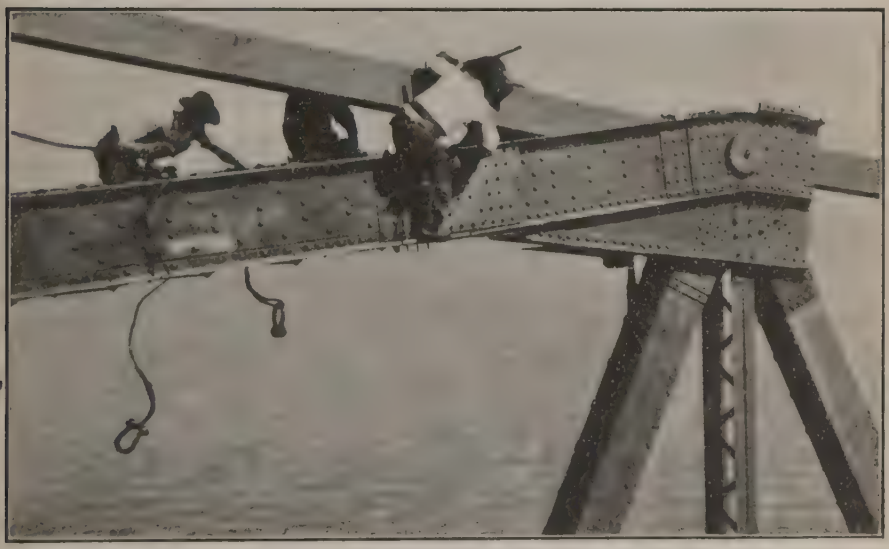

FIG. 17.—TOP CHORD DETAIL AT *U*-16, FLORIANOPOLIS BRIDGE.

Given the distance of 1 113 ft. 9 in., center to center of towers, a sag of 120 ft., twenty-seven equi-distant panels of 41 ft. 3 in. each, and twenty-six panel loads, of amounts varying from 85 000 to 98 400 lb., but symmetrical about the center line of span, it was possible to calculate the ordinates of the equilibrium polygon and the lengths of its rays. These lengths represented the lengths of the eye-bars under full dead load stress. The horizontal component of the eye-bar cable stress, which was constant from anchorage to anchorage, was calculated by the usual method and from this the stresses in the other eye-bar panels were computed. The elongation of each panel of eye-bars was computed from the formula, $\lambda = \frac{P\,l}{a\,E}$, using a value of 27 000 000 for E. The lengths of the eye-bars under dead load were shortened by the amounts of these elongations and the eye-bars were fabricated to these shortened lengths, center to center of pin-holes, making due allowance for the small amount of pin play. Table 10 gives the panel loads.

For connecting the 12-in. eye-bars of the cables, pins, 11½ in. in diameter, were used; consequently, with eye-bar heads the same thickness as the body of the bar, the bearing pressure on these pins would have exceeded the working tension in the eye-bars. To reduce this high unit bearing pressure the heads were made ⅛ in. thicker than the remainder of the bars, thus reducing the unit pressure from 6 to 9%, depending on the bar thickness. To resist the high unit stress the pins were made of special heat-treated steel with a yield point ranging between 60 000 and 65 000 lb. per sq. in., and a tensile strength ranging between 100 000 and 105 000 lb. per sq. in. A few of the pins are of chrome-nickel steel having the same range of strength.

To facilitate the entry of the pins during erection, a novel detail in the form of oval pin-holes was developed. (See Fig. 18.) The hole is made somewhat elongated axially and enlarged on the inside, to provide more clearance for the insertion of the pin or for slipping the bar over the pin, while

retaining a close fit in the segment in contact. The outer or bearing semicircle exceeds the diameter of the pin by only 0.005 in., while the inner semicircle is bored to the diameter of the pin plus $\frac{3}{32}$ in., and the two centers are separated $\frac{1}{8}$ in. along the axis of the eye-bar. The unusually close fit thus secured along the bearing surface reduces the secondary stresses in the eye-bar head. This detail is patented* by the American Bridge Company.

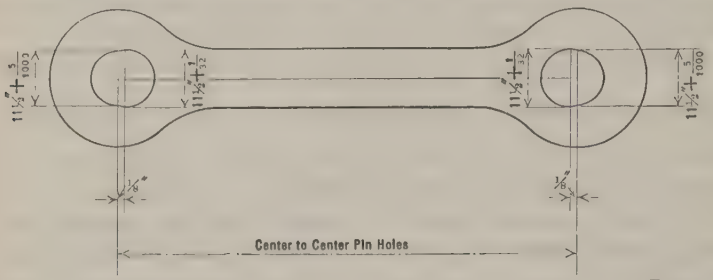

FIG. 18.—NOVEL PIN-HOLE DETAIL FOR EYE-BARS OF FLORIANOPOLIS BRIDGE.

DEVELOPMENT OF DESIGN OF SUSPENSION SPAN TRUSSES

The decision to make the central part of the top chord integral with the eye-bar cable presented some interesting studies in fabrication and erection. According to the design the eye-bar cable was to support the entire dead weight of the bridge; and the stiffening truss was designed for live load, wind, and temperature. This meant that when the entire dead load was suspended from the eye-bar cables they would occupy a definite fixed position in space at a given normal temperature and with no wind blowing. Top chord Points 2 to 14, inclusive, at each end of the truss, are supported from the cables by rope hangers, while top chord Points 16 to 16 are parts of the eye-bar cables.

The rope hangers are made with provision for permanent adjustment whereas between Points 16 and 16 there are no means of adjustment. For this reason all diagonal members of the truss between Points 16 were shipped with rivet holes in both ends of the diagonals; but the gusset-plates of the bottom chords to which these diagonals connected, were shipped blank. After the entire dead load was supported from the eye-bar cables the rivet holes could be drilled in these gusset-plates using the holes in the diagonals as templets and thus insuring the erection of the truss members under zero dead load stress.

This meant the drilling of 1 728 field holes; but as the material was in every case the $\frac{1}{2}$-in. gusset-plates, it was considered safer to do the field drilling than to run the risk of poorly matched holes which would involve either drifting and the introduction of dead load stress in the truss members or the necessity of excessive reaming.

The truss and bracing members were of normal sizes for heavy highway work and presented no special difficulties in the shop. In fact, the entire structure was fabricated without unusual difficulties.

* Patent No. 1,600,233, filed July 2, 1924, Serial No. 723,761.

Development of Method for Erecting Cables

The success of the construction was dependent on the successful erection of the eye-bars forming the main cables. When the entire dead load was carried by the cables the sag at the center should be 120 ft. with the main towers vertical. At that time the dead load of the main span, including the cables, was about 4 400 lb. per lin. ft. of bridge, and the dead load of the back-stay portion of the cable, which consisted of eye-bars and pins only, was 900 lb. per lin. ft. of bridge. The weight of the eye-bars and pins of the main span was about 850 lb. per lin. ft. of bridge. Therefore, under dead load the total weight per linear foot of the main span was about five times as much as for the cables themselves. When the eye-bar cables were swung under their own weight only, the main span portions weighed less per linear foot than the back-stay portions, and the calculated sag at the center of the main span was about 116 ft., based on the towers being tilted back so that the distance, center to center of column tops, was 1 115 ft. 7 in.

To make the erection of the eye-bars as simple and cheap as possible it was decided to hang them by hand-operated chain hoists which in turn were suspended from flexible ropes; then, after all the eye-bars and pins were placed and supported by the ropes, to swing the eye-bar cables by paying out the chain hoists. To make this vertical release movement of the eye-bars as small as possible, the ropes were made of such length that when all the bars were supported, the sag of the ropes (and, hence, of the bars) should be 115 ft., just 1 ft. less than the sag of the bars swinging under their own weight. The ropes had to support themselves as well as the bars. The weight on the main span portion of the ropes, consisting of the eye-bars, pins, ropes, chain hoists, clamps, and connections, was about 500 lb. per lin. ft of each cable.

To save as much erection material as possible flexible hoisting ropes, 1 in. in diameter, were used, so that after having served their purpose in the erection of the two eye-bar cables they could be cut up and used for ordinary hoisting rope in the Erecting Department. The grade selected had an approximate ultimate strength of 90 000 lb. per rope; a factor of safety of three was used for erection. Based on a sag of 115 ft. and a span of 1 115 ft. 7 in., the horizontal component of the stress in the ropes when they supported all the eye-bars was 660 000 lb. and the maximum stress that occurred in the anchorage portion of the ropes was 770 000 lb. At 32 000 lb. per rope, twenty-four 1-in. ropes were required.

After their completion the main towers will rock on their pedestals (see Fig. 10) under various conditions of loading in such manner as to make the horizontal components of the cable stresses constant from anchorage to anchorage and so give resultant vertical loads only. Therefore, the saddles (Fig. 7) were fixed to the tops of the columns. During the erection of the eye-bars, however, the main tower columns were locked into the 185-ft. spans. To insure that the horizontal components of the stresses in the erection rope would be taken entirely by the anchorages, temporary I-beam grillages were provided, bearing on rollers which in turn rested on top of the column castings (Fig. 29).

Wire rope is much more elastic than ordinary structural steel. It was necessary to ascertain either the modulus of elasticity of the ropes or their elongation under a stress of 32 000 lb. per rope. The lengths of the erection ropes, under full load, had then to be shortened by the amount of this elongation so that when they supported all the eye-bars, the sag at the center would not exceed 115 ft. Ordinarily, the rope used for suspension bridge cables, consisting of 6 strands with a wire center, has a modulus of elasticity of from 12 000 000 to 20 000 000, depending upon the lay of the rope and the stress it carries. Ordinary flexible hoisting rope consisting of 6 strands with a hemp center has a modulus of elasticity of from 5 000 000 to 10 000 000.

The method adopted for the erection of the eye-bars was to attach them and their pins to the lower ends of the hand-operated chain hoists, the upper ends of which were held by clamps around the ropes. The load at each panel point was 19 000 lb., so that hoists with capacities of 20 000 lb. were selected. When all bars were suspended, the chain hoists could be played out and the eye-bars lowered from a sag of 115 ft. until they were carrying their own weight under a sag of 116 ft. As the loads on the hoists were released, the erection ropes were relieved of their stress, and shortened to a length corresponding to their own weight but not to their original length because of the permanent set they had acquired. The sag meanwhile decreased from 115 ft. until it reached an amount dependent on the new length of the ropes. This decrease had to be determined in order to provide the proper amount of chain for the operation of the chain hoists. The greatest vertical movement was of course at the center of the span, the amount decreasing toward the towers at which points there was none. The center of the ropes was 6 ft. above the center of the main pins on top of the towers. The chain hoists were to be originally set so that the eye-bar pins would be a uniform distance of 6 ft. below the ropes when the eye-bars were first lifted into position. The problem therefore was twofold:

First.—To make the ropes short enough at the start so that when they had elongated under the weight of all the bars, the sag at the center would be such as to permit all the eye-bars to be placed. If the sag reached 116 ft. before all the eye-bars were placed it would be difficult to slip the remaining ones over the pins.

Second.—To make the ropes long enough at the start so that when they again supported their own weight only (after they had been relieved of the weight of the eye-bars and had received their permanent set), the sag would still come within the limits of the amount of chain provided for the operation of the chain hoists. Otherwise, it would be impossible to swing the eye-bar cables by the chain hoists alone.

Tests of Erection Rope

The success of the operation therefore depended on the movements and behavior of the erection ropes. As this method of erection of eye-bars was a new departure in bridge construction it was decided to make a series of tests on the actual ropes used. In conferences with the engineers of the

American Steel and Wire Company which fabricated the ropes, the following procedure was adopted. The distance, center to center of the girders that served to anchor the ropes, was about 1 700 ft., and to provide for proper end fastening each of the twenty-four ropes was made 1 800 ft. long. It was very desirable to have the ropes stretch uniformly so that as far as possible each should carry its share of the load. Hence, the rope fabricators decided to spin four ropes in lengths of 10 800 ft. each, using extra precautions in the spinning, and then to cut each of these four pieces into six equal parts of 1 800 ft. each, thus making the twenty-four ropes.

One test piece was cut from each end of each of the four 10 800-ft. ropes. The twenty-four ropes were to be lettered from *A* to *X* so that the test pieces were cut from Ropes *A, F, G, K, M, R, S,* and *X*. The second long length of rope was spun only to about 9 000 ft., so that an additional 1 800-ft. piece had to be made. This became Rope *L,* from which a test piece was cut so that there were actually nine test pieces. These were fitted with sockets at each end, the distance between sockets being the standard testing length of about 36 in. The tests were made on the Emery hydraulic testing machine at the Worcester Plant of the American Steel and Wire Company, the measurements being taken by an extensometer reading to 0.0001 in. in a gauge length of 10 in.

The ropes were to be used twice in the field during the erection of the bars. They were first to be put up over the north columns. Supporting its own weight, each rope would be stressed to about 3 000 lb. The eye-bars for the north cable were then to be supported from the ropes, the average stress per rope under this condition being about 30 000 lb. The north cable would then be swung and the ropes again would support their own weight only, under a stress of 3 000 lb. per rope. Next the ropes were to be transferred to the tops of the south columns and the operation repeated.

To approximate erection conditions as far as possible each of the test pieces was stressed twice to an amount exceeding 30 000 lb. After taking a zero reading at 200 lb., loads were applied in 200-lb. increments up to 3 000 lb., and then by 1 000-lb. increments up to 35 000 lb. The load was then released and the tests repeated to 50 000 lb. This method applied for test pieces from Ropes *A, F, G,* and *K*.

For the remaining five ropes (*L, M, R, S,* and *X*), the following method which more closely approximated service conditions was adopted. After an initial load of 200 lb., increments of 200 lb. were applied up to 3 000 lb., and from there in increments of 1 000 lb., up to 35 000 lb. Instead of releasing the load entirely it was lessened gradually to 3 000 lb. and then increased a second time by 1 000-lb. increments to 50 000 lb. These test loads corresponded to the excessive stresses during the erection. They were carried to 35 000 lb. and to 50 000 lb. merely to have information in case the loads exceeded 30 000 lb. per rope. Actually, the stress in the back-stay portions was about 32 000 lb.

Readings of the elongations at each increment were plotted, making it possible to compute the moduli of elasticity for any stresses. From these

moduli could be determined the proper lengths for the ropes and the movements that would take place during the erection of the cables. These tests were made in August and September, 1924. Table 11 shows a representative set of gauge readings of elongations and Figs. 19 and 20 show the corresponding plots of these readings.

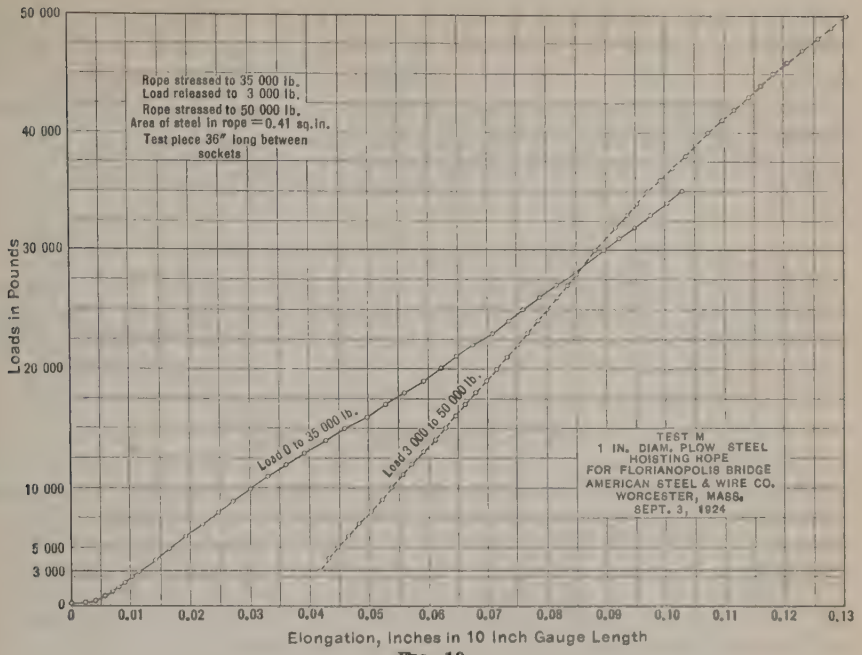
Location of Erection Ropes

In order to save in the length of ropes required and to facilitate their transfer from the north to the south side, the rope girders for fastening the ends of the ropes were placed at Points A and E (Fig. 21) above the viaduct floor level. The permanent eye-bars from Points X to CA-6 on the continent side and from Points IA-6 to Y on the island side were erected on falsework bents near the pins at their permanent elevations. The rope girder pins were long and rested on the permanent eye-bar heads at Points A and E; two temporary eye-bars extended from the rope girder pins back to the permanent pins at Points CA-7 and IA-7. After the permanent eye-bars were placed from Points X to CA-6 and from Points Y to IA-6, the temporary eye-bars, temporary pins, and rope girders were erected on the north side of the bridge. The horizontal and vertical locations of the rope girder pins were thus known with respect to the pedestals in the anchorages and also to the bases of the main tower columns.

When the sag of the erection ropes was 115 ft. (when they held all the eye-bars, Fig. 22 (c)), the calculated distance, center to center of rope shoes, on the tops of the tower columns was 1 115 ft. 7 in. and the rope shoes were assumed to be exactly over the center of the tops of the main tower columns. Under this condition the length of Rope AE was 1 717.1 ft., made up of AB = 275.4 ft., BD = 1 146.4 ft., and DE = 295.3 ft., measured



Rope stressed to 35 000 lb.
Load released to 3 000 lb.

FIG. 20.

along the ropes. Sections AB and DE had stresses of 768 000 lb., or about 32 000 lb. per rope, while Section BD had stresses varying from 660 000 lb. at the center of the span to 720 000 lb. adjacent to the tops of the towers with an average of 680 000 lb., or about 28 000 lb. per rope. From the tests the average modulus of elasticity of the ropes, when stressed the first time to 28 000 lb., was found to be 8 000 000 and the first time to 32 000 lb., to be 8 300 000.

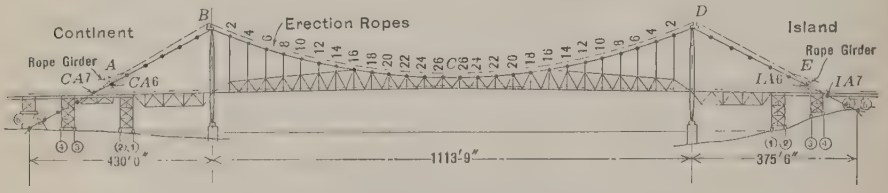

FIG. 21.—POSITION OF ERECTION ROPES.

These moduli were obtained by taking the average elongation of the test pieces at the various loads and substituting in the formula, $E = \frac{P\,L}{A\,\lambda}$, in which, P = the rope stress, in pounds; L = 10 in.; A = 0.41 sq. in., the area of a 1-in. rope; and λ = the elongation, in inches. Using the moduli of 8 000 000 and 8 300 000, the actual amounts of elongation of Sections AB, BD, and

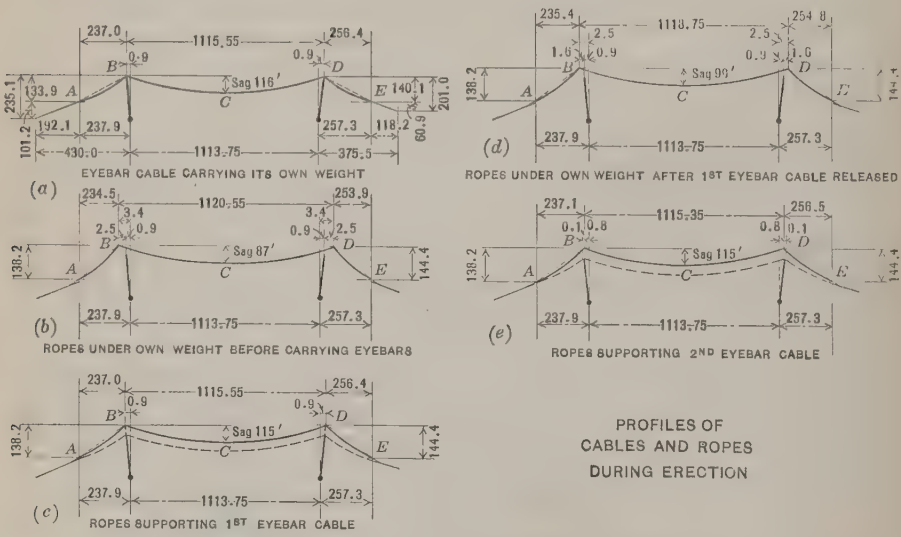

FIG. 22.—SAGS AND LENGTHS OF ERECTION ROPES.

DE were obtained. The elongation of the permanent eye-bars from Points X to CA-7 and from Points Y to IA-7 (Fig. 21) were determined, as were also the elongations of the temporary eye-bars. The temporary eye-bars were not the high tensile heat-treated grade, but were ordinary annealed eye-bars. For E a value of 27 000 000 was used for the heat-treated and

29 000 000 for the ordinary eye-bars. From these values and the known lengths the elongations of both the permanent and temporary eye-bars were ascertained.

Variation in Position of Ropes During Erection of Eye-Bars

When the main span part of the ropes had a sag of 115 ft., the continent and island portions of the back-stays had sags of 5.4 ft. and 6.3 ft., respectively. These sags were determined from the formula, $f_1 = f \frac{w_1}{w} \left(\frac{l_1}{l}\right)^2$, in which, f = main span sag; l = length of main span; l_1 = horizontal projection of back-stay; w = weight per linear foot of load on main span; and w_1 = weight per linear foot of load on back-stay, both lengths and loads being measured along the horizontal.

While the ropes had the same sections from A to E (Fig. 21), the loads of the eye-bars were applied at points approximately 40 ft. apart along the ropes. These loads were not equal so that the ropes hung in an equilibrium polygon such that the horizontal components of the rope stress were constant from anchorage to anchorage. The general shape of the curve, however, approximated a parabola and the lengths of the rope sections were computed on that basis. These rope lengths under full load being AB = 275.4 ft., BD = 1146.4 ft., and DE = 293.3 ft., and the elongations being 2.6 ft., 9.8 ft., and 2.7 ft., the lengths of the three sections under a stress of 200 lb. per rope were, therefore, 272.8 ft., 1 136.6 ft., and 292.6 ft., respectively, making a total length of rope between rope girders of 1 702 ft. The fabricating plant marked Pilot Rope M with wires at Points A, B, C, D, and E, such that AB, BD, and DE were 273 ft., 1 137 ft., and 293 ft., totaling 1 703 ft. The mark, C, was placed midway between Points B and D, and the distances from Points A and E to the two ends of the rope were about 48 ft. 6 in. The information for marking the pilot rope was given to the plant before the final calculations were made, which accounts for the difference between the computed distances of 1 702 and 1 703 ft.

Having fixed the distance between the marks under 200 lb. stress it was necessary to determine the stretch under the weight of the ropes themselves so as to place the rope shoes in proper position on top of the tower columns. Trial positions and a trial sag were assumed and the horizontal component of the stress then computed. From this the actual stress of the back-stay portions and the average stress of the main span portion were calculated and the elongations of the several parts determined. Adding these elongations to the lengths of AB, BD, and DE, under a stress of 200 lb. per rope, gave the three respective lengths when the ropes carried their own weights only (Fig. 22(*b*)).

Assuming the ropes to follow the parabolic form, the lengths of these distances, AB, BD, and DE, were calculated and the parabolic lengths compared with the lengths previously found by adding the elongations to the original fabricated lengths. Corrections were then made and new trial sags, or trial positions of the rope shoes on top of the towers, or both, were assumed and

the process was repeated until the two sets checked within small amounts. It was found that the second or third trial gave the desired results sufficiently close. These figures: AB = 273.3 ft., BD = 1 138.3 ft., and DE = 293.1 ft., totaling 1 704.7 ft., with a sag of 87 ft., gave the length and sag of the ropes when stretched between the towers for the first time.

The same procedure was followed for the determination of the lengths and sags of the ropes after the north eye-bar cable was swung and the ropes were again supporting their own weight only (Fig. 22 (d)). This corresponded to the condition of Test Ropes L, M, R, S, and X, after they had been stressed up to 35 000 lb. and then released to 3 000 lb. These lengths were AB = 274.1 ft., BD = 1 141.7 ft., and DE = 293.9 ft., totaling 1 709.7 ft., with a sag of 99 ft.

The sags and lengths of the ropes when supporting the eye-bars a second time (Fig. 22 (e)) were then computed as previously. This corresponded to the condition of the test ropes when stressed a second time to 30 000 lb. per rope. For comparison the various sags under the several conditions are shown together in Fig. 22. Table 12 gives a summary of these sags, the moduli of elasticity, the stresses in the ropes, and the lengths of the ropes under the different conditions of loading.

When the ropes had been returned to the United States after having been used in the successful erection of the span, two pieces were cut from the pilot rope, M, one from the back-stay portion near A and the other from the main span portion near B. These were tested in February, 1926, at Worcester.

Shipment of Material

The steelwork was shipped in four sections. The advance shipment, consisting of the eye-bars, pins, and girders that were to be embedded in the masonry, was shipped in 1923. This material was placed by the general contractors during the construction of the anchorages. The three remaining shipments, comprising the remainder of the material, were made during the period from June to October, 1924; in the first was included both viaduct approaches and parts of the main towers; in the second the remainder of the towers, the eye-bars, pins, and parts of the main span; in the third and last, the remainder of the main span, the railing, erection ropes, and miscellaneous material. The eye-bars were shipped in nests of three bars each, making shipping pieces with over-all dimensions about 28 in. by 12 in. by 50 ft. long and weighing about 6 tons.

All the material arrived at the site in excellent condition, the eye-bars particularly standing the 6 000-mile ocean voyage without any damage other than slight rust in some spots where the shop coat of paint had worn off in transit.

Field Organization

On account of the special nature of the erection, the field organization was selected with the greatest care. It was considered to be better equipped for foreign work than any other ever assembled by the United States Steel Products Company.

The whole scheme was a departure from the conventional method of suspension bridge erection, in the nature of an experiment 6 000 miles from office and plant, so that every precaution was taken to provide against possible contingencies. The superintendent was assisted by two foremen, seventeen American bridge men, and a time-keeper. Two field engineers were assigned to the field organization. In addition to the American nuclei of twenty-two men, the field force was augmented by local labor. This Brazilian labor did most of the work in the material yard while the Americans attended to the actual raising of the steel.

Several of the natives, however, developed into fairly good bridge men and were used on the erection of the main span. The Company was fortunate in obtaining the local services of two Italians who were familiar with steel erection and who were put in charge of the native labor in the material yard.

Unloading of Material

The first contingent of the erection organization left New York, on July 5, 1924, and arrived at Florianopolis about July 25. This part of the organization distributed the steel over the material yard, which was located at the mainland end of the bridge, as the several steel shipments arrived. The large, ocean-going freight boats could not enter the shallow strait between the Island of Santa Catharina and the mainland, and it was necessary, therefore, to discharge the cargo from the ships into lighters and tow the lighters about 10 miles from the ships to the landing dock.

The locomotive crane in the yard unloaded the lighter during the day and distributed the material over the yard. Usually, during the night the lighter was towed back to the ship, reloaded with another batch of material, and towed back to the dock, ready for unloading the following morning, although the barges were often unloaded also at night.

Erection of Approach Viaducts

Erection of steel was started on the continent end of the bridge by erecting Towers 1-2 and 3-4 (Fig. 21), using a locomotive crane. A "jinniwink" derrick was then raised to the top of Tower 3-4. The two trusses of the 110-ft. span, Tower 2-3, were riveted up on the ground and then raised into position. In the meantime falsework had been driven under the 185-ft. span (adjoining the tower), which was erected on the falsework by the jinniwink. The erection of the remainder of the continent viaduct was completed by the jinniwink, working back toward the west abutment. Using a track laid in the material yard parallel to the continent viaduct on the south side, the locomotive crane carried the viaduct steel to its proper location, from which it was raised to the viaduct floor level by the jinniwink.

The east or island viaduct was erected in the same general manner except that the steel had to be lightered over to the island from the material yard, and that there was no locomotive crane on the island side.

No special difficulties were encountered in the erection of the viaducts except that the rate of progress was somewhat slow owing to the large number of pieces to be handled.

The continent viaduct was completed about November 8, 1924, taking 3 months; and the island viaduct was completed about January 5, 1925, taking 2½ months.

Erection of Main Towers

The shoes of the continent tower were set in the center of the continent piers using the jinniwink derrick on top of the viaduct. The first sections of the continent tower columns (Fig. 23) were placed tilted back toward the viaduct so that the tops of the columns would come about 1 ft. back of their final position making the distance, center to center of column tops, 1 115 ft. 7 in. (for reasons already explained). The temporary struts attaching the tower to the 185 ft. span, during erection, are shown in Fig. 24. The lower bracing and the main cross-girder were placed as the column sections were erected. This much of the tower was erected using the jinniwink on the deck of the viaduct.

A special climbing traveler (Fig. 25) was then built around the tower and the remaining six column sections were placed by this creeper traveler, which climbed up the tower as the sections were added. The remainder of the tower bracing was placed as the column sections were added.

As a preliminary measurement across the channel had indicated that the distance, center to center of piers, might be 6 in. in error, these island piers were made 2 ft. larger in diameter than the continent piers. When the island piers were completed sufficiently to enable a more accurate measurement to be taken, it was found that the centers of the continent and island piers were 3 in. farther apart than the proper distance of 1 113 ft. 9 in. The island tower shoes, therefore, were set 3 in. off the center of the island piers in accordance with the triangulation measurements so that the steel towers would be the proper distance, center to center. With the island piers 2 ft. larger in diameter than the continent piers, the minimum distance from the main shoes to the edge of the island piers was at least as great as the same distance on the continent piers.

The island main tower was then erected in a manner similar to the continent tower (Fig. 26). The material for both towers was loaded on the lighter and brought to the foot of the towers. The creeper traveler performed its part of the work in a very satisfactory manner. The continent tower was completed about December 27, 1924, taking 6 weeks; and the island tower was completed about February 1, 1925, taking 5 weeks.

Erection of Ropes, Trolleys, Clamps, and Chain Hoists

The steel towers were erected by February 1, 1925. The beam grillages, temporary rollers, and rope shoes were then placed on top of the two north columns. All the eye-bars from the anchorages up to the viaduct floor level had been placed previously, and the temporary eye-bars and the rope girders on the north side of the bridge followed during the first week of February. A continuous ¾-in. rope was then run across the main channel, lifted to the top of each tower, and placed on the top transverse tower strut adjacent to the north eye-bar shoes.

Twelve of the twenty-four reels containing the erection ropes had been transferred from the continent to the island side and on February 10, 1925, everything was ready for the placing of the pilot rope. The free end of this pilot rope was unwound from its reel on the continent side and lifted to the floor level of the viaduct. It was then fastened to the continuous ¾-in. rope, hauled up to the top of the tower, across the strait, and over the top of the island tower, using the hoisting engine on the island viaduct. The two ends were then wound one and one-half times around the rope girders and clamped into position so that Marks *A* and *E* came at the proper position on the rope girders.

The centers of the rope shoes had been placed 2½ ft. back from the center of the eye-bar shoes on the tops of the main columns in accordance with the calculations. (Fig. 22 (*b*)). The pilot rope was then lifted into the grooves on the rope shoes, Marks *B* and *D* being placed in the center of these shoes. An observation taken on Mark *C* midway between Marks *B* and *D* showed the sag to be between 86 and 87 ft., or within 1 ft. of the calculated distance. During the next three days the remaining twenty-three erection ropes were placed in a similar manner and fastened to the rope girders so that the sags were the same as the sag of the pilot rope. The rope ends were fastened together in pairs, the free end of one rope after one and one-half complete turns around the rope girder being clamped to its adjacent neighbor by 6-rope clamps (Fig. 27).

After the main span and back-stay trolleys had been placed in position on the ropes, the main span trolley was moved across from the island to the continent side placing the clamps which bound the twenty-four ropes into one cable unit. These clamps were placed at variable distances along the erection ropes in such positions that the chain hoists would hang approximately vertical when all the eye-bars were supported by the ropes. After the twenty-six clamps were in position the main-span trolley moved back to the island side attaching the twenty-six Harrington chain hoists to the clamps. These two operations took about a week. In the meantime, the back-stay trolleys had been placing the clamps on the continent and island back-stay portions of the erection ropes, starting at the top of the towers and working down toward the rope girders.

Erection of North Eye-Bar Cable

By February 23 all the clamps and chain hoists were in place and everything was ready for the erection of the eye-bars. To eliminate the driving of pins up in the air, the two inner eye-bars of alternate panels were assembled in the yard and the two pins inserted in the holes (Fig. 28). In this manner all pins except those at the tops of the tower columns were inserted in the material yard.

The eye-bars were loaded on a lighter which was towed out to position under the ropes and anchored. The main-span trolley moved to a position over the lighter, picked up the two inner eye-bars with pins for Panel 24-26,

FIG. 23.—VIEW SHOWING ERECTION OF FIRST SECTION OF CONTINENT COLUMNS, FLORIANOPOLIS BRIDGE.

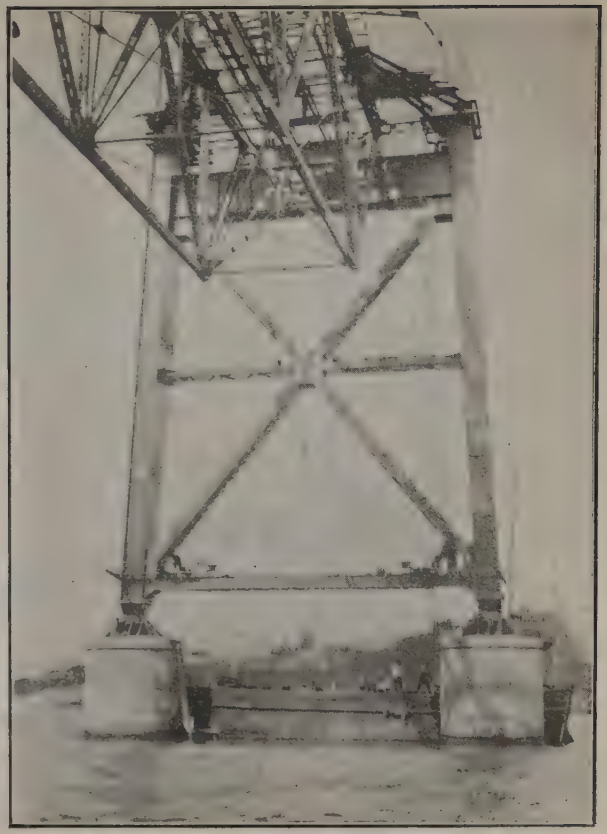

FIG. 24.—VIEW OF LOWER PART OF CONTINENT TOWER, FLORIANOPOLIS BRIDGE, SHOWING TEMPORARY STRUT CONNECTIONS.

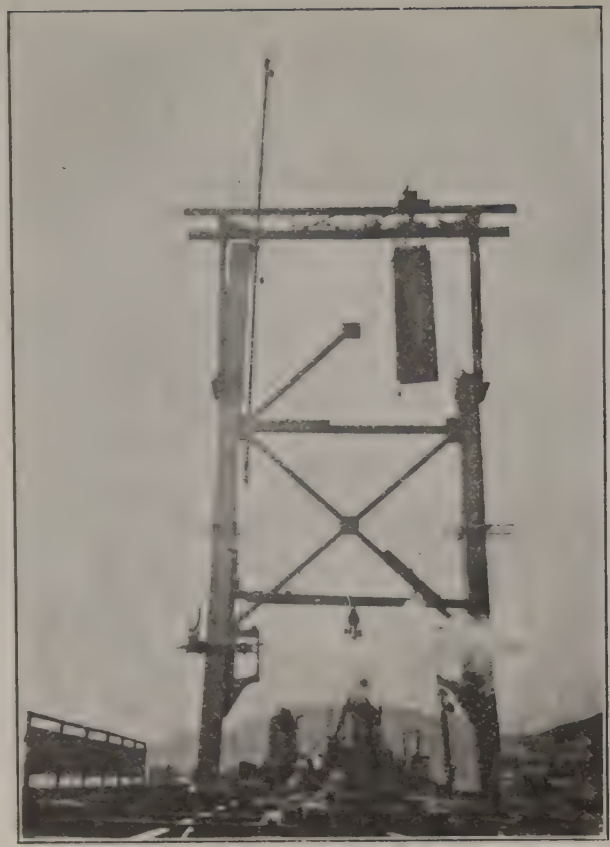

FIG. 25.—VIEW SHOWING ERECTION OF EIGHTH SECTION OF CONTINENT TOWER COLUMN, FLORIANOPOLIS BRIDGE.

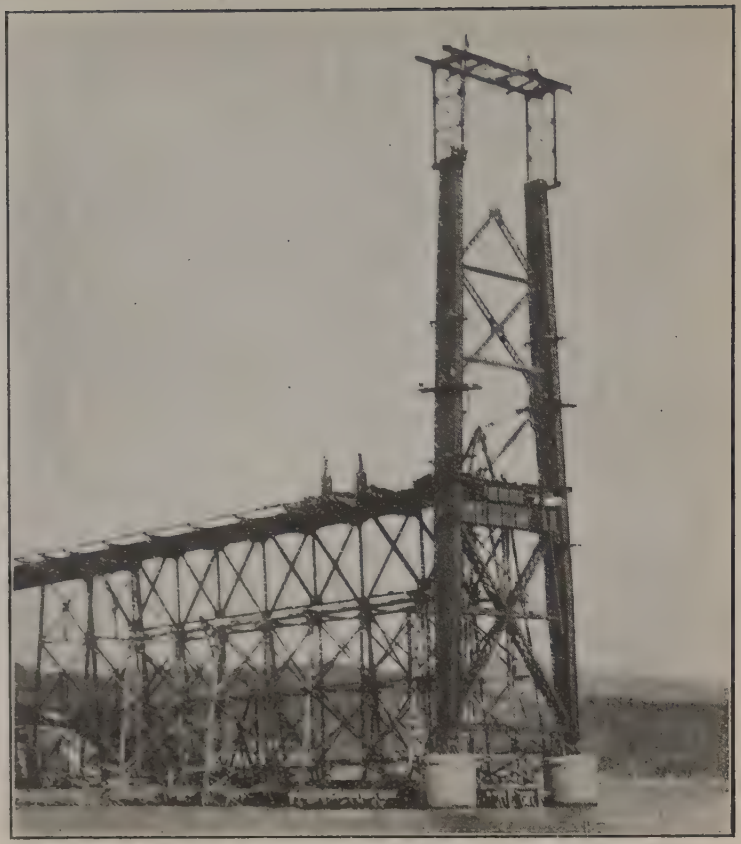

FIG. 26.—CREEPER TRAVELER ON ISLAND FOR TOWER ERECTION, FLORIANOPOLIS BRIDGE.

Island Side, raised them up into position at the proper chain hoists where they were fastened to the lower ends of the chain hoists approximately 6 ft. below the erection ropes. The trolley then lifted the eye-bars, 24-26, Continent Side, into position. Fig. 28 is a near view of a pair of eye-bars leaving the barge, while Fig. 31 shows the trolley lifting the second pair of eye-bars, the first pair having already been attached to the chain hoists.

On the main span the ropes were actually about 16 ft. longer than the chord between the tops of the columns while on the back-stays the arc was only about 2 in. longer than the chord. It was impossible, therefore, to pull the shoes off the towers by loading the main span; but it was possible for them to slip off backward if the back-stay eye-bars had been placed with few or no eye-bars weighting the main span.

At the start, therefore, the eye-bars were grouped toward the center of the span. The object was to put as much weight as possible on the central part of the main-span erection ropes so as to bring the rope shoes from 2½ ft. back of the center of the columns (Fig. 29) to a position over the center of the columns (Fig. 30) as quickly as possible. By the time twenty-six eye-bars had been supported on the erection ropes, the rope shoes had moved from a position 2½ ft. away from the column center to 1 ft. from the column center. It was then felt safe to commence the erection of the eye-bars on the two back-stays.

When all the eye-bars had been placed the temporary rope shoes had moved from the original position of 2 ft. 6 in. back of the saddle-casting to a position practically over the center of the saddle (Fig. 30). The entire erection of the 156 bars took 2 weeks.

By Saturday noon, March 7, all the eye-bars were erected, the entire eye-bar cable hanging from the erection ropes. The day being clear and calm, it was decided to swing the eye-bar cable that afternoon. The actual sag at that time when the erection ropes carried all the eye-bars was 113 instead of 115 ft., the difference being partly due to not placing the gusset-plates and hangers as was originally contemplated when the calculations were made. The eye-bars had been slipped over the pins without difficulty, thanks to the elongated pin-holes and also to the use of short pilot nuts on each pin. (See Fig. 28.)

Men took positions on the eye-bars at the chain hoists and at 2:30 P. M. the signal was given for the men to slacken off the chain hoists; and in a few minutes the normal 6-ft. gap between the erection ropes and eye-bars began to increase. Some of the men operated the chain hoists faster than others and to keep the eye-bar cable in a smooth curve it was necessary to have them wait until the slower ones could catch up. By 3:15 P. M. all the chain hoists were slack, showing that the eye-bar cable was swinging free of the ropes under its own weight and the erection ropes were carrying their own weight under a sag of between 99 and 100 ft. instead of the calculated sag of 99 ft. The entire operation of swinging took 45 min. and was a complete success in every respect.

Transfer of Ropes

As the next operation, the main-span trolley, starting from the continent tower, moved across the ropes removing the chain hoists and clamps and placing the rope hangers and steel hangers (Fig. 34). In the meantime the back-stay trolleys were removing the clamps and eye-bar supports from the back-stay parts of the ropes. These operations took about a week. The main-span and back-stay trolleys were taken down and the twenty-four ropes were moved from the north to the south of the towers.

The ropes were first lifted out of the rope shoes one at a time and spread out across the top transverse struts of the main towers. The ends were then unclamped, slipped off the rope girders, and fastened temporarily to the viaduct floor-beams. The rope shoes, rollers, and I-beam grillages were transferred to the tops of the south columns, and the rope girders and temporary eye-bars were transferred to the south sides of the viaducts. The rope ends were then fastened to the rope girders in a manner similar to that used for the north cable, and the ropes were lifted into the grooves on the rope shoes on top of the tower columns. The three trolleys were then re-erected on the ropes and the rope clamps and chain hoists placed. These several operations took about two weeks.

Erection of South Eye-Bar Cable

On March 26, erection of the south eye-bar cable was commenced. The method used here was the same as that used for the north cable and the entire 156 eye-bars were placed in one week, just one-half the time that it took for the north cable.

By April 2 all the eye-bars were hanging from the erection ropes. At 3:30 P. M. the signal was given for the men at the hoists to slacken off (Fig. 32); by 4:00 P. M. all the hoists were loose and the south eye-bar cable was self-supporting (Fig. 33). Clamps and chain hoists were then removed; rope hangers and steel hangers were erected; and the three rope trolleys were taken down. These operations took about four days.

Erection of Trusses

The first two truss panels at each end of the bridge were erected by jinniwinks standing on the viaducts, the remainder of the main span being erected by the overhead trolley method.

Two erection ropes were lifted from the rope shoe and placed on the wheels on top of the transverse struts adjacent to the cast-steel shoes. The ends of these ropes were then loosened from the rope girders and fastened around the rope-girder pins, each end being shortened 5 ft. so that when fastened to the pins the length of the ropes from pin to pin was 1 691 instead of 1 701 ft. This change was made so that when the center bottom chord section weighing 18 000 lb. was lifted into position the member would be above its proper elevation and could be easily slipped into position and connected to the bottom of the steel hangers.

By this time the verticals of the trusses had already been placed (Fig. 34). Before any other permanent member was erected a test load of 18 000 lb. was

placed on the small rope trolley that had been erected on the two 1-in. ropes, and the trolley was pulled out to the center of the span. This test checked the calculations and proved that it was possible to erect the bottom chords by this method. It would have been a simple matter to have made the ropes shorter; then the trolley would have been high enough to attach the truss member, but the stress per rope would have exceeded the 32 000 lb., and it was undesirable to use three ropes as the trolley equipment had been designed for support on two ropes only.

The south bottom chords were the first truss members erected by the overhead method. These were placed starting from the continent and working toward the island. When the continent half of the bottom chords was suspended from the hangers the weight distorted the eye-bar cable. As the remainder of the south bottom chord was placed the eye-bar cable gradually came back to its symmetrical form (Fig. 35); and when the last section of bottom chord was placed there was a gap of about 6 in., due to the camber being high under the partial dead load. The south truss diagonals were then erected, using the same trolley. The bottom chords were erected in 14 hours and the diagonals in an equal period.

Another trolley was then erected on two more of the erection ropes placed adjacent to the cast-steel shoes on the north columns and the north bottom chords and diagonals were erected in a similar manner. The bottom chords of this truss were placed in 10 hours and the diagonals also in 10 hours.

The north and south top chords were then erected, first on the continent side and then on the island side. This operation took about 18 hours. Fig. 36 shows a top chord being lifted into position. Erection of the floor-beams, stringers, and bottom laterals then took place, followed by the top laterals, top struts, and portals. The total time consumed in the main span erection was 45 working days for the erection of about 1 000 members. Fig. 37 shows a view from the continent tower looking toward the island during the erection of the trusses.

Placing Temporary Counterweight and Drilling Holes in Web Members

When all the steel was erected the total dead load was only 3 000 lb. per lin. ft. so that the sag had not reached 120 ft. Under this condition it was impossible to connect the web members and top chords because the fabricated lengths of these members were based on the geometric lengths they would occupy under a sag of 120 ft.

The delivery date of the floor lumber was uncertain so that some temporary load had to be placed upon the main span to bring the eye-bar cable to the correct dead load position, in order that the holes in the blank gusset-plates could be drilled and the diagonals outside Panel Points 16 could be connected under zero stress. As there was considerable sand on the beach along the continent shore it was decided to make use of this material. A sand load equivalent to 1 400 lb. per lin. ft. of bridge was placed on the steel floor system, and this brought the diagonals from Points 0 to 16 at each end of the bridge to such position that connections could be made with practically no drifting. The 1 728 holes in the bottom chord gusset-plates

between Points 16 were then drilled and the diagonals connected under this condition. One of the erectors set a record by drilling 240 holes (in ½-in. material) in 1 day of 8 working hours.

Riveting and Painting

There were more than 50 000 field rivets to be driven on the main span and this work was completed during July, 1925. The temporary sand counterweight was then removed and the structure given two coats of field paint.

The last contingent of the erection organization arrived in the United States on August 31, so that a few days less than fourteen months elapsed from the time that the first section of field forces left the country until the last section returned; the actual time of field erection was just about one year.

Summary of Erection

The successful design, fabrication, transportation, and erection of the Florianopolis Bridge has demonstrated the fact that suspension bridges with eye-bar cables are practical and that falsework of the ordinary kind, or, on the other hand, elaborate staging to support the eye-bars during erection, is unnecessary.

A particularly gratifying feature of the bridge from an engineering standpoint was the manner in which the actual movements both of the erection ropes and of the permanent steel towers and main span agreed with the designed movements. It was possible from the calculations to predict the movements or positions under various conditions of erection with a very small error.

The placing of the wooden floor was done by the general contractors, Byington and Sundstrom, and completed during March, 1926. The official opening of the bridge took place on May 3, 1926.

During the entire work in the field extending over a whole year from about August 1, 1924, to August 1, 1925, there was no loss of life. Furthermore, the actual cost of the entire steel superstructure was within the estimate. The Florianopolis type of suspension bridge, therefore, has shown itself to be a practical, a safe, and an economical type of structure.

Total Weights, Quantities, and Costs

The weight of steel in the Florianopolis Bridge, including the approaches, is approximately 4 400 tons, made up as follows:

Chains:		
Eye-bars and pins	780	tons
Main Span:		
Trusses and bracing	840	"
Floor system	420	"
Main Towers:		
Columns and bracing	830	"
Castings	90	"
Carried forward	2 960	tons

FIG. 34.—FLORIANOPOLIS BRIDGE: TROLLEY REMOVING CLAMPS AND HOISTS AND PLACING OF HANGERS.

FIG. 35.—FLORIANOPOLIS BRIDGE: VIEW OF SOUTH BOTTOM CHORD ERECTED.

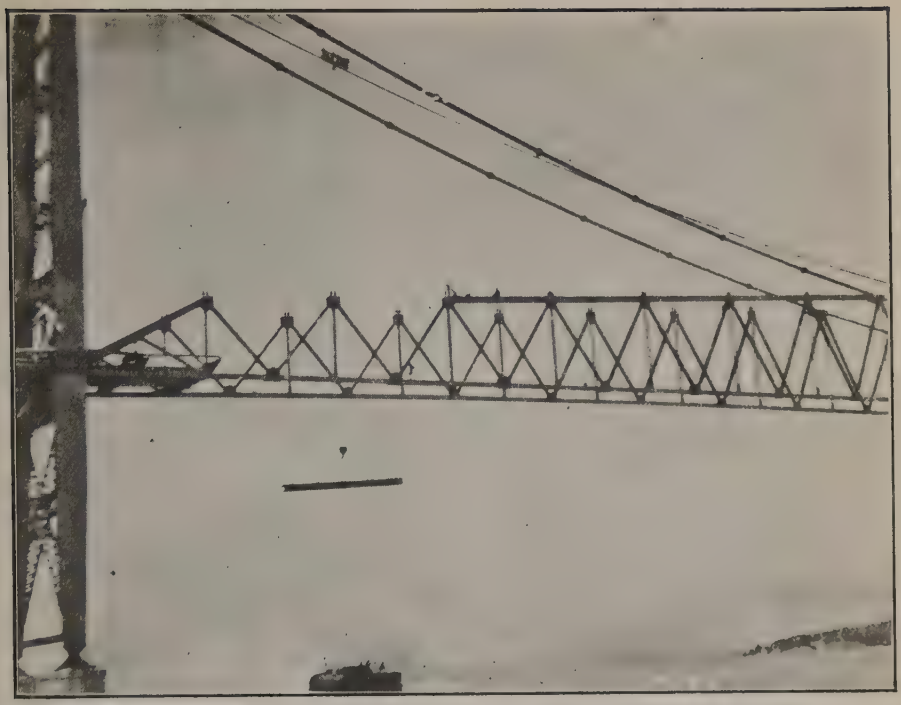

FIG. 36.—VIEW SHOWING ERECTION OF TOP CHORD, FLORIANOPOLIS BRIDGE.

FIG. 37.—VIEW FROM TOP OF CONTINENT TOWER LOOKING EAST TOWARD THE ISLAND. FLORIANOPOLIS BRIDGE.

Brought forward	2 960	tons
Anchorages:		
Eye-bars and girders	110	"
Approaches:		
Spans (including floor and bracing)	960	"
Towers and bracing	290	"
Miscellaneous:		
Railings, etc.	80	"
Total	4 400	tons

The total quantity of concrete in the anchorages and piers is approximately 14 500 cu. yd., made up as follows:

Island anchorage	3 500	cu. yd.
Continent anchorage	6 000	" "
Piers and abutments	5 000	" "
Total	14 500	cu. yd.

The total cost of the Florianopolis Bridge, including the contractor's profit, as represented by the amount of the general contract, was upward of $1 400 000 (the exact amount is difficult to state on account of the fluctuating value of the Brazilian currency at the time). Of this total amount, the cost of the superstructure, as represented by the amount of that sub-contract, was approximately one-half.

Acknowledgments

The Florianopolis Bridge was built for the Brazilian State of Santa Catharina under a general contract awarded to Byington and Sundstrom, of São Paulo. That firm handled the substructure work, including the foundations, piers, anchorages, and abutments.

The principal contractors retained Messrs. Robinson and Steinman, of New York, as Consulting and Designing Engineers, and L. N. Gross as Associated Consulting Engineer on construction, plant, and equipment. G. A. Brinkerhoff, Assoc. M. Am. Soc. C. E., went to Florianopolis to superintend the carrying out of the Consulting Engineers' plans for the foundations and masonry. W. E. Joyce, Assoc. M. Am. Soc. C. E., was in charge of the office organization of Robinson and Steinman during the preparation of the final design. Mr. J. Gunnar and A. Johnson, J. London and R. Boblow, Juniors, Am. Soc. C. E., assisted in the preparation of the design.

The steel superstructure was fabricated by the American Bridge Company, the late C. W. Bryan, M. Am. Soc. C. E., Chief Engineer, and erected by the United States Steel Products Company, W. H. Stratton, Manager, Bridge Department. The development of the design was done in the Eastern Division of the American Bridge Company, J. E. Wadsworth, M. Am. Soc. C. E., Division Engineer, S. J. Ott, M. Am. Soc. C. E., Assistant Engineer. The detail

drawings were made at the Trenton Plant, J. E. Elliot, M. Am. Soc. C. E., Engineer. The eye-bars, pins, and large castings were fabricated at the Ambridge Plant and the remainder of the material at the Elmira Plant.

The wire rope was manufactured at the Worcester Plant of the American Steel and Wire Company, J. F. Howe, Engineer, the railing by the Somerville Company, and the hand-operated chain hoists by the Harrington Hoist Company. The shop paint was Dixon's red lead graphite primer and the field paint was Dixon's silica graphite.

The field work was carried out under the direction of R. Khuen, Jr., M. Am. Soc. C. E., General Manager of Erection, and C. S. Garner, Manager of Foreign Erection. Messrs. E. G. Amesbury was Resident Engineer and T. S. Melton was Field Superintendent.

Mr. Sundstrom, of the contracting firm, dividing his time between New York and Brazil, gave his personal attention to the preliminary surveys and studies, final designs, construction of the substructure, and the superstructure contract. Acknowledgment is due him for his good offices in the various negotiations with the local officials, which smoothed over many difficulties usually encountered in foreign work due to lack of familiarity with local customs and procedure.

The success of the structure was made possible by the experimental work on the method of heat-treating eye-bars, to get an elastic limit of 75 000 lb. per sq. in., developed by the late C. W. Bryan, Chief Engineer, and by C. G. E. Larsson, M. Am. Soc. C. E., Assistant Chief Engineer (now Chief Consulting Engineer), of the American Bridge Company. One of the writers, Mr. Grove, Assistant Engineer, was in charge of the engineering features of the steel superstructure and spent several months at Florianopolis during the erection of the eye-bar cables and of the stiffening trusses.

DISCUSSION

J. A. L. Waddell,* M. Am. Soc. C. E. (by letter).—This bridge marks a forward step in the development of economics in suspension-bridge designing. All those concerned in its evolution are entitled to the hearty thanks of the Engineering Profession for their valuable contribution to the science and art of bridge building.

The structure contains a number of important innovations in bridgework, the principal ones of which are the utilization of the cables for forming a portion of the top chords of the stiffening trusses, the employment of rocker towers, the use of eye-bar cables, and the heat-treatment of carbon-steel eyebars. It is true that these features of design and construction are not absolutely new; but they are unusual—especially in the United States—hence the designers and builders deserve much credit for their courage and enterprise in departing from the beaten paths.

The authors have pointed out many economies in making the cables serve as a portion of the top chords of the stiffening trusses; and the summation of these constitutes a saving in cost that must be of considerable magnitude. The authors state that "this utilization of the cable as the upper chord of the stiffening truss should preferably be limited to the central half of the span." From Fig. 2 it appears that this limit has not been utilized, because there are eleven double panels in the central portion and eight in each side portion. By adding two double panels to the center and taking one from each side, the central portion would be made almost the half-span length; and, in the writer's opinion, the appearance would be improved, especially as the side portions could be made to appear almost identical with the halves of the central portion of the stiffening trusses. In Fig. 38 this suggested layout is shown beneath the layout adopted.

Possibly the designer of the structure had some good and sufficient reason for using the short central portion; and it would be interesting to learn what it was. It is evident (page 280) that he recognizes the improvement in appearance that could be effected by curving the outer portions of the top chords of the trusses. The writer, however, is of the opinion that if that had been done, the variation from parallelism of chords would not have been sufficiently pronounced in the adopted layout.

The writer is in agreement with the authors' claims of "esthetic values" for their structure, Fig. 2 (*a*), as compared with the previous design, Fig. 2 (*b*). The latter would have had a better appearance had one-half the suspenders been omitted, and had the truss been made a little deeper.

The esthetics of the cantilever design, Fig. 2 (*c*), could have been improved somewhat by accentuating the apices and the points of suspension, for the truss depths are too nearly uniform from anchorage to anchorage.

Rocker towers, compared with those fixed at the bottom, are both more scientific and more economical of metal; but it must be remembered that they will have to be guyed, or otherwise held in correct position, during erection.

* Cons. Engr. (Waddell & Hardesty), New York, N. Y.

Whatever method may be adopted, some extra expense will be involved. The writer is of the opinion, however, that ultimately the hinging of the tower feet would prove to be economical.

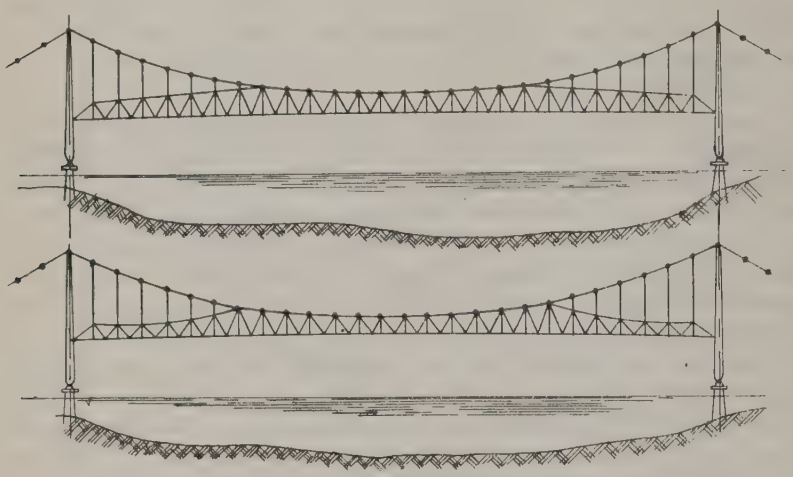

FIG. 38.

In May, 1920, the writer stated* that, under the then ruling prices, heat-treated, carbon-steel eye-bars having an elastic limit of 50 000 lb. per sq. in., could not compete with wire cables, even for spans as short as 1 000 ft., although the difference in costs was not great. Since then, however, the elastic limit of such eye-bars has been raised to 75 000 lb. per sq. in. This would reverse the conclusion for comparatively short spans; but, on the other hand, the cost of wire has been reduced about 25%, consequently it is still a mooted point as to whether wire cables or heat-treated, carbon-steel, eye-bar cables are the cheaper. A good test of this question for long spans will soon appear in the competitive bidding on the superstructure of the proposed Hudson River Bridge to be built for the Port of New York Authority.† The competition in the case of the Florianopolis Bridge does not afford any conclusive comparison, because the manufacturers of the new type of eye-bars were greatly desirous of introducing them on the market.

The manufacture of eye-bars, so common in the United States three or four decades ago, is now a monopoly, hence low prices for heat-treated bars need not be anticipated, unless some rival company should start making them. In the old days, eye-bars were generally considered to be the cheapest part of the metal work of any pin-connected bridge, but nowadays the reverse seems to be the case.

As for the heat treatment of eye-bars, that question appears to have been settled by the American Bridge Company to its own satisfaction; but facilities for the inspection of the manufacture and the testing of full-length

* *Proceedings*, Engrs. Soc. of Western Pennsylvania, Vol. 36, 1920-21, p. 418.

† As a result of this bidding, a contract was awarded for the wire cable type.—EDITOR.

bars will have to be furnished before consulting bridge engineers in general will be willing to utilize the new product. It seems to the writer that a working intensity of 50 000 lb. is rather high for an elastic limit of 75 000 lb., and that, for a time at least, it would be more judicious and conservative to limit the stress to 45 000 lb. per sq. in.

The claims for greater rigidity in the new type of stiffening truss appear to the writer to be well founded, but he would like to ask whether any deflection tests have been made on the finished structure, and, if so, with what results. Incidentally, the "novel" pin-hole detail "patented by the American Bridge Company," was evolved by the writer* about 1912.

Spencer Miller,† M. Am. Soc. C. E.—The authors have made a notable contribution to engineering art in the design of the cableways for the erection of this bridge. It was a brilliant thought to use a large number of small cables grouped together, to act as a trackway, which afterward were available as hoist ropes. It would be interesting to know how many cables were really in contact with the main sheave pulleys in the traveling carriage itself, and how an equality of stress was provided on the part of the individual cables? Perhaps a cross-section of the cables as they actually appeared in practice, showing the dimensions and the character of the pulleys and their grooving, would be instructive.

Another question concerns the method of applying power for lifting loads from the barge. A diagrammatic view illustrating how the ropes were led from hoisting drums to the traveling carriage and fall-block, together with all leading sheave pulleys, would further add to the value of the paper.

Lloyd G. Frost,‡ Assoc. M. Am. Soc. C. E. (by letter).—In departing from conventional practice in suspension bridge design and construction, the authors have met the conditions peculiar to this problem in a signally efficacious manner. Further, they have rendered a distinct service to the Engineering Profession in establishing the practicability and economy of certain innovations in design and erection.

Most engineers specializing in bridge work find little occasion to investigate or design a long-span suspension bridge. In the light of conventional practice, with the massive towers, foundations, and expensive erection methods required, the use of the suspension bridge has been necessarily restricted to certain exceptional cases.

In the design and execution of the Florianopolis Bridge the authors have laid a basis for revising accepted practice in this regard. The exceptional economy of foundations, secured by the use of rocker towers, together with the generally improved conditions of rigidity and economy, point to a possibility of widening the range of use of suspension bridges to include many cases to which the conventional type of structure could not be adapted. Particularly does this seem possible in the case of highway structures with light loads and comparatively short spans, where the difficult and expensive foundations

* "Bridge Engineering," pp. 611–612.

† Cons. Engr., South Orange, N. J.

‡ Cons. Engr., Shreveport, La.

required in other types of bridges might be largely or wholly obviated by an adaptation of this variety of suspension bridge.

A study of this paper in connection with a projected structure has led the writer to make an estimate of the cost of a similar design in comparison with arch and cantilever types previously considered. Until the results of this and similar studies have been secured and thoroughly digested, no definite idea can be had of the effect of the Florianopolis project on suspension bridge design; but it is not improbable that the noteworthy economies attained will largely affect the design of suspension bridges in the future.

C. G. Emil Larsson,* M. Am. Soc. C. E. (by letter).—As the design for the Florianopolis Bridge was made possible by the use of high-tension, heat-treated eye-bars, it may be of interest to note the development of the eye-bar industry.

About 1880 the first non-welded steel eye-bars were made. These bars had a minimum elastic limit of 28 000 lb. per sq. in., a minimum ultimate strength of 55 000 lb. per sq. in., and a minimum elongation of 15% in 10 ft. They fulfilled the construction requirements until in 1904 New York City undertook to build the Queensborough Bridge. As this long-span structure carried a heavy load, it was felt that a material reduction in cost could be accomplished if eye-bars could be made to have higher physical qualities than standard bars. After considerable discussion nickel steel was adopted as the material. Full-sized tests showed a minimum elastic limit of 47 000 lb. per sq. in., a minimum ultimate strength of 80 000 lb. per sq. in., and a minimum elongation of 10% in 18 ft. This type of bar was found to be quite expensive, and considerable study was devoted to the possibility of making a cheaper bar having about the same physical properties.

By 1914 study had led to the consideration of heat-treated carbon steel. Experiments were undertaken and after various difficulties were solved it was considered safe to state that heat-treated eye-bars could be produced of such quality that tests on full-sized bars would show a minimum elastic limit of 50 000 lb. per sq. in., a minimum ultimate strength of 80 000 lb. per sq. in., and a minimum elongation of 8% in 18 ft. Since 1914 full-sized bars to the number of 134 have been tested under the supervision of the purchaser's engineers. These tests indicate an average elastic limit of 57 800 lb. per sq. in., an ultimate strength of 86 200 lb. per sq. in., and a minimum elongation of 10.7% in 18 ft., showing that the specification proposed by the manufacturer was rather conservative. Of the 134 bars tested only one proved to be unsatisfactory to the purchaser, due to too small elongation, although even this item was considerably larger than that obtained on riveted tension members.

On account of the good results from this type of bar, it was considered practicable to produce eye-bars having still higher physical qualities. Therefore, a second series of experiments on full-sized bars was undertaken in 1921, with the result that eye-bars can now be made which are guaranteed to show a minimum elastic limit of 75 000 lb. per sq. in., a minimum ulti-

*Chf. Cons. Engr., Am. Bridge Co., New York, N. Y.

mate strength of 105 000 lb. per sq. in., and a minimum elongation of 5% in 18 ft. (See Table 2.) Almost always full-sized eye-bar tests have been made during the construction of a structure of any magnitude, while it has been quite unusual to make full-sized tests of riveted work. The knowledge of the strength of eye-bars is, therefore, much greater than that of riveted work.

Concern is expressed in the paper regarding the policy of secrecy covering the manufacture of these bars. One reason for this policy was that the manufacturer, being responsible for the quality of the bars, wanted to be free to adopt any variation in method that would improve them. The art of making heat-treated eye-bars has advanced so far, and the process is so well established, that the policy of secrecy has been discontinued.

Clyde T. Morris,* M. Am. Soc. C. E. (by letter).—A number of important long-span bridges have recently been constructed or proposed. Three unusual features of the Florianopolis Bridge make this design a notable one: (*a*) Eye-bar cables; (*b*) hinged towers; and (*c*) the combination of the stiffening truss with the central portion of the cables. The marked economies possible with the new type of stiffening truss and its increased efficiency seem evident; for these the authors deserve great credit.

They state that "the Florianopolis Bridge is the first suspension bridge in the Americas to be built with rocker towers." In 1914-15, a suspension bridge 700 ft. long was built over the Muskingum River at Dresden, Ohio, in which rocker towers were used (Fig. 39). The design was made by the writer, and the bridge was built under the supervision of Ralph H. Strait, County Engineer of Muskingum County, Ohio. This bridge also had eye-bar cables and an unusual stiffening truss. A brief description of it may be of interest here.

The first bridge over the Muskingum River at Dresden, was begun in 1851, and completed and opened to traffic in 1853. It was a private enterprise, constructed under a charter from the State of Ohio granted in 1848, and operated as a toll bridge until July, 1868, when it was purchased by Muskingum County and became a free bridge.

This old bridge was a suspension structure supported on four stone towers, with a central span of about 450 ft. Each of the four cables carrying the roadway was composed of 200 wires, No. 10 gauge, and was about 3 in. in diameter. It had wooden stiffening trusses and a wooden floor with a 17-ft. roadway, and was designed and constructed under the supervision of Mr. George Copeland.

The flood of March, 1913, rose above the tops of the stiffening trusses, and the current pulled the cables off the towers, thus wrecking the bridge. Local residents were strongly against changing the type of bridge. For years it had been the only suspension bridge in the State, and as the U. S. War Department objected to locating piers in the river, it was decided to use the suspension type for the new bridge.

The abrupt bank on the east side of the river in contrast with the wide flood plain on the west side, made an unsymmetrical bridge desirable. The

* Prof. of Structural Eng., Ohio State Univ., Columbus, Ohio.

river span was made 450 ft., with an approach span of 200 ft., suspended from the cable on the west side and a short 50-ft. simple span on the east. The east cables run directly from the tower to the anchorage.

Considerable study was given to the relative merits and costs of eye-bar and wire cables, and bids were asked for the two kinds, but both the preliminary estimates and the bids received showed the eye-bar cables to be the more economical. The material was open-hearth structural steel of 60 000 to 70 000 lb. ultimate tensile strength.

The erection was carried on during the winter when there was no river traffic (there is very little river traffic at any time of the year). This permitted falsework to be used for the entire length of the bridge. Probably the possibility of erection from falsework is partly responsible for the low cost of the eye-bar cable bridge.

Three-hinged stiffening trusses with parallel chords were used. According to the usual assumptions of constant shape of cable curve and equal hanger loads, such trusses are statically determinate, and their deflections are only slightly greater than those of a two-hinged truss. One objection to the three-hinged truss is the localization of the bending at the center hinge, thus causing a cusp in the camber curve at this point under extremes of temperature. This is quite noticeable at mid-summer when the maximum temperature deflection occurs. It may be rendered unnoticeable by adjusting the hangers so that the curve is smooth at mid-summer, allowing the center to rise in winter.

The stiffening trusses are suspended from the cables by square hanger rods with turn-buckles. The ends of the trusses are supported at the piers on independent rocker bents instead of on the main towers. (See Fig. 40.)

The 20-ft. roadway is paved with creosoted wood block on 3-in. creosoted plank. The bridge has been in service now for twelve years, and has proven entirely satisfactory. It is very rigid under traffic.

V. R. Covell* and T. J. Wilkerson,† Members, Am. Soc. C. E., and A. D. Nutter,‡ Esq. (by letter).—From the standpoint of economy, rigidity, and general structural efficiency, the Florianopolis Suspension Bridge is a splendid type, having advantages that cannot be questioned. The authors' claim for its esthetic value is not so easily established. They state very truthfully, that "æsthetic values in structural designs are generally unsatisfying on account of the existing differences of individual taste." Very rarely, in fact, have those who are considered competent to judge, been in agreement.

The design of L. S. Moisseiff, M. Am. Soc. C. E., for a bridge across the Kill van Kull (see Fig. 42) gives a more satisfactory outline, in that the side spans are supported by the back-stays and the same type of stiffening truss carried from end to end of anchorages. This gives a desirable continuity to the structure, which is lacking in the Florianopolis Bridge, with its straight back-stays and separate deck viaduct construction for the side spans.

FIG. 39.—GENERAL VIEW, NEW SUSPENSION BRIDGE, DRESDEN, OHIO, BUILT IN 1915.

FIG. 40.—DETAIL OF WEST MAIN TOWER, DRESDEN BRIDGE.

Both bridges are more pleasing in an outline drawing than in the finished structure because the actual widths of members influence the appearance so greatly. As viewed in the field, the wide built members stand out boldly (particularly the top chord of the stiffening truss), while the eye-bar chain and wire rope hangers seem to be much more faint and tend to disappear entirely when viewed from a distance. This results in an outline profile which every one except the members of the Engineering Profession finds rather difficult to understand and reconcile with such a long span. The appearance of this type of suspension bridge would be greatly improved with a slight sacrifice in economy, by using a light false member to maintain the full width of the top chord of the stiffening truss over the part where it is combined with the eye-bar chain.

The weight of steel in the Florianopolis Bridge, given as approximately 4 400 tons, is surprisingly low for a structure with a main span of more than 1 100 ft. and a total length of about 2 700 ft. This is an average of less than 3 300 lb. per ft. of bridge and approaches. The following factors account mainly for the lightness of the structure: (1) The use of a timber floor with the consequent saving of dead load; (2) the use of high-tension, heat-treated carbon steel eye-bars for the chain; and, (3) the economy of metal in the type of span used.

The first factor makes impossible a direct comparison with highway bridges, as built in the larger centers of population in the United States. The practice of using timber floors is fast becoming obsolete, especially on bridges in highly congested centers; but where the traffic is rather light, causing relatively little mechanical wear, and where a minimum cost is the outstanding requirement governing the design, a timber floor is undoubtedly the most satisfactory type to adopt.

During the past few years there has been a great increase in the loads passing over highways and these must, necessarily, pass over some of the bridges. While floor systems are being designed for 18-ton trucks, very frequently electrical equipment and road machines, weighing from 26 to 35 tons, must be accommodated. The legal weight for trucks using highways in Pennsylvania is 13 tons. It would be interesting to know whether the 6-ton truck used for the highway loading of the Florianopolis Bridge is the maximum load anticipated. The use of 4-in. plank on a stringer spacing varying from 3 ft. 9 in. to 4 ft. 6 in., apparently contemplates no increase and no exceptional loads.

A question arises as to the advisability of using high-tension, heat-treated carbon steel for bridge members. On the Florianopolis Bridge it was specified that this material should meet the following requirements:

Ultimate strength	105 000 lb. per sq. in.
Elastic limit	75 000 "
Minimum elongation in 18 ft.	5 per cent.

Both the elastic limit and ultimate strength are easily controlled by the carbon content and heat treatment, but with a sacrifice of ductility; and a favorable combination of the first two characteristics gives no positive information as to what may be expected in the third. For ordinary carbon

steel, annealed eye-bars, the minimum elongation in 18 ft. is generally specified as 12% and for heat-treated eye-bars having an elastic limit of 50 000 and an ultimate strength of 80 000, as 8 per cent. While most of the test bars give an elongation of more than 6%, one gave the very low value of 3.8%, and it is quite possible that a number of bars used in the chain, if tested, might run below 5 per cent.

Nickel, manganese, and silicon alloy steels combine the desirable qualities of high tensile strength and ductility and should undoubtedly be given careful consideration in conjunction with high-strength, heat-treated bars for any particular condition, where high ductility is necessary.

The designers of the Florianopolis Bridge have used the proper material for the eye-bar chain, the only question being, what is a satisfactory minimum value for ductility? It seems as if 5% were sufficient, but that the higher values should be used for truss members.

Following a suggestion of the American Bridge Company, the use of heat-treated eye-bars was adopted by Allegheny County, Pennsylvania, in the design of all large county bridges constructed since 1924, or under construction, with unit stresses somewhat lower than those used in the bridge under discussion, all such eye-bars being tested by the Brinell hardness test to insure uniformity of treatment. By taking lower unit stresses, it is possible to use bars without thickened heads, and, in many cases, to use ordinary carbon steel for pins. These heat-treated eye-bars have been used in three bridges of the suspension type, in three of the cantilever type, and in two of the simple truss type.

The hinged tower for the suspension bridge is a step in the right direction, and this design was adopted in the 6th, 7th, and 9th Street Suspension Bridges over the Allegheny River at Pittsburgh, Pa.

The elongated pin-hole in the eye-bar heads leaves an opening in front of the pin. Was it considered necessary to fill this space to exclude water and prevent corrosion at these points?

The authors have met all the limiting conditions imposed on them in the development of the design of this structure, and it is an outstanding example of a large project consummated in a satisfactory manner with a limited amount of material and funds.

Frederick C. Carstarphen,* M. Am. Soc. C. E. (by letter).—This paper is a worthy contribution to engineering literature. It is complete. It gives the primary premise, the analysis, and the conclusions drawn from the structure in place. Engineers who are interested in suspension bridges, are glad to know that, in design, another milestone has been passed, and they feel that the authors should be complimented on their boldness in using the mid-portion of the cable for the upper chord of the stiffening truss, thus securing in practice, an economy of material that others have contemplated but have not attained.

It is possible that engineers have hesitated to adopt an obvious economy because extreme accuracy must be secured in design and fabrication to attain

* Cons. Engr., Denver, Colo.

a satisfactory deck position without excessive use of shims beneath the girders. One-half of the Florianopolis Bridge is without suspender adjustment. The completed structure is a testimonial to the accuracy of the calculations, the care of fabrication, and the competency of erection.

This bridge is noteworthy for the use of eye-bars under tensions of 50 000 lb. per sq. in. Those who have been interested in heat-treated and alloy steels knew that their use under high tensile stresses could not be long deferred. The supremacy of wire cables for suspension bridges having a span of 2 000 ft. and less is now challenged by high-tension eye-bars. The use of overhead or messenger cable in the erection of the eye-bar spans is also a forward step.

From the data presented it might be inferred that the calculation of the initial position of the messenger cable can best be made by trial methods, but such is not the case. It is important to the contractor that the problem be correctly solved, so that the eye-bars may be joined and the chain-blocks released; although the latter could be accomplished (with additional expense), by the aid of auxiliary tackle.

The writer has been interested in this problem ever since anchored spans for the track cables of aerial tramways became the vogue. The problem is to determine the position of the empty cable so that, when it is loaded, the resulting tension will not exceed a predetermined value. The cable positions recorded during the erection of the Florianopolis Bridge will serve as an excellent control of the method of calculation.

If a wire cable did not stretch or possess elasticity, an increase in symmetrical loading would not cause it to change its position, but it would increase the tension. The supports are assumed to be rigid. Unfortunately, for simplicity of analysis, this is not the case.

When they are first placed in tension, cables become longer because of the compression of the core and other adjustments of the component wires. This set is noted in all wire ropes, but its magnitude differs somewhat with the use of hemp or wire centers, or lock-coil construction. Reference is here made to the accompanying stress-strain graphs (Fig. 41). They show the effect of progressive and retrogressive loadings applied successively to a 2½-in., 6 by 37 monitor plow-steel cable.

The permanent set of the rope was not fully developed until after the third application of the load. It will be noted that the graphs do not coincide, but after the third alternation they form a closed curve. They are foot-pound diagrams, similar to those secured with an indicator, and may be used to determine the magnitude of the internal friction, or resistance to stretching. They might be called frictional hysteresis graphs.

Up to a certain point the modulus of elasticity varies with the tension. As the loads increase the elongations become proportional to the stress, and the value of the elastic modulus is nearly constant. This is so when the internal friction is sufficient to cause the rope to behave as a homogeneous bar, although the value of the modulus of elasticity of the rope is never equal, numerically, to that of the steel from which it is made.

Two applications of a load are not sufficient to determine the true value of the modulus of elasticity (see Fig. 41 (*a*) and (*b*)). To this extent the

values given by the authors for 1-in. ropes are open for scrutiny. It will be shown from the behavior of the ropes in service that the modulus of elasticity was nearer 12 000 000 than the 8 300 000 lb. per sq. in. reported to have been used in the calculations. If Fig. 19 is a correct plotting of the stress-strain curve of Specimen *M*, under successive loading, then the crossing of these graphs is difficult to understand. It implies a recapture of the permanent set of the rope, which is not in accord with experience, and leaves the accuracy of the test in doubt.

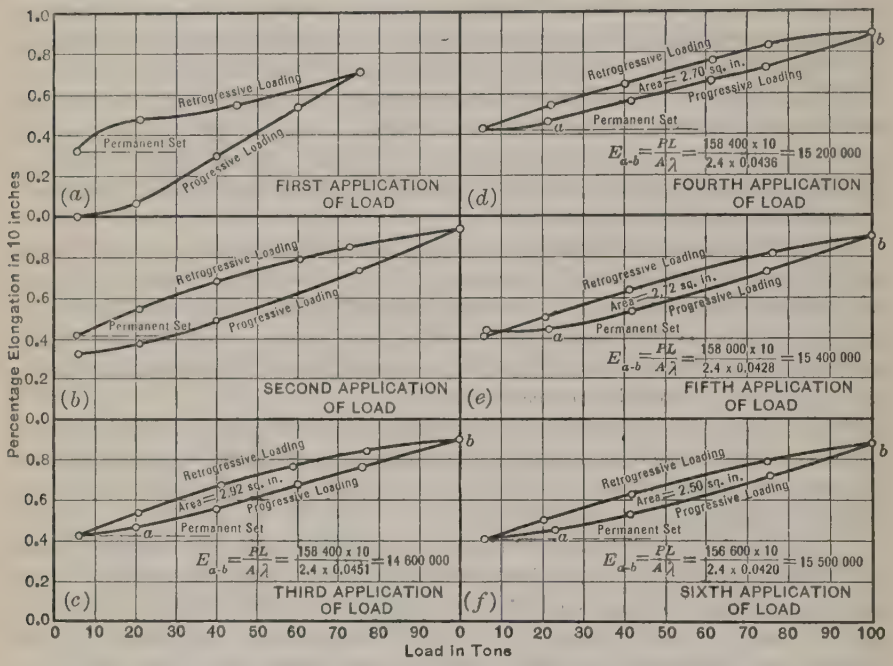

FIG. 41.—RESULTS OF CABLE TESTS.

To secure a factor of safety of 3, ropes having an ultimate strength of 90 000 lb. (monitor plow grade) were selected to sustain the eye-bar chains. The increase in tension per rope from 27 500 lb. in the horizontal portion of the main span to 32 000 lb. in the back-stays is discussed, but the authors seem to be silent as to the additional stress in the cables due to bending them around the tower and anchorage shoes. Was the factor of safety in the ropes approximately 3, or was it less than 2?

A few years ago the inquiry would have proceeded along these lines: What is the direct stress? 32 000 lb. What is the minimum radius of curvature of the shoes? 7½ in. What is the resulting bending stress?* 17 920 lb. What is the total stress? 49 920 lb. If the ultimate strength of the rope is 90 000 lb., what is the factor of safety? 1.8. By the Hewitt and Rankine formulas the factor of safety vanishes. However, these views concerning the magnitude of bending stress in wire ropes could not be reconciled with the

* See "American Wire Rope," 1913 Edition, p. 38.

experience of the rigger who knows that the ropes do not fall apart when bent around the small sheaves of the usual rope-block, but on the contrary lift loads weighing tons. When a ¾-in. 6 by 19 plow-steel cable is bent around a sheave having a 3-in. radius, its ultimate strength is reduced only 3 000 lb.

The reduction in the strength of 1-in. ropes due to bending them around a 7½-in. radius would be about 600 lb. so that this factor need not be considered further.

Wrapping the rope 1½ times around the anchor post prevented the equalizing of tensions in the two parts of the bight, but relieved the rope clips of the greater part of their load. The method of using a nest of sheaves for the anchorage results in low tensions when the ropes are looped around the sheaves and clipped. The present method is a departure from the usual one.

Since the eye-bar chain does not hang as a parabola, due to the variation in the loading, a determination of its position is in order, so that its departure from this curve may be known. (See Table 13.) The case is illustrated in Fig. 22 (*a*), the eye-bars carrying only their own weight, the span, 1 115.55 ft., the center deflection, 116 ft., and the loading as given in Table 10.

The panel length (41.25 ft.) is based on a span of 1 113.75 ft. and must be adjusted to the new length of 1 115.55 ft. The same purpose will be served if the 1.80-ft. difference is divided (0.07 ft. in each of 26 panels) so that the new spacing is 41.32 ft.

The reaction at each support is one-half the sum of the span loads, or 213 120 lb. With a center deflection of 116 ft., the span is in equilibrium when the horizontal component of the tension amounts to 519 527.8 lb. To find the deflections of a parabolic span having the same tension and center deflection, the value of the panel-point loads must be decided. The natural tendency would be to average the tabulated values to 16 393 lb., but if these loads are used with a 116-ft. center deflection, the tension will be more than that developed by the actual loading. The equal loading may be easily found by the formula:*

$$y = \frac{g\,s\,n}{4\,t}\left(1 - \frac{n}{2}\,q\right) + \frac{w\,s^2}{8\,t} \pm \frac{h}{2} \qquad (1)$$

in which,

y = center deflection.
g = load.
n = number of loads.
t = horizontal tension.
q = ratio, load spacing to span.
s = span.
h = difference in elevation between the supports.

Solving:

$$116 = \frac{g \times 26 \times 1\,115.55}{4 \times 519\,527.8}\left(1 - 13\,\frac{41.32}{1\,115.55}\right)$$

$$g = \frac{116}{0.0072345} = 16\,034.3 \text{ lb.}$$

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1388, Case III.

Notice that the last two terms drop out of this equation because w and h are zero.

Having discovered the loading, the deflections can now be found most easily by the sum of the first and second differences.* These differences are numerically equal and are found from the expression:

$$-\frac{a\,g}{t} = -\frac{41.32 \times 16\,034.3}{519\,527.8} = 1.27527.$$

The deflections of a series of equal loads on a parabolic arc as compared with those at Florianopolis, both with a tension of 519 527.8 lb., are as given in Table 13.

TABLE 13.—Comparison of Deflections in Florianopolis Cable and True Parabola.

Panel points.	0.	2.	4.	6.	8.	10.	12.	14.	16.	18.	20.	22.	24.	26.
Parabolic curve deflections, in feet.	0.00	16.53	31.83	45.86	58.61	70.09	80.29	89.22	96.87	103.25	108.35	112.74	114.73	116.00
Florianopolis deflections, in feet.....	0.00	16.95	32.48	46.64	59.44	70.91	81.03	89.80	97.41	103.68	108.65	112.34	114.78	116.00

The differences in these deflections illustrate the influence of small changes in loads on the position of the equilibrium polygon. With a center deflection of 115 ft., the tension becomes,

$$\frac{116}{115} \times 519\,527.8 = 524\,045.1 \text{ lb.}$$

This is the horizontal component of the tension required to support the eye-bars with a center deflection of 115 ft. The number of ropes required to support the chain and their own weight may next be approximated. One-inch monitor plow, 6 by 19 hoisting ropes have a tabulated breaking strength of 90 000 lb. With a factor safety of 3, the working tension can be 30 000 lb. The useful load tension is three-fourths of the working tension, or 22 500 lb.; $\frac{524\,045.1}{22\,500} = 25$ ropes, thus checking nearly the 24 ropes used. The actual tensions are less than 30 000 lb. so that checks the use of 24 ropes.

The manner of erection now must be considered. If the eye-bar chain is joined in the center of the span, the messenger cables must support all loads as well as a 20 000-lb. traveler, causing an increase in the tension of the cables that cannot be ignored. This method will be the easier for the erection crew because it insures the proper position of the eye-bars along the span. However, if the eye-bars are started at the center of the span, the tower connections can be made without the traveler being at the center. The contractor is to be complimented on the successful manner in which the eye-bars were handled, using the last method.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1388.

The panel loading of the messenger cables may be taken as 16 034.3 + 510 (chain-blocks) + 106 lb. for clips, or a total of 16 650 lb. The weight per foot of cable is 24 by 1.58 = 37.92 lb. The horizontal component of the tension of the assembly, may be found by the formula * extended to include the cables, thus:

$$t = \frac{g\,s\,n}{4\,y}\left(1 - \frac{n}{2}\,q\right) + \frac{w\,s^2}{8\,y} \qquad (2)$$

$$= \frac{16\,650 \times 1\,115.55 \times 26}{4 \times 115}\left(1 - \frac{13 \times 41.32}{1\,115.55}\right) + \frac{37.92 \times 1\,115.55^2}{8 \times 115}$$

$$= 544\,335.84 + 51\,291.72 = 595\,627.56 \text{ lb.}$$

The slope of the tangent at the support is easily found as follows:†

$$\tan \beta = \frac{n\,g}{l}\left(1 - \frac{(n+1)\,a}{2\,s}\right) + \frac{w\,s}{2\,t} \qquad (3)$$

$$= \frac{26 \times 16\,650}{595\,627.56}\left(1 - \frac{13.5 \times 41.32}{1\,115.55}\right) + \frac{37.92 \times 1\,115.55}{2 \times 595\,627.56}$$

$$= 0.36335 + 0.03551 = 0.39886 = \tan 21° 45'$$

The tension of the ropes at the tower of the long span is:

$$595\,627.56 \text{ lb.} \times \sec 21° 45' = 641\,282.41 \text{ lb.}$$

It will be noted that the horizontal tension of the messenger cables (when supporting the eye-bars at a 115-ft. center deflection, span 1 115.55 ft.) is 595 627.56 lb. instead of 660 000 lb. as mentioned on page 311. The tension of the abutment cable is:

$$595\,627.56 \text{ lb.} \times \sec 30° = 687\,770 \text{ lb.}$$

compared with the 770 000 lb. reported.

These tensions may be reduced to stresses in the single ropes, as: Abutment span, 28 657 lb.; main slope, 26 720 lb.; and horizontal tension, 24 817.8 lb. The factor of safety is 3.14, a figure well within that desired by the contractor.

The length of the loaded span may be approximated by the formula:‡

$$L = s + \frac{8}{3}\,\frac{y^2}{s} \qquad (4)$$

$$= 1\,115.55 + \frac{2.6667 \times 115^2}{1\,115.55}$$

$$= 1\,146.15 \text{ ft.}$$

The approximate nature of this formula, when the deflection exceeds one-twentieth of the span, is well known.

It is easy to ascertain the change in slope at the panel points from the relation of $\frac{g}{t}$ to the load intersection angle, and $\frac{w\,a}{t}$ to the cable angle. The sum of these tangents is 0.03059 = tan 1° 45′.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 1388.

† *Loc. cit.*, p. 1387.

‡ *Loc. cit.*, p. 1393.

The length of the loaded span may be determined for an odd number of links by taking the summation of the hypotenuse of triangles composing the equilibrium polygon of the deflection, as follows:

$$L = a\,[2\,\Sigma \sec \alpha + 1] \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

$$L = 2 \times 41.32 \times 13.35156 + 41.32 = 1\ 144.689 \text{ ft.}$$

Having found the length of the loaded span (Table 14), the next step is to find the length of these cables, or the tension, when hanging as an empty span, so that when carrying the given loads, the tension will not exceed 595 627.56 lb.

For convenience, a single rope will be used in making this calculation; weight, 1.58 lb. per ft.; and tension, when loaded, 24 817.8 lb., say, 24 820 lb.

It is obvious that the loading of the empty span increases its length and increases the tension to the limiting amount, hence the loaded span length, L, is the sum of the length of the empty span and the stretch, and so the expression takes the following form*:

$$L = s + \frac{w^2 s^3}{24 t^2} + \lambda (T - t)\, s \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

TABLE 14.—Tabulated Computations for Σ sec α.

Member.	Angle.	Secant α.	Deflection, in feet.

Σ sec. α = ...	.....	13.35156	.....

The position of the cable, will be ascertained by using both 8 500 000 and 12 000 000 lb. per sq. in. for the value of the modulus of elasticity in tension. The value of the elongation per 1 000 lb. per ft. is:

$$\lambda = \frac{1\ 000}{0.41 \times 8\ 500\ 000} = 0.000287 \text{ ft.}$$

$$\lambda = \frac{1\ 000}{0.41 \times 12\ 000\ 000} = 0.000203 \text{ ft.}$$

Substituting in Equation (6):

$$1\ 144.69 = 1\ 115.55 + \frac{1.58^2 \times 1\ 115.55^3}{24\ t^2} + 0.000287\ (24\ 820 - t)\ 1.11555$$

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1387.

Reducing:

$$21.19 = \frac{144\,400\,000}{t^2} - 0.00032\,t$$

This is a cubic equation, having one real root and is in a form that admits of easy solution by means of a slide-rule, thus:

$b = \frac{t}{1\,000}$	$\frac{144.4}{b^2}$	$-0.32\,b$	21.19
2.56	22.05	0.82	21.23
2.57	21.90	0.82	21.08
2.565	22.00	0.81	21.19

Therefore, 2 565 lb. would be the erection tension if there were no adjoining spans or back-stays. The amount of run of rope from these spans must be found when the tension changes from 2 960 to 28 659 lb. actual, or 25 700 lb. The chord lengths of the spans are 272.23 and 292.16 ft.; sag, 0.26 and 0.27 ft.; stretch, 2.02 and 2.16 ft.; and run, 2.28 and 2.43 ft. The total run is 4.71 ft. Allowing for the increase in length of the temporary eye-bars when under tension, the allowance of 5 ft. for run (made during erection), was correct. The span of the empty cable, therefore, would be increased to 1 115.55 + 5.00 − 1 120.55 ft., and the equation for tension becomes:

$$1\,144.69 = 1\,120.55 + \frac{1.58^2 \times 1\,120.55^3}{24\,t^2} + 0.000287\,(24\,820 - t)\,1.12055$$

$$16.16 = \frac{146\,300\,000}{t^2} - 0.000287\,t$$

$b = \frac{t}{1\,000}$	$\frac{146.3}{b^2}$	$-0.3216\,b$	16.16
2.92	17.1	0.94	16.16

Therefore, if the main cables are to have a center deflection of 115 ft. when loaded, and their modulus of elasticity is 8 500 000 lb. per sq. in., the pilot cable should be erected with a horizontal tension of 2 920 lb., or a center deflection of 84.12 ft.

Instead of 84 ft., a deflection of 87 ft. was used, and it will be noted that the loaded cables deflected to 113, and not 115 ft. This loading of the messenger cable may be regarded as a method of determining the modulus of elasticity. The cables, when erected with a deflection of 87 ft., were under a horizontal tension of 2 820 lb. each; at 99 ft., the tension was 2 480 lb. Loaded to a deflection of 113 ft., the tension was 25 476 lb. The difference in the length of the cable between a deflection of 113 ft. and 87 ft. is 7.54 ft.; the difference in tension is 22 656 lb.; from which the modulus of elasticity in tension may be computed:

$$E = \frac{22\,656 \times 1\,703}{0.41 \times 7.54} = 12\,400\,000 \text{ lb. per sq. in.}$$

It has been stated* that 12 000 000 lb. per sq. in. was adopted for wire ropes with hemp centers, after making numerous and careful tests, and, therefore, it appears that these ropes were not exceptional in this regard.

* "American Wire Rope," p. 33.

The tension equation, using elongation based on a modulus of 12 000 000 lb. per sq. in., becomes:

$$1\ 144.69 = 1\ 120.55 + \frac{1.58^2 \times 1\ 120.55^3}{t^2} + 0.000203\ (24\ 820 - t)\ 1.12055$$

$$18.44 = \frac{146\ 300\ 000}{t^2} - 0.000229\ t$$

The value of t is 2 760 lb. and the corresponding deflection is 89 ft. It is known from experience that if these empty cables were so placed they would sag to the desired 115 ft. when loaded. Fortune favored the contractor, for the excess of cable length, resulting from approximate methods of calculation offset the effect of using 8 300 000 lb. per sq. in. for the modulus of elasticity.

The messenger system of erecting eye-bar spans has proved to be a meritorious one, and it has been a pleasure to study its application to the Florianopolis Bridge.

A. DE H. HOADLEY,* JUN. AM. SOC. C. E. (by letter).—The writer's interest in the Florianopolis Bridge began in 1925 when Charles M. Spofford, M. Am. Soc. C. E., suggested that he make a stress analysis of this bridge for thesis work. The writer presents a brief account of the method used and shows that it is merely another form of expressing the influence line equation given by Mr. Steinman for the method of elastic weights.

Castigliano showed that if the stress in each member of a structure which is indeterminate to the first degree, as is the bridge in question, is expressed in terms of a single unknown internal stress, the derivative of the internal work with respect to the unknown stress will be equal to zero, thus giving an equation from which the unknown can be found. Here the panel load, x, due to a unit load at some point on the bridge, was taken as the unknown. This load was assumed to be equal at all points because the truss deflection was neglected. The stress, U, in each member was then expressed in terms of x, and the unit load and the value of the derivative of the internal work with respect to x, were found and equated to zero. It was decided to neglect the effect of shear, so that the internal work of the truss could be expressed in terms of the bending moment, M, and the moment of inertia of the truss. This gave the equation:

$$\frac{d\,w}{d\,x} = 0 = \sum \frac{U\,s}{A\,E}\frac{d\,U}{d\,x} + \frac{E}{E\,c}\sum \frac{U\,s}{A\,E}\frac{d\,U}{d\,x} + \frac{A}{A_1\,A_2}\sum \int \frac{M}{\delta^2}\frac{d\,M}{d\,x}\,d\,y$$

in which,

U = total stress in member.
s = length of member.
A_1 = area of top chord.
A_2 = area of bottom chord.
$A = A_1 + A_2$.
δ^2 = depth of truss at any point.

$$I = \frac{A_1\,A_2\,\delta^2}{A}$$

* Asst. Prof., Civ. Eng., Union Coll., Schenectady, N. Y.

Solving this equation for a unit load, successively placed at different points on the span, gave the influence line for x from which the H-influence line was readily obtained.

The first term deals with the work in the towers, the second with that in the cable and back-stays, and the third with that in the stiffening truss.

In order to bring the last term of the writer's equation into an integrable form, δ had to be expressed as a function of the horizontal distance, y. For the end thirds, δ varied directly with y. In the middle third it was found that a parabola through U-16 and U-27 nearly coincided with the cable curve, so that δ was the distance from that parabola to the one on which the lower chord was laid.

The following results were obtained.

Panel Point.	Ordinate to H-Influence line.	Panel Point.	Ordinate to H-Influence line.
2	0.2012	16	1.2831
4	0.3705	18	1.3926
6	0.5445	20	1.4896
8	0.7104	22	1.5773
10	0.8684	24	1.6367
12	1.0108	26	1.6774
14	1.1516		

This shows the elastic weight value to be 5% less than the least work value at Panel Point 26. If the elastic weights for the diagonals are omitted, the writer found, on the basis of the other elastic weights given by Mr. Steinman, the H-influence line ordinate at Panel Point 26 to be 1.5621. This is 7% less than the least work value in which the diagonals were neglected and shows the omission of diagonals to reduce the elastic weight values 2 per cent.

The effect of the top chord members in the middle third of the truss appears in both the second and third members of the least work equation. In the second term there is positive work due to cable tension and in the third term also positive work usually due to compression from bending in the truss. The actual internal work is not the sum of that caused by the forces acting separately (as here taken), but is that due to the algebraic sum of the forces. This may account for a part of the discrepancy between the least work and elastic weight values.

The least work equation readily lends itself to a study of the effect of varying the chord sections on the H-influence line. Once having evaluated the integrals for the different positions of the unit load, it is a simple matter to substitute different values of $\frac{A}{A_1 A_2}$ for each section and compare the results obtained. The third term of the equation, which is that involving the chord members, has much greater weight than either of the other two terms. Consequently, the factor, $\frac{A}{A_1 A_2}$, is an important one. This is shown

in the summation of $u \Delta s$ (the denominator of the H-equation) given by Mr. Steinman in Table 5. Here, $u \Delta s$ is given as $1\,188.7069 \times 10^{-8}$ ft-lb., to which the chord members alone contribute $1\,051.4886 \times 10^{-8}$ ft-lb.

The influence line equation given by Mr. Steinman can be obtained by assuming H as the unknown, expressing the internal work of each member in terms of H and of the unit load, and equating the derivative of the internal work with respect to H to zero.

S = length of member.
u = stress in member due to $H = 1$.
Z = stress in member of a simple span truss with same dimensions as the stiffening truss due to unit load.
U = total stress in member $= Z + uH$.

The total internal work is,

$$W = \frac{U^2 S}{2 A E}$$

$$\frac{d W}{d H} = 0 = \sum \frac{U S}{A E} \frac{d U}{d h} = \sum \frac{Z u S}{A E} + \sum \frac{u^2 H S}{A E}$$

$$H = \frac{-\sum \frac{Z u S}{A E}}{\sum \frac{u^2 S}{A E}} = \frac{-\Sigma Z \Delta s}{\Sigma u \Delta s}$$

as

$$\Delta s = \frac{u S}{A E}$$

If only one or two points on the H-influence line were desired, they could be found more rapidly on the basis of this equation than by the method of elastic weights. However, if all the ordinates were desired, the method of elastic weights will be much shorter, because $\Sigma Z \Delta s$ has to be evaluated for every ordinate to the influence line. Taking the value of $\Sigma u \Delta s$ given in Table 5 and the values for Δs given in Tables 3, 4, and 5, the writer computed $\Sigma Z \Delta s$ for a unit load at the center of the bridge and found the corresponding value of H to agree (as it should) with that found by the method of elastic weights.

F. N. Menefee,* M. Am. Soc. C. E. (by letter).—The use of heat-treated carbon steel in bridge construction is very interesting. Readers of the *Transactions* of the Society will recall the studies by J. A. L. Waddell, M. Am. Soc. C. E., of alloy steels a few years ago.† At that time, however, heat-treating was confined almost entirely to smaller units than those usually found in bridges, and was only economical when a large number of small parts were being produced.

* Prof., Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

† "The Possibilities in Bridge Construction by the Use of High Alloy Steels," *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 1.

The secrecy of the heat-treatment process need not cause any general concern among engineers. There is no longer any real mystery about heat-treatment, and it will soon be found that all the large companies will produce heat-treated bridge members as wanted.

The Brinell test will form a fairly reliable check on the uniformity of the treatment and of the tensile strength. Comparisons may be made against a standard by Brinelling a few full-sized members throughout their length and then testing them to destruction to determine their physical properties.

Considering the fact that stresses in a pin-connected structure, such as a suspension bridge made up of eye-bars, are more accurately determinable than those in a stiff-jointed structure, and that impact, as it is generally understood, on railroad bridges has little or no effect on a bridge the joints of which will yield, as in the case of the suspension type, it would seem that the working stress of 46 500 lb. per sq. in. is well within the limits of safety on steel the elastic limit of which is 80 000 lb. per sq. in.

Secondary stresses due to uneven settlement of piers do not enter into the stress conditions of the cable portion of the suspension bridge. Axial loading reduces the amount of members which otherwise might have bending moment and shear, and this at once introduces some heavy material in a neutral zone where it does little or no work.

Eye-bars, instead of cable, in the upper chord, will serve two purposes: (*a*) By adding stiffness in vertical and horizontal planes, and (*b*) by decreasing deflection. For the same total area of steel, a cable will elongate under load more than a solid piece of steel.

T. Kuo,* Esq. (by letter).—In considering the question of rigidity of suspension bridges, one must recognize at the start the characteristic features of two different types of construction with special regard to the make-up of their principal carrying member, the cable. The degree of rigidity attainable in each design depends to a large extent on the question whether the cable is free or braced.

Theoretically, a flexible free cable may be viewed as a structural polygon with an infinite number of hinges connecting bars of infinitesimal lengths. Such a polygon will never constitute a rigid system. While an inverted three-hinged arch would be just sufficient to be stable, the free cable alone, as a structural system, is extremely defective.

Such a flexible cable not only possesses the characteristic property of altering its position of equilibrium with new distribution of loading, but this change of shape, causing excessive deflections in an actual bridge system, has nothing whatever to do with the question of stress and strain. Until the final position of equilibrium is reached, the cable will never be stressed.

Therefore, a free cable suspension bridge is by nature a flexible structure. Even with the stiffening truss, which is designed only to prevent undue deflection, it still retains these basic characteristics to a greater or less extent, depending on the rigidity of the stiffening truss used and the relative magnitude of the live load over the dead load.

---

* Structural Draftsman, with Ralph Modjeski, Cons. Engr., New York, N. Y.

When the cable is combined into a rigid system of triangles (braced-cable construction), the result is a stable trussed structure, radically different from a purely free cable suspension bridge made adequate for practical requirements by a secondary stiffening truss. Although this braced cable construction retains much of the general nature of a suspension bridge, it lacks the flexible character of an unstable system. All deflections are directly due to the internal deformation of its component members and not to a mere unrestrained movement of a loose system to satisfy a new set of loadings.

One, therefore, must look on the greater flexibility of a free cable suspension bridge somewhat as an inherent characteristic of a certain type of construction and tolerate it as a necessary disadvantage, because of the superior qualities in its other features.

By adopting an unusually heavy and deep stiffening truss, it is possible to design even a free cable suspension bridge to any desired degree of rigidity. Nevertheless, this departure from the usual proportions set by the best modern practice results in a very uneconomical and clumsy design.

Moreover, there are other ways of limiting and controlling the deflection of suspension bridges. In the Florianopolis Bridge, the designer has accomplished this in a very scientific and economical manner. The structure belongs to the partly braced type.

On the other hand, deflection is certainly not desirable if it is excessive. Besides the good reasons relating to practical requirements, as set forth in the paper, there is another of more than technical interest for controlling and limiting the deflections in suspension bridges. As the stiffening truss deflects, the floor system deflects with it. This forced deformation on stringers rigidly connected to the girder (except expansion ends), produces secondary stresses that are not taken care of in the stringer design.

Knowing the deflection of the truss, and assuming the curve to be parabolic, the change of end slopes of the stringer and the movement of one end relative to the other, can be readily computed. Then, using the general slope-deflection formula involving these factors, the actual stresses are not difficult to ascertain. The writer has found them to be so extremely high, that they cannot be rightly regarded as being of secondary importance.

While the writer does not doubt the wisdom of using rocker towers in this design for that particular location, he is of the opinion that the use of such towers, like that of pin-connected trusses in ordinary bridge construction, should in general be discouraged.

In time of earthquake, the fixed ended towers are in a much better position to resist the forces produced, and it is quite possible that objectionable displacement between the rocker and the foundation is likely to occur. A rocker tower, due to its construction, is not in integral connection with its supporting pier. When destructive horizontal ground movements are taking place, the inertia of the tower acts against them. Unless the movements are extremely slow, which is hardly the case with an earthquake, the tower cannot be expected to move back and forth along with the pier.

Severe earthquakes are usually infrequent at any one place, and, therefore, elaborate and expensive precautions against them are not to be recommended

in all locations. However, in view of the existence of a potential earthquake, even in regions that are generally considered dependably quiet, it seems to be good engineering policy to utilize the superior advantage of fixed ended towers against possible hazard of this kind. Moreover, they involve only a little extra cost.

The new departure of the stiffening truss from parallel chords and the union of the cable with the middle portion of the top chord into a single member are two of the most admirable features of the design. Striving for a more scientific proportion in the height of the stiffening truss and for a more economical structural combination in the make-up of the whole bridge, the designers of the Florianopolis Bridge have established a distinct development in the art of suspension bridge construction. The remarkable results achieved in regard to rigidity and economy of material from this seemingly theoretical complication has been already comprehensively treated in the paper.

That the height of the truss should vary with the magnitude of the maximum bending moment seems to be one of the broad and fundamental principles of good design. Compliance with it always results in a better design. It is in perfect accord with structural requirement: A longer arm for a bigger moment.

It also converts the outline of the bridge into a more expressive form, which is virtually a modified maximum moment diagram. While it may not be possible for one to write into the structure the story of its conception so that "all who run may read", nevertheless it can be at least plainly felt in the minds of designers that structural fitness could not be more strikingly expressed in other ways.

Leon S. Moisseiff,* M. Am. Soc. C. E.—This paper is of much interest. It tells of the design of a new type of suspension bridge and how it has been successfully erected and put in use in a foreign country. It also tells of a novel material that has been used in bridge building. The engineers who have planned, designed, erected, and managed the enterprise and now report on it deserve much credit.

The form used for the stiffening truss of the Florianopolis Bridge has undergone a long evolution and has been discussed at various times in engineering offices and publications before it took its present shape. It may be well to sketch here briefly the development of the stiffened cable bridge.

Since the time when suspension bridges, stiffened by a railing, had been found to be too limber, it has been the aim of many engineers to stiffen the cable directly by making it serve either wholly or partly as a stiff member. The simplest form that this idea took was that of splitting the cable in two parallel chords placed vertically apart and bracing them to each other so as to form an inverted arch. This form has been realized in several smaller bridges, and several decades ago it was proposed by Gustav Lindenthal, M. Am. Soc. C. E., for a bridge over the Hudson River. In 1874, the late James B. Eads, F. Am. Soc. C. E., patented a design of a braced cable in the form of

* Cons. Engr., New York, N. Y.

an inverted three-hinged arch made of two bi-convex halves. The same idea found a simpler expression later in the bowstring type of which the Old Point Bridge, built at Pittsburgh, Pa., in 1878, by Hemberle, offered an excellent example. In 1875, Fidler, in England, proposed a modified type of bridge consisting of two intersecting cables tied together by web bracing. Each cable was to take the form of an equilibrium curve with one half span uniformly loaded. The upper branches of these curves then become straight lines and constitute the upper chords of the stiffening truss. When the bridge is fully and uniformly loaded the equilibrium curve of the system will coincide with the neutral curve of the braced arch. The stress in the chords will always remain in tension. They can be built, therefore, as tension members exclusively. This, of course, offers a substantial advantage in economy.

It appears that Fidler's braced arch is but a special case of a general type of a suspension bridge formed of two curves intersecting at mid-span and braced to each other and possessing the characteristic mentioned, of tensile stresses in the chords exclusively. Résal, in France, published in 1893 a sketch, and, in the same year, Max am Ende, in England, published the general analysis, of this type of truss. Ende shows that, by selecting a depth of truss at the quarter-points that is a function of the ratio of the live load to the dead load, two curves can always be adapted that will form the chords of two crescents hinged together. These curves will remain in tension under all positions of the specified intensity of live load. In other words, the axial stress, due to the weight of the bridge and the live load on it, will never be exceeded by the stress caused by the flexure of the truss.

In 1895, the speaker, under the guidance of William H. Burr, M. Am. Soc. C. E., selected as a thesis the then much discussed bridge over the Hudson River, with a span of 3 000 ft., and developed a design on this type. In 1910, the Pennsylvania Steel Company submitted several designs for the second Quebec Bridge. One of them was the design proposed by Mr. Lindenthal for a suspension bridge. It consisted in the center span of two intersecting curves forming two braced crescents hinged together at mid-span. The side spans consisted of braced segments formed of a lower curve and an upper straight line chord. In 1924, the McClintic-Marshall Company, among other designs for the Sydney Harbor Bridge, also proposed a 1 600-ft. span on practically the same lines.

German engineers have been always much interested in these forms of stiffened suspension bridges and since the Nineties many and various forms of this kind have been discussed in German engineering literature.

In 1903, Mr. Lindenthal, while Commissioner of Bridges of New York City, proposed an eye-bar bridge for what is at present the Manhattan Bridge. The main feature of his plan was a chain of eye-bars that would sustain the dead load of the bridge and form an equilibrium polygon. To the chain a truss was attached which consisted of a lower chord capable of resisting tension, and also a compression and a web system. The lower chord, beginning from the hinged support of the chain on the tower, descended to the roadway level at about the quarter-points and continued parallel with the roadway grade so that

the middle half of the span was practically horizontal. The live load and temperature that would come on the bridge, would be jointly sustained by the chain and the lower chord forming an inverted braced arch.

In designing this bridge it soon became apparent that an additional wind chord would be required for the outer quarters of the span, or for about one-half the bridge. The speaker, who was in charge of the design, then arrived at the conclusion that the form now adopted for the Florianopolis Bridge would prove more suitable, as it does not require an additional wind chord and presents a more pleasing appearance.

In 1907, the speaker made a design for a bridge across the Kill van Kull between Staten Island, New York, and New Jersey, in which he proposed a stiffened suspension bridge of exactly the type adopted subsequently for the Florianopolis Bridge. An outline of its elevation and cross-section is shown in Fig. 42.

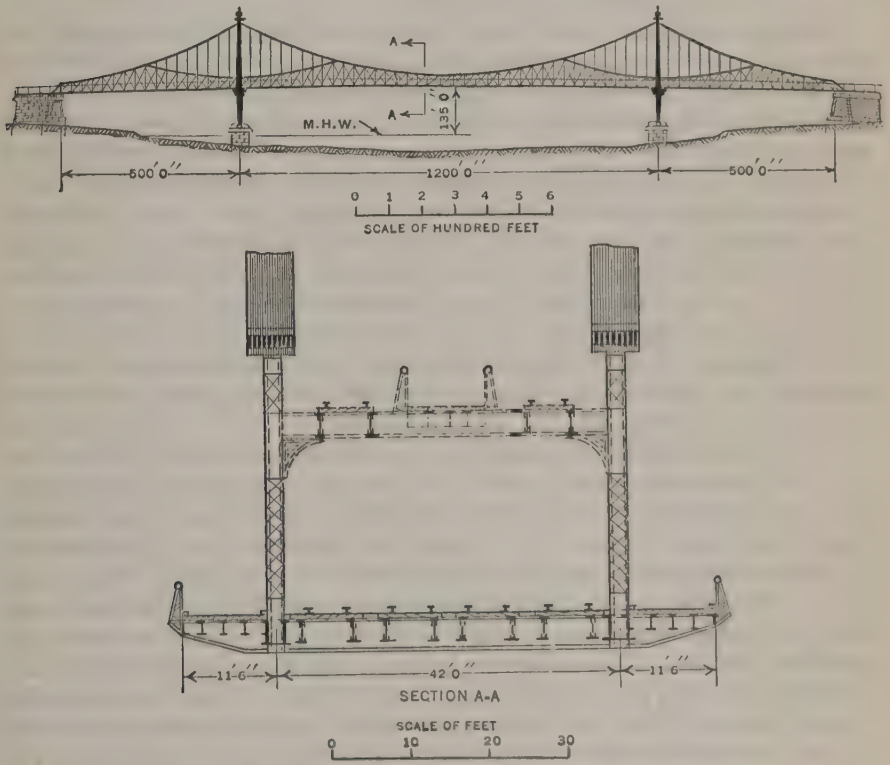

FIG. 42.—SECTION OF PROPOSED BRIDGE OVER THE KILL VAN KULL.

The bridge was planned as a combination railroad and highway bridge. It was proposed to provide for four railroad tracks, two surface-car tracks, two narrow roadways, and a footwalk. With the heavy live load, amounting to 22 000 lb. per lin. ft. of bridge, and the greater stiffness required for railroad traffic, a deep stiffening truss became a necessity. The design shown was

the more suitable because the comparatively short span of 1 200 ft., which was slightly longer than that of the Florianopolis Bridge, lent itself to the economic use of nickel-steel eye-bars. At that time these bars were the strongest structural steel bars available. The arrangement of the eye-bars is shown on the cross-section. The lower chord was utilized as the chord of the horizontal wind truss. For better appearance, the truss ends at the towers show the line of the upper chords continued.

The type of the stiffening truss of the Florianopolis Bridge, however, has its limitations. As the span grows longer the depth at the peaks of the truss becomes greater, with the result that the web members become excessively long and limber. This is still more accentuated by the fact that to obtain the most economy with this type of truss the versine of the chain should be relatively large and with it the depth of the truss at the peaks increases in proportion. Thus, for example, a span of 2 000 ft. would well result in a depth of truss at the peak points of more than 85 ft.

Another limitation which effects one of the reasons for the type is the fact that the moment curve of the stiffening truss begins to flatten as the span and the dead load increase and its depression from the quarter-points toward the middle are much reduced. Considering that the wind moment is greatest in the middle portion, the combined moment curves become nearly parallel to the lower chord. Much of the advantage of this type will thus be lost. Only a very heavy live load will overcome this limitation. This type of stiffening truss, therefore, will make its best showing where the live load is heavy and the span not too long. This points directly to railroad bridges carrying freight as well as passengers. The stiffened chain bridge, therefore, will be found to be most suitable for long-span railroad bridges.

For modern long spans with relatively light loads of highway traffic, surface cars, and even rapid transit trains, the suspended stiffening truss with parallel chords will be found suitable for the center span.

In discussing the rocker towers of the Florianopolis Bridge the authors state that "the evolution of suspension-bridge tower design has been marked by three successive types". First, the rigid tower; second, the flexible tower; and "as a further step toward the reduction and simplification of tower stresses, the rocker type of tower has been developed." Historically, this is not correct. The chain design proposed in 1903 for the Manhattan Bridge provided for towers of the rocker type; so were also the towers of the Budapesth Bridge. At that time no bridge of any size, with towers designed to bend, was either proposed or built. The present towers of the Manhattan Bridge were the first to be designed in 1905 with fixed saddles and proportioned to allow for their horizontal displacements by bending of the steel posts. The fixed-tower design was then chosen for its better appearance as well as easier erection. The Budapesth and the Cologne Bridges are low-level bridges and of comparatively short spans, their towers are not high, and to deflect them horizontally was impracticable. For these bridges rocking towers were considered best. However, where the towers attain great heights, their resistance to the horizontal displacement of the top becomes very small, and the bending

stresses caused by it become light for slender towers. One needs only to recollect that the unit stress for bending is inversely proportional to the square of the tower height. This is the guiding principle in the technical selection of the tower. Correctly designed and proportioned, a tall tower with a fixed base should hardly require more material than a rocker tower.

It may be of interest to state that the McClintic-Marshall Company, that is building the Detroit River Bridge with a span of 1 850 ft., has adopted towers of the fixed-base type.

R. McC. Beanfield,* Assoc. M. Am. Soc. C. E. (by letter).—This paper presents much information of great value and considerable interest, especially from an economic standpoint, in the design and erection of long-span bridges. The novel features in the design and installation of this large structure have demonstrated some economical advantages that will doubtless have considerable influence in the planning of future long-span bridge projects.

The writer has had occasion to check the stresses in a structure containing several groups of eye-bar members. Extensometer readings were made with considerable care (with a Berry 8-in. machine) and temperature changes checked with a standard try-bar. Considerable variation in stress was found in the individual eye-bars that were grouped to form a member of the truss. While the cause of this variation in stress in each eye-bar is not definitely known, it is the writer's opinion that the pin clearance, minor differences between pin-hole distances that require extreme care in shop measurements, and secondary stresses and deformations in the eye-bar heads, were the underlying reasons.

It would be interesting to know if extensometer readings were taken on the eye-bar chains to ascertain if there was any great variation in stress in the individual eye-bars that were grouped to form a unit or link of the chain. By comparison, it would be of further interest to know if there is much variation in stress in the wire strands in some of the large suspension bridge cables.

One of the most important structural units in a suspension bridge is the tower castings supporting the cable. Maximum intensity of stresses in these castings should be comparatively low. In this connection, there may be some question as to the amount and intensity of the secondary stresses induced in the casting and connecting eye-bars due to fixity or lack of rotation in the pin joint. If the primary stresses in the eye-bars are not sufficient to overcome the frictional resistance of the pin, rotation will not occur, and the joint may be considered as fixed. According to experiments of Föppl, the coefficients of friction for steel pins on steel may vary from 0.25 to 0.29, which would indicate that the pin friction would permit stresses of about 50% in excess of the primary stress prior to rotation on the pin.

Data on the frictional resistance of pins are very meager. Any assumption made relative to the coefficient of pin friction is more or less a matter of guesswork which, in turn, reduces the reliability of secondary stress analysis relative to pin joints.

* Structural and Mech. Engr., Los Angeles, Calif.

The design of the rocker casting details at the base of the tower (Fig. 7) presents some very interesting features that raise some questions, as follows:

(*a*) Security against displacement by earthquake shock, particularly by horizontal shear.

(*b*) The extreme high bearing stress on the contact surface of the rocker castings extending over a line of contact 45 in. long, on which 4 840 000 lb. must be supported.

The action of the horizontal component, or wave of an earthquake, sets up a violent movement of the earth's crust which, in turn, is transmitted to the lower supporting medium of the structure. The upper part of the structure, due to its inertia, tends to remain in its original position. Therefore, the hinged or flexible tower castings, together with the four 3-in. screwed dowels and columns, must resist violent successive forces (shears) before they can move the superstructure in the direction of the vibration.

Furthermore, the effect of the period of seismic vibrations on the induced stresses in the structure, combined with the period of elastic vibration of the structure itself, is a matter of considerable importance, especially in the tower frames, where nearly all the load of the suspended spans is supported on the top of the towers. This condition tends to intensify the oscillatory movement, thus increasing the destructive forces induced in the structure. For this reason, it would indicate that suspension bridges, in general, are not adaptable for locations known to have (active) seismic disturbances.

In general, more serious consideration should be given to the resistance to seismic forces in structures, particularly those projects involving millions of dollars in cost. It is a fact that there are no white spots on the earth that are free from seismic disturbances. There are ample records showing that the eastern slopes of the Western Hemisphere have had a fair number of very destructive earthquakes, such as a series of violent earthquakes in the St. Lawrence region in 1633, the Boston earthquake in 1755, the Missouri earthquake in 1811, and the Charleston earthquake in 1886.

Engineers on the Pacific Coast are giving serious consideration to the subject of seismic analysis of structures, probably more than ever, due to the influence of the recent Japanese earthquake. Also, since the Pacific Coast earthquake, the insurance rates have been unduly increased, the same applying alike to properly and poorly designed structures.

In the design and construction of the Carquinez Strait Bridge, in California, one of the largest cantilever type bridges in the world, resistance to seismic forces was considered by the installation of hydraulic buffers to absorb some of the shock and automatically bind the structure together, to increase its rigidity.

The cost of providing proper resistance to minimize damage from earthquake shocks is a very small percentage of the total cost of most structures; therefore, from an economic standpoint, it would be a wise policy.

Relative to the rocker bearing, which is virtually a linear contact 45 in. long, supporting about 4 800 000 lb., there must be considerable deformation

of the contact surfaces with a unit bearing stress of high intensity. It would be interesting and instructive to know the basis of design for this important detail.

Charles F. Stowell,* M. Am. Soc. C. E. (by letter).—The Florianopolis Bridge marks an epoch in suspension bridge construction and although it is of comparatively moderate dimensions for a bridge of that character, in design and construction it so typifies, in nearly all its elements, the most advanced ideas and research that it is likely to serve for a long time as an example to be followed by those who seek perfection in the building of such bridges. While many of the distinctive elements have been previously suggested, it remained for the designers of this bridge to put them into practical use for the first time; and the designers' clear and complete explanation of the steps and processes leading to their results make this paper a classic of its kind.

The one discordant note in the otherwise harmonious whole is the unfortunate predominance of the single element of cost, which prevented the use of wire instead of eye-bars for cables "by a small margin". The superiority of wire over eye-bars for cables is so great that a difference in cost "by a small margin" should not be a controlling factor in deciding between them.

In any long-span bridge of whatever type the dead load is always the chief part of the weight to be supported, and various devices are adopted to reduce this weight to its lowest terms. This is accomplished both by skillful designing and by the use of various kinds of alloy steel of greater strength than ordinary structural steel, thus permitting a smaller quantity to be used; or, as in this case, by special heat treatment of steel normally of less strength, to increase its strength and thus reduce the dead weight of the structure.

The cables of the Florianopolis Bridge are made of eye-bars, each cable composed of four bars 12 in. wide and approximately 41 ft. long and of a thickness varying from $1\frac{1}{8}$ to 2 in., proportionate to the varying maximum stress in the different panel lengths. The chemical composition of the steel used for these eye-bars is not given, so that its approximate normal strength before heat treatment cannot be estimated; but, after treatment, the thirteen bars used for full-sized tests gave an elastic limit (yield point) varying from 78 180 to 96 830 lb. per sq. in. and an ultimate strength of 115 970 to 137 900 lb. per sq. in., the specified requirements being a minimum of 75 000 lb. and 105 000 lb., respectively. The capacity of the machine on which full-sized tests were to be made, was limited to lengths of 40 ft., or less than the lengths generally to be used for the cables; so that of the twelve bars originally decided upon for such tests, only two were actually selected from those made and intended for use in the bridge, while the other ten were bars made expressly for testing purposes and not actually representative of those to be used in the bridge. It is contrary to the experience of human nature not to assume that, knowing that these ten bars were the ones made expressly for test purposes, extraordinary care would have been taken to make them in every particular as nearly perfect as was humanly possible; and yet one of them failed signally in that it did not give nearly the percentage of elongation expected and specified; and so another test bar was made, which fortunately did fill all the

* Civ. Engr., Albany, N. Y.

requirements. How many of the other bars, which were not tested, might show similar results there is no possible means of determining. All the bars made, including the one that failed, were subjected to delicate and ingenious tests to determine their degree of hardness and the uniformity of their texture; but, unfortunately, no one can tell how much a bar is going to stretch without stretching it.

It may be interesting to consider what may be the result if even one of these were to have as low a percentage of elongation as the test bar that failed. This bar measured 12 by 2 in. and showed a percentage of elongation of 3.8 on a measured length of 18 ft., while the other ten bars tested showed an average percentage of 6.996, or, say, 7 for the same length. The bars of this size are mostly used in the back-stays (176 in all) and in each panel length there are four such bars, bearing a total maximum stress of 4 381 000 lb., or 45 635 lb. per sq. in., if all four pull equally. When placed under stress all these four bars must elongate to an equal amount and if any one of them is abnormal in respect of having a lower elongation ratio than the other three then that bar must bear more than its normal proportion of the total stress and the others will be correspondingly relieved. With one bar in a group of four having an elongation percentage of 3.8, while the percentage of the others is 7.0, means that, in order to stretch all of them to an equal amount, the abnormal bar will have to carry 35.2% of the total load and each of the others 21.6% thereof; that is, for a maximum total stress of 4 381 000 lb., the abnormal bar will carry 1 542 112 lb., or 64 250 lb. per sq. in., while the three normal bars carry 2 838 888 lb., or 39 429 lb. per sq. in., instead of the intended maximum of 45 635 lb. per sq. in. which all were designed to carry.

This, of course, is pure hypothesis and is only offered as an illustration of the uncertainty necessarily incidental to the use of chains of this type and against which there is no positive insurance.

With every kind of forged or riveted structural members, full-sized tests are destructive to the members tested and, at best, knowledge of the actual strength of the members used in the structure is based inferentially on the behavior of similar members tested to destruction; but with cable wire two full-sized tests on every individual wire in the cable can be made; and these tests, moreover, are always made on parts of the wire known from experience to be the poorest, namely, near the ends. The process of wire-drawing itself is a good criterion of quality and uniformity. Occasionally, but not very often, a wire will break in drawing, which indicates some undiscovered flaw or inequality in the metal, and, of course, causes the rejection of that particular wire. There is no kind of steel construction about which there is such absolute and accurate knowledge of qualities and strength as modern wire bridge cable.

Another advantage of wire over eye-bar cables is the very much less weight of metal used for splicing purposes. In the Florianopolis Bridge the cable bars are connected at intervals of about 41 ft. and the amount of metal used for connection purposes only, consisting of eye-bar heads, pins, nuts, etc., is obviously large, but the given data are not sufficient to estimate it accurately. In a wire cable the wires are ordinarily about 3 300 ft. long and weigh approx-

imately 330 lb., each wire being spliced to the next one by a sleeve-nut. In the Manhattan Bridge these sleeve-nuts are $1\frac{3}{8}$ in. long and weigh about $\frac{1}{2}$ oz. On the Delaware River Bridge they are 2 in. long and weigh about $\frac{7}{8}$ oz.

In an eye-bar cable, moreover, there are many places accessible to moisture, which cannot be reached by a paint brush or even by a spray, such as the spaces between eye-bar heads and, in the case of elongated eyes, as in the Florianopolis Bridge, the vacant part of the eye. In a wire cable, the entire interior is saturated with a rust-resisting mixture, tightly squeezed under powerful pressure, tightly wrapped with galvanized wire, and, finally, painted, making every part of the cable as nearly proof against rust as it possibly can be.

The strength of ordinary cable wire, moreover, is such that it may safely be used for a maximum unit stress of 80 000 to 100 000 lb. per sq. in., as against 46 500 lb. for heat-treated eye-bars, thus effecting a further saving in the important item of dead weight.

There is, apparently, among some steel manufacturers a fascination for secrecy in parts of their work, which is amusing even if rather silly. In olden times metal workers ascribed their success in producing some particular results to conjuring, and apparently the idea or something like it seems still to persist. One of the largest manufacturers of wire used to, and perhaps still pretends to, claim that there is a mystery about the bath of molten lead through which the wire is drawn for the purpose of so-called "galvanizing", and the receptacle for this bath is carefully locked and guarded throughout the process. A large manufacturer of steel plates for rust-resisting floor-treads declines to furnish any analysis of his product on the ground that it is a secret that he prefers not to make public, apparently oblivious to the fact that any one who wants such an analysis can very easily make it. As a matter of fact, these plates are made of an ordinary grade of steel with the addition of as much copper as can be used without making it "red short". It is a good mixture and well adapted for its purpose, but the pretense of secrecy about its composition is amusing. In the case of the eye-bars for the Florianopolis Bridge the manufacturers adopted a policy of secrecy and refused to permit any investigation of their proceedings; whereupon the engineers wisely declined any responsibility for such bars. Heat treatment of steel for the purpose of increasing its strength is not a new idea, but its application on a considerable scale has not been practiced until recently, and, although the manufacturers of these bars deemed it necessary to clothe their operations in a smoke-screen of mystery, there is no reason to believe that any skillful eye-bar maker could not duplicate their results after very little experimenting and without any pretense of conjuring. Apparently, however, the makers of these bars did not foresee that their secret operations would necessarily lead to the result that engineers in charge of work would decline responsibility for any manufactured article produced by pretended secret processes. It is gratifying to learn that the manufacturers of the eye-bars have accordingly decided to discard the element of secrecy, under the somewhat tenuous pretext that the process is now so far perfected that resort to secret operation is no longer necessary.

HARDY CROSS,* M. AM. SOC. C. E. (by letter).—That this paper represents a valuable contribution to the art of bridge design and construction is at once recognized. The writer's comments are restricted to only one aspect of the design.

The authors indicate doubt as to the propriety of applying to suspension bridges criteria for stiffness borrowed from other types of bridge construction. In this they are probably correct. The question is of importance in considering the economics of continuous and other structures. Live-load deflection is often only the obvious and measurable phenomenon which accompanies other phenomena of greater importance.

Large deflection of bridges may be objectionable because:

(*a*) It produces unsightly distortions. This can almost always be corrected by camber.

(*b*) Distortion produces grades in the roadway which interfere with traffic operation. This is a definite limit on deflection; so far as the writer knows, it occurs only in suspension bridges.

(*c*) Vibration accompanies deflection, and vibration is to be avoided because: (1) It wears out the structure; and (2) it may be psychologically objectionable, producing a sense of fear in the pedestrian or passenger.

In most bridges the objections to deflection are associated with vibration. It is clearly recognized that vibration wears out—or tends to wear out—a structure; it loosens rivets in steel work and probably destroys bond in reinforced concrete. It may also produce what is usually called fatigue. While this is clearly recognized qualitatively, a quantitative measure seems impossible in the present state of the structural art. Structural mechanics commonly ignores entirely those phenomena which occur while parts of the structure are in motion and restricts itself to conditions existing when the structure has come to rest. Vaguely, designers treat the effects of deflection by the application of an "impact" coefficient.

It is probably true that a large deflection is an indication of high "impact" effects; but that it is a satisfactory measure, or that the durability or the freedom from shock is a function chiefly of deflection, independent of the type of structure, there seems to be no evidence at all.

As regards the objectionable psychological effect of vibration, it is probable that deflection is no fair measure at all. Objectionable movement probably means high acceleration; passengers apparently are not conscious of uniform movement.

It is possible to establish certain relations between the acceleration produced at any point by a unit load at any other point and the velocity of the load, but this does not help the problem very much.

The whole subject becomes of great importance in many cases. The limitations on deflection borrowed from practice in the design of simple spans affect the economy of continuous girders and trusses adversely. There

* Prof. of Structural Eng., Univ. of Illinois, Urbana, Ill.

is not much basis for a comparison of the types. The writer would appreciate any information as to who first established the existing rules in this regard, and why they were established.

D. B. Steinman* and William G. Grove,† Members, Am. Soc. C. E. (by letter).—The economic advantages of the Florianopolis type of suspension bridge has received commercial recognition and confirmation in the proposal and adoption of this form of construction in two successive bidding competitions. These are the 700-ft. spans over the Ohio River at Point Pleasant, W. Va., and St. Mary's, W. Va., respectively. In each case, the Florianopolis type was proposed by the American Bridge Company as an alternative bid, at a price sufficiently below the tenders on the conventional suspension designs to win the respective competitions. The bids showed that, for a span length of 700 ft. and for the relative unit stresses specified, heat-treated eye-bars are more economical than wire cables at present prices; and that the combination of the eye-bars with the Florianopolis type offers a further saving in the cost of the structure.

It is true, as stated in some of the discussions, that the relative economy of eye-bars and wire cables was not conclusively demonstrated by the case of the Florianopolis Bridge. The relative unit stresses specified for the two materials and the length of the span are governing factors. In the wire cable design for Florianopolis, the specified working stress was 70 000 lb. per sq. in., and the heat-treated eye-bars were offered (at equal total cost) to be used with a working stress of 50 000 lb. per sq. in. Had a higher stress been specified for the wire or a lower stress for the eye-bars, so as to provide equal factors of safety for the two materials, it would have been more difficult for the eye-bars to be offered at equal cost. In the opinion of the designers of the Florianopolis Bridge, the fair stress ratio to use is 2 to 1, since that is approximately the ratio of the respective specified yield points or ultimate strengths of the two materials. This suggested ratio of working stresses has not yet become established because of the difficulty of overcoming the conventions of past conservative practice in wire cable design—a handicap from which the newer material of heat-treated eye-bars does not suffer.

There is, however, a marked present trend toward the adoption of higher unit stresses for cable wire. For the Ohio River Bridge, at Portsmouth, Ohio, the adopted design stress for the wire cables was 80 000 lb. per sq. in. In the recent bidding competition for the Hudson River Bridge, at New York, N. Y., the respective specified unit stresses were 50 000 lb. per sq. in. (with the secondary stresses included) for the heat-treated eye-bars, and 82 000 lb. per sq. in. (with secondary stresses not included) for the wire cables. During the past few months, heat-treated cable wire has been developed, offering a minimum yield point of 190 000 and a minimum ultimate strength of 220 000 lb. per sq. in. This wire has been adopted for the international bridge at Detroit, Mich. (span, 1 850 ft.) and for the Mount Hope Bay Bridge, in Rhode Island (span, 1 200 ft.), with a working stress of 84 000 lb. per sq. in.

* Cons. Engr. (Robinson & Steinman), New York, N. Y.
† Asst. Engr., Am. Bridge Co., New York, N. Y.

for the former and 88 000 lb. per sq. in. for the latter. Heat-treated bright wire is now offered with a yield point of 200 000 and an ultimate strength of 240 000 lb. per sq. in., for which still higher unit stresses would be specified.

In the bidding on the Hudson River Bridge, the wire design won by a margin of $2 000 000, indicating that the eye-bars cannot compete with wire cables for extremely long spans. The awards on the Point Pleasant and St. Mary's Bridges indicate that heat-treated eye-bars, at present relative prices and working stresses, are more economical than wire cables for spans as short as 700 ft. It is difficult to predict the relative economy of the two materials for span lengths between these limits (700 ft. and 3 500 ft.) without further bidding competitions. Any conclusions are subject to revision with changes in relative working stresses and with fluctuations in unit prices.

Although the manufacture of eye-bars is now a monopoly, the prices for heat-treated eye-bars are affected by the economic competition offered by wire cables. This competition, which came into play with the bidding on the Florianopolis Bridge following the development of the heat-treated eye-bars, has had a wholesome effect in stimulating improvements in the materials for higher physical properties and improvements in economic production toward reduced unit prices; also in prompting engineers to scrutinize established conventions with a view toward securing a more consistent basis for the specification of working stresses.

The writers fully appreciate the generous discussions that have been contributed to this paper, and will refer to them in the order of their presentation.

Mr. Waddell raises some questions in regard to details of proportions and form for designs of the Florianopolis type. The writers' statement that the utilization of the cable as the upper chord of the stiffening truss "should preferably be limited to the central half of the span", referred only to the loss of economy if the construction were extended to the ends of the span; it was not intended to specify any definite proportion as most economical. A variation of a few panels on either side of the quarter-points would produce a negligible difference in economy of material; practical considerations govern instead. In the case of the Florianopolis Bridge, after several variations of the design were studied, the outline shown in Fig. 2 (*a*) was adopted, with somewhat less than one-half the span (11 double panels out of 27) utilizing the cable as the top chord; this was done to avoid excessive height, and excessive variation in height, of the truss. In the design adopted for the Ohio River Bridges at Point Pleasant and St. Mary's, the central construction also extends over less than the half-span (12 panels out of 28), on the basis of similar practical considerations.

The proportions and outlines suggested by Mr. Waddell were included among those studied for the Florianopolis Bridge and were abandoned in favor of the adopted layout. The question of the comparative appearance of the design used and that suggested by Mr. Waddell in his Fig. 38 is one of individual taste; this also applies to his remark that the conventional design, Fig. 2 (*b*), would have had a better appearance with a deeper truss and with fewer suspenders; on both these points there are many who would take the

opposing view. In the adopted design, the top chords in the outer quarters of the span were made straight, rather than curved, for the advantages of economy and simplicity in detailing and fabrication, as well as for structural efficiency. It is questionable whether curved top chords in the outer quarters (Fig. 38) really offer improved appearance, except where the construction is carried symmetrically into the side spans as in Fig. 42.

Mr. Waddell, while recognizing the justification of the claims for greater rigidity of the new type of stiffening truss, inquires in regard to confirmatory deflection tests on the finished structure. Such tests cannot be made without great difficulty until the railroad, which was intended to traverse the bridge, is built; and it is doubtful whether the local governmental authorities would be sufficiently interested in the scientific value of the results to authorize the expense of deflection tests. The designers are confident of the confirmation that would be yielded by such tests, for it is invariably found that the actual measured deflections of a suspension bridge are less than the calculated amounts. Although no live load deflection tests have been recorded for the Florianopolis Bridge, a close verification of the computed dead load deflections was afforded by the official test to determine whether the required vertical under-clearance from water level had been realized.

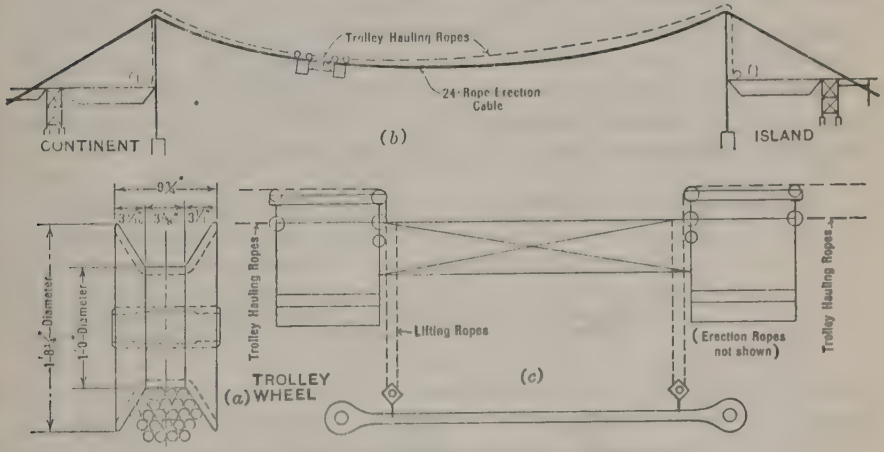

FIG. 43.—MAIN SPAN EYE-BAR TROLLEY OPERATION.

The problem of supporting the rocker towers during their construction and during the erection of the eye-bar cables was given considerable study. A solution was found whereby the actual amount of erection material required was very small, consisting merely of some plates and angles at the ends of the temporary struts which tied the tower columns to the U-1 and L-1 points of the adjoining 185-ft. spans. The struts themselves consisted of material later used for the suspension-span bracing in the finished structure.

The principle of the double-bored pin-hole in the eye-bar heads was used by the American Bridge Company in 1912 in the connecting links joining the

spans of the Kenova Bridge* during cantilever erection, in order to facilitate the swinging of the spans. To the writers' best knowledge, this principle had never actually been incorporated in holes in the heads of eye-bars, prior to its use on the Florianopolis Bridge.

The writers appreciate the complimentary remarks of Mr. Miller, relative to the use of 1-in. ropes to form the temporary cable from which the eye-bars were erected.

The twenty-four erection ropes were grouped together in the form of an elongated hexagon shown in Fig. 43 (*a*). The wheels of the main-span trolley used to erect the eye-bar cables were made to fit this hexagon, so that eight ropes were actually in contact with the wheels. They were closely compacted to the remaining sixteen ropes by the weight of the trolleys and by the loads of eye-bars applied to the ropes by the chain hoists.

After the pilot rope was erected, the remaining twenty-three ropes were placed and adjusted to the same sag as the pilot rope. Each rope under its own weight then had a stress of approximately 3 000 lb. and had stretched about 2.7 ft. in 1 700 ft. Later, when the entire weight of the eye-bars was supported by the ropes, each rope had an average stress of approximately 30 000 lb. and had stretched about 15.1 ft. in 1 700 ft.

The actual elongations of the nine test pieces of rope, when stressed the first time to 30 000 lb., are given in Column (2) of Table 15. The actual elongations of Ropes *L*, *M*, *R*, *S* and *X*, when stressed the second time to 30 000 lb., are given in Column (4). The average elongation for Column (2) is 0.0895 in. in 10 in., very close to the elongation of Test Rope *M*. For Column (4) the average elongation is 0.0891 in. in 10 in., very close to the elongations of Test Ropes *M* and *X*, or practically 0.89 per cent.

TABLE 15.—ELONGATION AND STRESSES IN TEST PIECES OF ROPE.

	First Application of Load.		Second Application of Load.	
	Elongation, in 10 in.	Imaginary cable stress, in pounds.	Elongation, in 10 in.	Imaginary cable stress, in pounds.
(1)	(2)	(3)	(4)	(5)
Rope *A*	0.0950	28 300	.....	.....
" *F*	0.0905	29 700	.....	.....
" *G*	0.0997	27 000	.....	.....
" *K*	0.0976	27 500	.....	.....
" *L*	0.0984	27 300	0.1042	25 600
" *M*	0.0897	30 000	0.0884	30 200
" *R*	0.0657	41 000	0.0712	37 600
" *S*	0.0850	31 600	0.0929	28 800
" *X*	0.0841	32 000	0.0886	30 200
Average	0.0895	30 500	0 0891	30 500

Assuming a composite cable made up of the nine test ropes to carry an average of 30 000 lb. per rope when elongated 0.89%, it is found that Test

* See "Reconstruction of the Norfolk and Western Railway Company's Bridge Over the Ohio River at Kenova, West Virginia," by William G. Grove, M. Am. Soc. C. E., and Henry Taylor, Esq., *Transactions*, Am. Soc. C. E., Vol. LXXIX (1915), p. 411.

Rope *R* would carry more, and Test Rope *L* less, than 30 000 lb. The actual stress that each test rope would carry when the 9-rope cable is stressed to 30 000 lb. the first time is given in Column (3) of Table 15 and the actual stress that each of Test Ropes, *L, M, R, S,* and *X* would carry when this rope cable is stressed to 30 000 lb. the second time is given in Column (5). It is seen that the actual stress in the nine test ropes would vary from 27 300 to 41 000 lb. when the 9-rope cable is stressed to 30 000 lb. the first time, and the actual stress in the five test ropes would vary from 25 600 to 37 600 lb. when the 5-rope cable is stressed to 30 000 lb. the second time. From this analysis it may be reasonable to assume that the actual stress in the twenty-four ropes used in the cable varied from 25 000 to 40 000 lb., when the entire 24-rope cable carried an average stress of 30 000 lb. per rope.

In reference to the operating ropes for the main-span trolley used to erect the eye-bars, Fig. 43 (*b*) is a diagrammatic view of the operating lines running to the tops of the towers and thence down to engines on the viaduct floor. Fig. 43 (*c*) shows, to enlarged scale, both the operating and the load lines. When the continent engine pulled the trolley westward, the island engine played out the operating rope. When the trolley had been properly spotted, both engines were used to raise the eye-bars. Either end of the eye-bars could be raised or lowered slightly by operating the particular engine controlling that end of the bar without operating the other engine.

Fig. 44 shows diagrammatically the trolley used for the erection of the suspended span. In the upper view (Fig. 44 (*a*)) are seen the operating lines to the two engines which controlled the movements of this trolley in a manner similar to that in which the movements of the main-span eye-bar trolley were controlled. The lower view (Fig. 44 (*b*)) shows both operating and load lines. In the case of the load line, there was only one set of falls and the line ran continuous from engine to engine. When the lift was near the continent, the continent engine was operated; when near the island, the control was by the island engine. When the trolley itself was moved, the lifting line ran idle through the block.

Mr. Frost states that the Florianopolis design and its method of erection may extend the range of use of structures of the suspension type. In this connection, it may be noted that the past few years have marked a period of renewed activity all over the United States in the design and construction of suspension bridges, especially for spans ranging in length from 600 to 1 200 ft. Contributing factors have been improvements in economical design and erection, the development of higher strength eye-bars and wire, and the competitive reduction of unit prices on the two materials. Erroneous notions of the relative expensiveness of suspension construction have been partly dispelled, and the advantages of the type have become more widely recognized. It is difficult, at this stage, to appraise the influence of the Florianopolis design and method of erection on this development. Nevertheless, it may be significant to note that four Ohio River bridges (Portsmouth, Steubenville, Point Pleasant, and St. Mary's) commenced in 1926-27, are suspension struc-

tures, where cantilever construction previously prevailed; and that only two of these bridges are wire cable designs, the other two being eye-bar designs of the Florianopolis type.

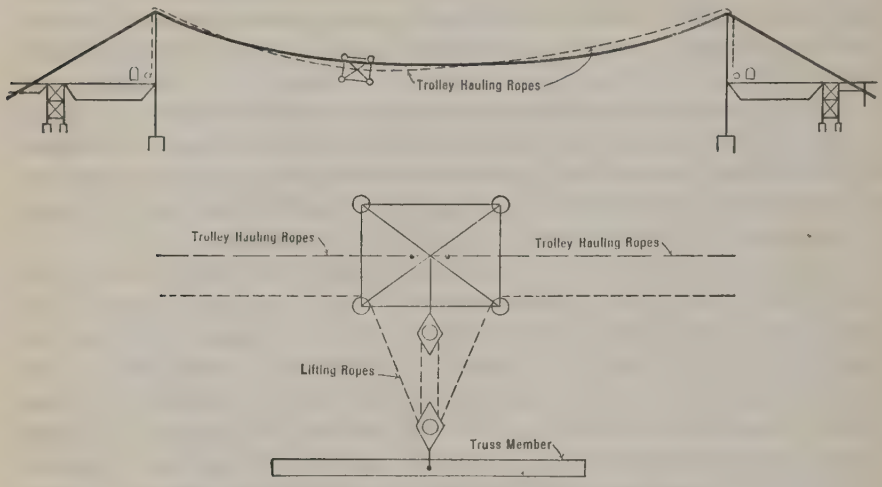

FIG. 44.—TROLLEY USED FOR SUSPENDED SPAN ERECTION.

Mr. Larsson presents an interesting historical outline of the development of the eye-bar industry. As is generally well known in the profession, Mr. Larsson with the late C. W. Bryan, M. Am. Soc. C. E., Chief Engineer of the American Bridge Company, deserves full credit for the development of the heat-treated eye-bars, first in the medium grade (elastic limit, 50 000 lb. per sq. in.) developed in 1914, and, subsequently, in the high-tension grade (elastic limit, 75 000 lb. per sq. in.) developed in 1921 and receiving its first practical application in the Florianopolis Bridge. It was this high-tension grade of heat-treated eye-bars that made it possible for an eye-bar design to be proposed for competitive bidding as one of the two alternative official designs for the 3 500-ft. Hudson River Bridge.

A deterrent to the more ready acceptance of the new material has been the policy of secrecy covering its manufacture. Structural engineers hesitate to accept a material without full privileges of inspection and chemical analysis. Mr. Larsson's announcement that the policy of secrecy has been discontinued, will be welcomed by the profession. The remaining deterrent, namely, the difficulty of making full-sized tests, should next be removed by the provision of a testing machine large enough to take the longest bars furnished for any structure.

Professor Morris reports an eye-bar suspension bridge of 450-ft. span built in 1914-15 over the Muskingum River, at Dresden, Ohio. The writers regret that they did not know of this structure and that Professor Morris had therein preceded them in the adoption of rocker towers. It is also of interest to note that for this span of 450 ft., constructed in 1914-15, eye-bars of struc-

tural steel grade (ultimate strength, 60 000 to 70 000 lb. per sq. in.) won over wire cables in the bidding competition.

An instructive joint discussion has been submitted by Messrs. Covell, Wilkerson, and Nutter. They commend the Florianopolis Bridge as "a splendid type" from the standpoint of economy, rigidity, and general structural efficiency. On the question of its esthetic value, they express a preference for a curved side-span design with symmetrical contruction, like Fig. 42; but such design would not have suited the local conditions at Florianopolis. On the question of economy, they point out that the total weight of steel in the Florianopolis Bridge is surprisingly low for a structure with a main span of more than 1 100 ft. and a total length of about 2 700 ft.; and the credit for this showing of economy they rightly ascribe to the type of span and the use of high-tension heat-treated eye-bars and a timber floor. On the last point, it may be stated that advantage was taken of the availability of South American hardwood to provide a floor material of great strength and longevity.

The maximum loadings of 50-ton locomotives for the railway and 6-ton trucks for the highway were the official Government specifications for the design; and the local authorities regard as extremely remote any possibility of these loadings ever being exceeded in that locality.

Messrs. Covell, Wilkerson, and Nutter agree that the high-tension heat-treated eye-bars are a proper material for an eye-bar chain (as in the Florianopolis Bridge), but they question whether the ductility of 5% would be sufficient for the use of this material for truss members. To the writers' knowledge, the high-tension eye-bars have not thus far been used in any truss structures; only the medium grade heat-treated eye-bars (8% elongation) have been so used, as in the Carquinez Cantilever Bridge, with two spans of 1 100 ft., and in the Oil City simple spans of 260 and 350 ft.

The three engineers also agree with the writers that the hinged tower for the suspension bridge is a step in the right direction, and they cite their adoption of the rocker-tower design for the Sixth, Seventh, and Ninth Street Suspension Bridges over the Allegheny River at Pittsburgh, Pa.

With respect to appearance, it is impossible to get a real profile view of the Florianopolis structure except when crossing the Strait. From any point on either shore, the bridge is viewed obliquely, and the eye-bar cable seems larger due to seeing all four eye-bars of each cable. The photograph, Fig. 3, does not do justice to the appearance of the structure as ordinarily viewed.

The writers desire to thank Mr. Carstarphen for his comprehensive discussion of the erection problem with reference to the behavior of the wire ropes used to erect the eye-bar cables.

They agree with him that two applications of the load are not sufficient to determine the true value of the modulus of elasticity of wire rope. In the use of the ropes at Florianopolis, however, the modulus of elasticity was not of direct interest, except as a means for determining the actual elongations of the ropes under certain conditions of loading during the erection. There were only two eye-bar cables to erect so that there was an actual condition in

the field corresponding to Mr. Carstarphen's Tests (*a*) and (*b*) of Fig. 41. For these requirements, it was necessary to compute the elongations starting from the original length of the rope, and not from a permanent set value determined from a previous stress in the rope. Referring to Fig. 41, if the modulus was based upon an elongation starting not from the permanent set points, but from the zero points, the result would be as shown in Table 16. The resulting average value of the modulus is fairly close to 8 300 000 lb. per sq. in., the value used at Florianopolis.

As Mr. Carstarphen states, it is known from actual practice that hemp center ropes do not fall apart when bent around sheaves. In fact, the American Bridge Company uses 16-in. sheaves as standard sheaves with 1-in. rope.

In Mr. Carstarphen's discussion, he arrives at a horizontal component in the erection ropes (messenger cables), when these ropes supported all the eye-bars, of 595 627 lb. instead of 660 000 lb. mentioned in the paper. To obtain the horizontal component of 519 527 lb. in the eye-bar cable under its own weight, with a sag of 116 ft., he used the dead load panel concentrations for the eye-bar cable only, as given in Table 10. It was the original intention to erect not only the eye-bar cable, but also the permanent rope hangers (at the ends) and the top chord gusset-plates (at the central portion of the span) from the erection ropes; and the 116-ft. sag was based on the eye-bar cable plus this additional weight. Considering these additional loads, the horizontal component in the eye-bar cable would be 569 000 lb. instead of 519 527 lb. He also assumes 616 lb. for the weight of the chain hoists and their connections; this latter figure was actually very close to 1 000 lb. These additional weights on the erection ropes account for the difference between the two calculated values of 660 000 lb. and 595 627 lb. for the horizontal component in the ropes.

TABLE 16.—Elongations in Test Specimens.

Reference.	Load, in pounds.	Percentage of elongation in 10 in.
Fig. 41 (*c*)	158 400	0.451
" (*d*)	158 400	0.436
" (*e*)	158 000	0.428
" (*f*)	156 600	0.420
Average	157 850	0.434

$$E = \frac{157\,850 \times 10}{2.4\,[0.0434 + 0.0410]} = 7\,800\,000$$

The length of the erection rope cable was based on the assumption of a parabolic curve, but the formula was extended to include the third term in the series,

$$L = l + \frac{8}{3}\frac{y^2}{l} - \frac{32}{5}\frac{y^4}{l^3} + \ldots.$$

it having been found that this last term had an appreciable influence on the length.

Mr. Hoadley reports an independent stress analysis which he made of the Florianopolis Bridge for thesis work. He presents an outline of his method, using the "least work" equation based on Castigliano's principle, and he shows that it is merely another form of expressing the influence line equation for the method of elastic weights as used by the designers of the bridge. The values derived by Mr. Hoadley for the H-influence line are somewhat higher than those of Messrs. Robinson and Steinman (5% higher at mid-span), and he volunteers the explanation that this may be due to an inherent error in his method. His treatment of the top chord members in the middle part of the span requires him to add the contributions of the opposing tension and compression components arithmetically, whereas they should be added algebraically. A review of Mr. Hoadley's thesis shows that his resultant values for the governing stresses in the stiffening truss are lower than the values obtained by Messrs. Robinson and Steinman and used by them in proportioning the structure, affording a welcome independent check on the safety of the design analysis. Mr. Hoadley also derives the H-influence line equation by a modified method, and computes therefrom a value of H agreeing with that found by Messrs. Robinson and Steinman by the method of elastic weights.

Professor Menefee states that there is no longer any real mystery about heat treatment, and he predicts that all the large companies will soon be producing heat-treated bridge members as wanted. He approves the use of the Brinell test as a check on the uniformity of the heat treatment and of the tensile strength. Referring to the absence of the usual secondary and impact stresses, he considers 46 500 lb. per sq. in. (as used in the Florianopolis eye-bar cables) a safe working stress for steel with an elastic limit of 80 000 lb. per sq. in.

The writers agree with Professor Menefee that the substitution of eye-bars for wire cables adds stiffness and reduces deflections. His statement that a cable of equal sectional area will elongate under load more than a solid piece of steel requires clarification. For the same load and the same area of cross-section, a parallel wire cable and a chain of heat-treated eye-bars should show substantially the same elongation, since the respective values of the modulus of elasticity are substantially equal (about 27 000 000 lb. per sq. in.). The more recently developed heat-treated cable wire has a higher value of E (29 000 000 lb. per sq. in.), and, therefore, would elongate about 7% less than heat-treated eye-bars. The reason an eye-bar chain as applied in an actual design would yield smaller elastic elongation and resulting deflection than a parallel wire cable is because the eye-bar chain would be designed with a lower working stress and, therefore, would be provided with a proportionally larger sectional area. With the incorporation of the Florianopolis type, this increase in rigidity is further augmented (very materially) by the effect of the modified form of stiffening truss.

Mr. Kuo presents a valuable discussion of the inherent problem of providing rigidity in suspension bridges. He distinguishes between free cable bridges (with suspended truss) and braced (triangulated) cable types; and he points out that to secure high rigidity in a free cable suspension bridge requires an unusually heavy stiffening truss, resulting in an uneconomical

design of clumsy appearance. He considers the Florianopolis Bridge (which he classifies as a partly braced type) a very scientific and economical solution of the problem.

To the practical reasons given in the paper for seeking rigidity, Mr. Kuo adds another of more technical nature, namely, the reduction of forced deformations in the floor system. He reports having calculated extremely high secondary stresses in stringers resulting from stiffening truss deflections.

In regard to the use of rocker towers, Mr. Kuo points out a possible objection, in some locations, on the score of reduced security against severe earthquake effects. The dowels provided in the base castings of the Florianopolis towers are intended to provide resistance to displacement by such forces; and the writers believe that, with proper design of the base details, rocker towers can be given the same security as fixed base towers against earthquake forces.

Mr. Kuo commends the new departure of the stiffening truss from parallel chords and the unification of the cable with the middle portion of the top chord as the two most admirable features of the Florianopolis design, representing a distinct development in the art of suspension bridge construction. He also points out the visible structural fitness of a design in which the truss depth varies with the magnitude of the bending moments.

Mr. Moisseiff recounts the evolution of stiffening truss forms to that used at Florianopolis. On this subject, to facilitate a review of structural and chronological relationship, the writers have prepared Fig. 45, showing successive developments of suspension bridge forms, illustrated as far as possible with actual applications and their dates. The development of braced cable types embraces the form with full trussing between cable and roadway (like the bridge at Frankfort-on-Main, Germany, 1869-1921, Fig. 45(*c*)); the three-hinged form (Fig. 45(*d*)), with parabolic lower chord and straight top chords (represented by Hemberle's Point Bridge at Pittsburgh, 1877-1927); the forms with parallel chords (like the Seventh Street Bridge, at Pittsburgh, 1884-1926, Fig. 45(*e*), designed by Gustav Lindenthal, M. Am. Soc. C. E., and his more recent design for a Hudson River Bridge at 59th Street, New York); the Fidler truss and other three-hinged forms (Fig. 45(*f*)), using intersecting cable curves (like the bridge built in 1889 over the Tiber at Rome; also Mr. Lindenthal's 1910 design for the Quebec Bridge and his design in 1923 for the Sydney Harbor Bridge); and the two-hinged type (Fig. 45 (*g*)) with parabolic upper chord and polygonal bottom chord (like Mr. Lindenthal's 1899 design for the Quebec Bridge and his 1903 design for the Manhattan Bridge). In comparison with the last type, Mr. Moisseiff arrived at the same conclusion as the writers, namely, that the form now adopted for the Florianopolis Bridge (Fig. 45(*h*)) would be more advantageous, as it dispenses with the necessity of additional wind chords and presents a more pleasing appearance.

Mr. Moisseiff's contribution of an illustrated description of his design in 1907 for a proposed bridge of 1 200-ft. span over the Kill van Kull (Fig. 42), anticipating the Florianopolis design, helps to make the record complete.

Mr. Moisseiff would limit the economic applicability of the Florianopolis type to bridges where the live load is heavy and the span not too long. These

suggested limitations, however, appear to be subject to qualification, as is indicated by the recent adoption of the Florianopolis type in successive bidding competitions for two light highway bridges over the Ohio River. The writers are satisfied that the type can be applied advantageously for span lengths from 700 to 2 000 ft., as indicated by the two Ohio River spans of 700 ft., the Florianopolis span of 1 114 ft., Mr. Moisseiff's Kill van Kull design of 1 200 ft. span, his suggestion for the Manhattan Bridge design of 1 470-ft. span, Messrs. Robinson and Steinman's design (1923) for the Sydney Harbor Bridge, with a main span of 1 600 ft., and a design study (1925) by the American Bridge Company for a railroad bridge of 2 000-ft. span. This range embraces the majority of suspension spans built, and future designs and competitions may further extend these limits of span length for the applicability of the Florianopolis type.

For the longer spans, Mr. Moisseiff advances the objection that the depth of the truss at the peak where the truss joins the cable becomes too deep. In the previously mentioned design by the American Bridge Company for a 2 000-ft. span, shown in Fig. 46, the truss depth at the peak was only 65 ft. The panels in this case were long, so that it was still possible to obtain a satisfactory slope for the diagonals. For spans still longer, it would probably be necessary to resort to a sub-divided panel arrangement to obtain a satisfactory diagonal slope. The writers agree with Mr. Moisseiff, however, that for extremely long spans, relatively shallow independent parallel-chord stiffening trusses would probably be more economical and satisfactory, unless the span is so long and the dead load relatively so high that no stiffening truss at all is necessary.

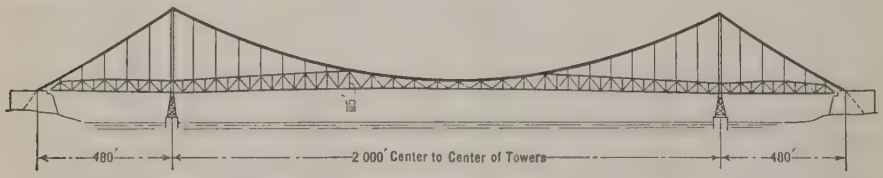

FIG. 46.—PROFILE OF 2 000-FOOT SPAN.

On the chronological sequence in the evolution of different tower types, a distinction should be drawn between priority of mere proposals or designs and precedence of actual adoption and general acceptance. On the latter basis, the rocker-tower type rather than the flexible type appears to be the later development. The flexible design of tower was adopted in 1905 for the Manhattan Bridge, New York (completed 1909), which precedent was followed in American practice in the Massena, Ohio, Bridge (1911), the Parkersburg, W. Va., Bridge (1916), the Kingston, N. Y., Bridge (1921), the Bear Mountain, New York, Bridge, (1924), and the Philadelphia, Pa., Bridge (1926). The rocker type of tower, first used in this country in the Muskingum River, Ohio, Bridge in 1915, did not receive general acceptance prior to its use in the Florianopolis Bridge (completed 1926); it has since been adopted for all new Ohio River bridges, including Portsmouth (1927), Point Pleasant (1928), Steubenville (1928), St. Mary's (1928), as well as for the three new Pittsburgh suspension bridges at Ninth Street (1926), Seventh Street (1927),

and Sixth Street (1928). For two decades (1905-25) the flexible type of tower prevailed, almost without exception; then, commencing with the Florianopolis Bridge, the rocker tower design was generally accepted, with eight bridges of this type built in three years as against only three of the fixed base type undertaken in the same period. This succession of types in actual practice is what the writers had in mind in their remarks on the evolution of suspension-bridge tower design.

Mr. Moisseiff suggests that the choice between rocker and flexible types would depend on the height of the tower, since "a tall tower with a fixed base should hardly require more material than a rocker tower". There are other considerations, besides economy of material, that affect the choice, such as the difficulties and expense of cable erection adjustments with fixed base towers on the one hand, and the availability or lack of convenient means for holding the rocker towers during erection on the other. That the erection advantages of the rocker type are recognized by experienced erectors is indicated by the request of the American Bridge Company, during 1927, for permission to change the towers of the Mid-Hudson Bridge at Poughkeepsie, N. Y. (1 500-ft. span) from the flexible type to the rocker type under its contract.

The use of rocker towers greatly facilitates the necessary erection adjustments. Such towers are easily tilted back shoreward any amount as required for the connection of the back-stays to the saddle castings in bridges with eye-bar cables, or for the balancing of the catenaries during cable construction in bridges with wire cables. To hold the rocker towers in the required position during erection generally requires only a small amount of temporary material at the tower bases. With the use of fixed base towers, the necessary tower-top adjustments for cable erection are made more difficult.

Mr. Moisseiff cites the fact that the designers of the Detroit River Bridge (of 1 850-ft. span) have adopted towers of the fixed base type. Calculations recently made by Messrs. Robinson and Steinman, in the course of their erection studies for the cable contractors on this bridge, reveal the fact that the tower tops have to be moved shoreward the unprecedented amounts of 7.34 ft. on the American side and 5.04 ft. on the Canadian side, in order to balance the cable catenaries during erection. Pulling the towers back these indicated amounts would be a difficult and expensive operation, and methods for obviating this necessity also involve unanticipated difficulties and expense. If these results had been foreseen, it is doubtful whether fixed base towers would have been selected, since the adoption of rocker towers would have eliminated these difficulties.

The required tower movements during cable erection are most serious in designs with "straight" (unloaded) back-stays as in the Florianopolis, Bear Mountain, and Detroit Bridges. In such layouts, the rocker type of tower has especial advantages.

In addition to the advantages of economy of material in the towers and the elimination of expensive tower or saddle adjustments during erection, another advantage of rocker towers must not be overlooked; namely, the reduction of stresses (and consequent possible reduction of dimensions) in the masonry piers from the elimination of tower bending stresses.

Mr. Beanfield refers to extensometer readings made on bridge members composed of groups of eye-bars and reports that he found considerable variation of stress in the individual eye-bars of a group. He attributes this to pin clearance, minor differences between pin-hole distances, and deformations in the eye-bar heads. The writers regret that no extensometer readings were taken on the eye-bar cables of the Florianopolis Bridge to ascertain, as suggested, if there is any great variation in stress in the individual eye-bars of each link. Neither, to their knowledge, have such measurements ever been made on the wire strands of large suspension bridge cables. In the case of a wire cable, the method of stringing (to equal sags) practically assures uniform tension of all the wires; and any local slackness of a wire is not material since it is only one of thousands of wires composing the cable and, therefore, represents only a very small fraction of 1% of the total section. Moreover, the compacting of a wire cable after stringing is such as to assure unified stress action; even if a wire is cut at any point, it will be found to have full stress again (transmitted by the frictional bond) a short distance away from the section.

Referring to the details of the top castings on the towers, Mr. Beanfield raises the question of secondary stresses arising from the frictional resistance to rotation of the eye-bars on the pins. In the case of the Florianopolis Bridge, the anticipated deflection movements under live load are so small that the resulting angle changes at the ends of the eye-bar cables would not produce any serious secondary stresses.

That the eye-bars rotated about the pins to take care of angle changes during erection was visibly demonstrated just after the first two panels of truss members at the continent end were erected by the "jinniwink" standing on the 185-ft. span. When the jinniwink was moved out to Panel Point 2 in order to erect truss members in Panels 2-4, there was a heavy local concentration on Point *C*2 of the eye-bar cable. This heavy load distorted the equilibrium polygon of the eye-bar cable so much—causing the eye-bars, *C*0-2 and *C*2-4, to rotate about Pin *C*2—that it was impossible to place the top chord, *C*2-4. The distance between Points 2 and 4 at the top chord was about 4 ft. too short for that chord to enter. The frictional resistance of the eye-bar stress on the pins was certainly overcome in this instance.

Mr. Beanfield, like Mr. Kuo, expresses concern as to the security of the tower base castings against earthquake forces. Although provision against earthquake effects was not definitely specified or allowed for in the design of the Florianopolis Bridge, a few minutes with the slide-rule are sufficient to show that the tower base details are amply proportioned to resist displacement under the most severe seismic disturbances thus far recorded. These sixteen 3-in. dowels provide a total resisting section of 112 sq. in., or a safe shearing resistance (at 15 000 lb. per sq. in.) of 1 680 000 lb. The total weight of the suspension bridge (including towers, cables, back-stays, and suspended structure) is approximately 3 000 tons. This total weight would have to be subjected to a horizontal acceleration of 28% of gravity, or 9 ft. per sec. per sec., before the safe shearing resistance of the steel dowels would be exceeded. This acceleration (representing earthquake intensity) is seven times as high as that assumed in the design of the Carquinez Strait Bridge which, as cited by Mr.

Beanfield, was designed with especial consideration to possible earthquake forces. Moreover, the foregoing comparison assumes the Florianopolis Bridge to be a free structure, with its entire inertia resisted solely at the tower bases. Actually, the structure has safe additional restraint in the fact that the tops of the towers are securely tied back to the massive concrete anchorages.

Mr. Beanfield voices a common misconception when he states that suspension bridges, in general, are not adaptable for locations subject to earthquake disturbances. Consideration of the functional characteristics of the suspension type should show that it is pre-eminently the bridge type best adapted to resist seismic forces. The longitudinal continuity of the principal element, the positive anchorage at each end, the comparative lightness of weight, the low center of gravity, and the characteristic resilience of the structure—all combine to give the highest security against earthquake effects. The contrary misconception is perhaps prompted by the thought of the relative flexibility of a suspension span; but this very flexibility gives safety against seismic shock or any suddenly applied force. A suspension bridge functions like an anchored steel spring, whereas other bridge types would act like stacks of blocks. Resilience is a valuable factor of safety against seismic effects. The Eiffel Tower would obviously be safer than Cleopatra's Needle in an earthquake; and the Florianopolis Bridge is likewise many times safer than the Carquinez Bridge against seismic effects. Where the suspension type is at all suitable, the writers would choose it every time in preference to a cantilever bridge in earthquake country.

On the question of the proportioning of the rocker bearings, the following notes may be of interest: For the base castings with a radius of contact of 12 ft., the designers adopted an allowable working pressure of 108 000 lb. per lin. in., equal to $750r$, or $375d$. This is five-eighths of the linear bearing pressure ($600d$) allowed by the specifications for steel rollers adopted by the Society's Special Committee on Specifications for Bridge Design and Construction.* Specifications of this form are based on theoretical derivations which take into account the anticipated elastic deformation of the line of contact into a narrow strip of contact area. They also take into account the supporting and relieving effect of the unloaded metal adjacent to the strip of contact. Actual tests on large steel roller or rocker bearings are needed in order to verify the theoretical deductions and to fix the coefficients more definitely.

Mr. Stowell remarks that the element of cost is the "discordant note in the harmonious whole" of the Florianopolis Bridge project. This phase, however, may be viewed from a different angle. Had there been plenty of money available, a cantilever bridge of the type shown in Fig. 2 (*c*) would have been adopted. While this cantilever span would have held the record for monumental bridges in South America, still, no new features in bridge design and erection would have been introduced. Necessity is the mother of invention, and the scant supply of money taxed the ingenuity of the engineers connected with the development and execution of the project, and resulted in the production of the suspension type of structure with all its novel features.

* *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 1281.

Mr. Stowell expresses his conviction that the superiority of wire over eye-bars for cables is so great that the question of relative cost should not be a controlling factor in deciding between them. On this point, there will be legitimate differences of opinion. Each type has its advocates and, apparently, a field for its appropriate utilization.

Mr. Stowell questions the reliability of the heat-treated eye-bars, on the score that the limitations of the testing machine necessitated the use of bars especially made for test instead of permitting selections from the finished lot to be used for testing. He cites the low elongation (3%) of one of the test bars as compared with the 7% average of the others, and he directs attention to the hazard of using eye-bars of different elongation in the same cable member. In justice to the eye-bars, however, it is only fair to note that the varying elongations shown in the test reports relate to the ultimate load and not to the working stresses below the elastic limit.

In further reference to the results of the full-sized tests on the eye-bars, the following explanatory notes are submitted: The American Bridge Company was under contractual obligation to have the test bars pass the minimum requirements of 75 000 lb. per sq. in. elastic limit, 105 000 lb. per sq. in. ultimate strength, and 5% elongation in 18 ft. As long as these requirements were met, the Company felt that here was an opportunity to experiment and ascertain whether eye-bars with 100 000 lb. per sq. in. elastic limit could be produced. This accounts for the variations in the elastic limit values, since the Company was not trying to produce uniform results. As a matter of fact, an elastic limit of 100 000 lb. per sq. in. was not quite attained, the nearest approach being 96 830 lb. per sq. in. While it is true that one bar failed in the elongation requirement, that same bar had an elastic limit of 82 780 lb. per sq. in., 10% higher than the guaranteed minimum, and an ultimate strength of 116 720 lb. per sq. in., 11% higher than the guaranteed minimum. On the additional bar which was tested, the elongation was 8.1%, or well above the guaranteed minimum.

Mr. Stowell appears to have misinterpreted the results of the eye-bar tests in his reasoning with respect to the variation of stress in the several eye-bars in any one panel. The entire theory of elastic structures is based on Hooke's law that, within the elastic limit of the material, unit stress is proportional to unit strain or distortion, the constant ratio between them being the modulus of elasticity. While it is true that the value of this modulus may vary slightly in different specimens of the same material, there is no such variation as would cause the distribution of stress among four eye-bars in one panel to be, as Mr. Stowell suggests, 35.2% in one bar and 21.6% in each of the other three bars. Before testing, each bar was marked with points 1 ft. apart for a distance of 13 ft. on two bars and from 34 to 38 ft. on the remaining eleven bars. After failure, the distances between these points were measured and the results were as plotted in Fig. 47. These curves show a very uniform elongation at all points on the bar except at the point of failure.

Mr. Stowell points out the exceptional reliability of wire for cables, in that two full-sized tests are made on each individual wire in addition

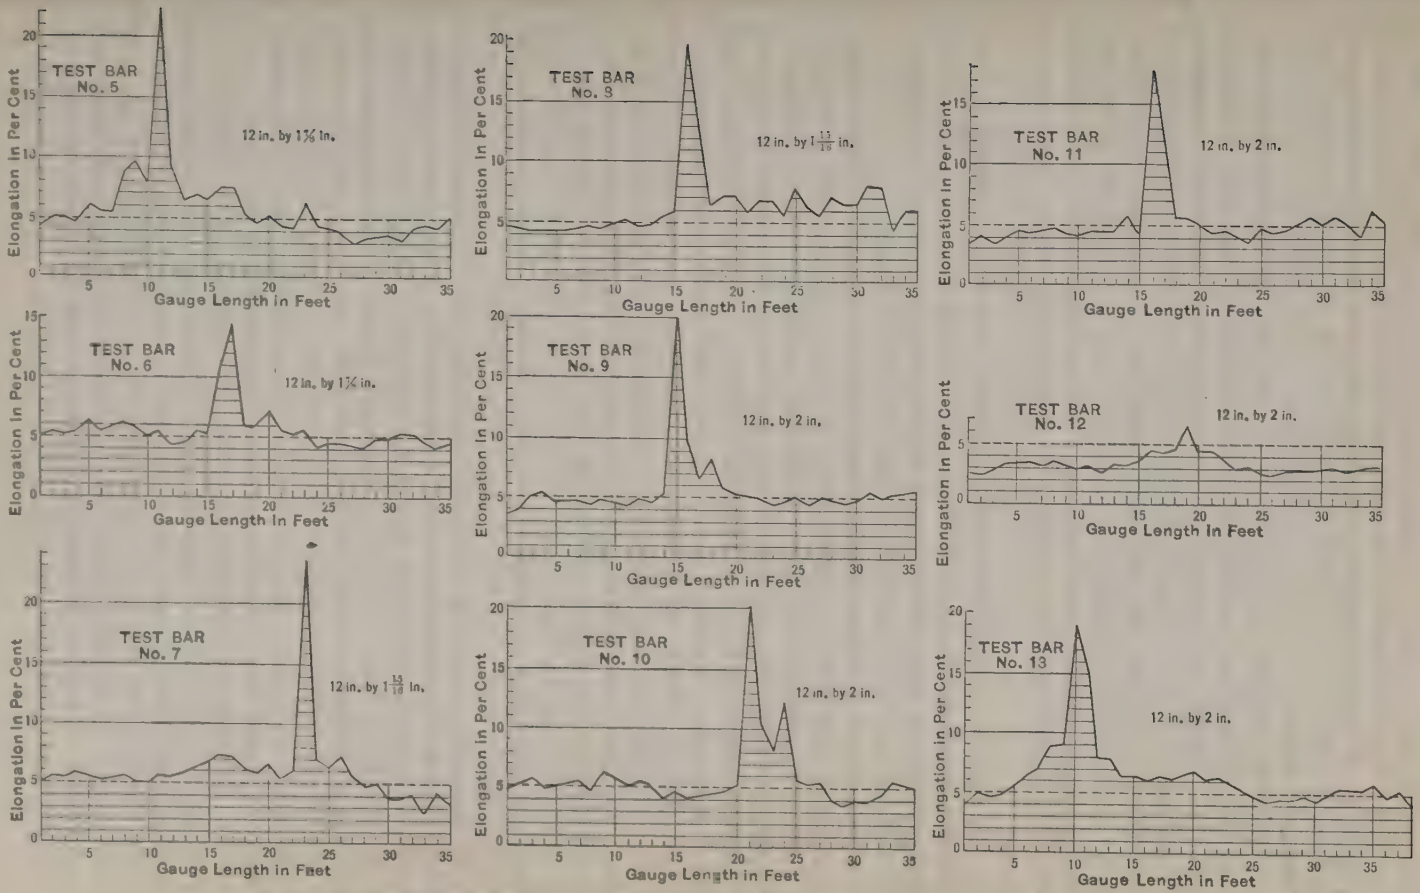

FIG. 47.—GRAPHIC REPRESENTATION OF ELONGATION OF EYE-BARS AT EACH FOOT OF GAUGE LENGTH.

to the automatic testing of quality and uniformity in the process of wire drawing. He also mentions other advantages of wire cables, including smaller percentage of details, elimination of points that are accessible to moisture and difficult to paint, and the reduction of dead load by the much higher safe working stresses.

When Mr. Stowell comments on the extra material in pins and eye-bar heads for connections far outweighing the small sleeve nuts used for splicing wire, he overlooks the fact that the pins are used for attaching the suspenders in the case of eye-bar cables, while for the wire cable it is necessary to provide for this purpose cast-steel cable bands and high-tension bolts. Moreover, in the case of eye-bars, it is possible to vary the thickness of the bars in accordance with the stress variation along the length of the cable, instead of requiring the maximum section to be carried undiminished from tower to tower.

Mr. Stowell deprecates the policy of secrecy sometimes displayed by steel manufacturers, and he cites instances where the mystery was only pretense. His gratification at the abandonment of the element of secrecy in the manufacture of heat-treated eye-bars is shared by the writers.

Professor Cross confines his comments to a discussion of the significance or lack of significance of relative deflections as a basis for the comparison of different bridge types. He indicates his agreement with the writers in doubting the propriety of applying to suspension bridges criteria for stiffness borrowed from other types of bridge construction. The writers are satisfied that larger deflections may properly be permitted in suspension designs than in other bridge forms. Such larger deflections are not a measure of impact effect. On the contrary, they may be regarded as a protection against impact. It is an established principle of mechanics that, if the same weight is dropped from equal heights on two beams of equal strength, the one with the greater deflection (in consequence of difference in form, material, or yielding supports) will suffer the smaller damage. The larger deflection reduces the kinetic impact effect.

A larger deflection of a suspension bridge, compared with that of a simple truss, does not mean overstress or greater wear. In other structures, deflection movements or vibrations may mean loosening of rivets, wear at joints, and reduction of useful life. In a suspension bridge, the principal carrying element (the cable) is free from joints in which rivets can loosen or wear can take place. The stiffening truss is of secondary importance. Moreover, it is so much shallower than the trusses of other bridge types, that a given deflection means much smaller stress and strain at the joints.

The objectionable psychological effect of vibration, as pointed out by Professor Cross, should be measured not by relative amplitude but by relative acceleration. The deflection movements of a suspension bridge are sluggish in comparison with the high-speed vibrations of a simple truss or an arch, or the jerky vibrations of a cantilever. Different bridge types obviously call for different criteria for permissible deflections, and for a different handling of the deflection problem in all its phases.

Concluding Remarks.—An interesting confirmation of the economy of material in the Florianopolis Bridge as compared with other suspension structures is found in a paper by Mr. W. H. Thorpe on "Steel Bridge Weights".* Mr. Thorpe has analyzed the weights of steel per unit of live load for a large range of bridges and, after making corrections for differences in relative floor weight, has plotted the results as a function of span length to establish a mean curve for each respective type of bridge. In the graph of plotted points for suspension bridges, one point stands out prominently as the lowest one relative to the mean curve, and that is the point representing the steel weight factor of the Florianopolis Bridge. In comparison with the neighboring points in the plotted graph, the respective steel weight factors (per unit of live load) are:

Bridge.	Steel weight factor.
Elizabeth Bridge (951-ft. span, eye-bars).....	2.4
Florianopolis Bridge (1 114-ft. span, eye-bars).....	1.6
Manhattan Bridge (1 470-ft. span, wire).....	2.5

The low weight factor recorded for the Florianopolis Bridge cannot be ascribed to the use of a timber floor, since correction for relative floor weight has been made in Mr. Thorpe's analysis; nor is the use of high-tension eye-bars a governing factor, since bridges with wire cables of higher unit tension are included in the comparison. The form of the structure, therefore, must be the principal reason for the low value of the weight factor. This is a gratifying independent verification of the steel-weight economy of the Florianopolis type of suspension structure.

Since this paper was written, the Florianopolis Bridge has been thrown open to highway traffic. A. Y. Sundstrom, M. Am. Soc. C. E., reports that the traffic amounts to approximately 1 000 vehicles and 10 000 pedestrians per day. The tolls charged are 100 reis (about 1 cent) per pedestrian and 1 milreis (about 10 cents) per vehicle, and thus amount to about $200 per day. A local firm, Corsini Brothers, has the contract, on a fixed annual basis, for the maintenance of the bridge and the collection of tolls, the surplus receipts being turned over to the Treasury of the State.

In conclusion, the writers wish to thank all those who have so generously enhanced the usefulness of the paper by the contribution of their discussions. If, as predicted in some of the discussions, the novel features in the design and construction of the Florianopolis Bridge will serve to enlarge the field of usefulness of suspension structures, the writers will feel fully repaid for their efforts.

Any departure from precedent in structural form, materials, or erection methods, is offered, not to replace, but to supplement those previously developed. The availability of alternative forms, materials, and methods should serve to increase the resources and to stimulate the resourcefulness of the bridge engineer. The healthiest condition in a profession is not the blind following of standardized precedent, but the open-minded evaluation and selection of the best of various possible solutions for a given problem.

Paper No. 1663

THE RELATION OF HIGHWAY TRANSPORTATION TO THE RAILWAY*

By Ralph Budd,† M. Am. Soc. C. E.

With Discussion by Messrs. John V. Hanna, E. A. Hadley, F. G. Jonah, W. W. Crosby, William T. Lyle, M. H. Gerry, Jr., and Ralph Budd.

In the past twenty-five years (since 1900) the American public has increased the investment in its transportation plant from $10 500 000 000 to $50 000 000 000, and its annual expenditure for transportation of property and persons from $1 500 000 000 to between $18 000 000 000 and $20 000 000 000. The change has been most rapid in the last five years (since 1920), during which the investment has increased from $36 000 000 000 to $50 000 000 000, and the annual transportation charge from about $12 000 000 000 to more than $18 000 000 000. This increase in the annual transportation charge in five years has been due entirely to the increased expenditure on highway travel, which has more than doubled in that time, while the charge for railway transportation has actually declined.

The public is supporting two transportation plants, in each of which is invested upward of $25 000 000 000. The property owned by the railway companies is reasonably permanent, while the equipment used on the highways is of more transient character. The annual cost of transportation furnished by the railways is about one-half that produced on the highways.

An inventory of the nation's transportation system at the beginning of 1926 would have disclosed something like the following:

* Presented at the Spring Meeting, Kansas City, Mo., April 14, 1926.
† Pres., G. N. Ry., St. Paul, Minn.

Railways and Equipment.		Improved Highways and Motor Vehicles.	
Miles	251 000	Miles	495 000
Locomotives	70 000	Motor trucks....	2 500 000
Freight cars	2 440 000	Automobiles	17 430 000
Passenger cars ..	56 500	Motor buses	70 000
Rail motor cars.	500		
Total units	2 567 000	Total units	20 000 000
Investment $25 000 000 000		Investment $25 000 000 000	
Annual cost $6 310 000 000		Annual cost $12 125 000 000	

Five years ago it would have been like this:

Railways and Equipment.		Improved Highways and Motor Vehicles.	
Miles	253 000	Miles	370 000
Locomotives	70 600	Motor trucks ..	1 000 000
Freight cars ...	2 400 000	Automobiles	8 220 000
Passenger cars ..	56 150	Motor buses	5 000
Rail motor cars..	50		
Total units	2 526 800	Total units	9 225 000
Investment $22 000 000 000		Investment $13 800 000 000	
Annual cost $6 360 000 000		Annual cost $6 000 000 000	

Twenty-five years ago the inventory would have been blank so far as modern highway transportation is concerned; railway investment would have been about $10 500 000 000, and the annual cost of railway transportation about $1 500 000 000, or only one-twelfth as much as the country's present annual transportation bill.

Influence of Transportation

Means of communication always have been a controlling factor in the life of every country. Until the Nineteenth Century, water transportation was so much cheaper and more efficient than any other, that population and industry concentrated only where it was available.

The most important single factor which influenced the character of settlement in the interior parts of America was the substitution of overland transportation by rail for that by canal, river, and highway. The railway eliminated the backwoods and caused cities to be built at what had been the frontier. It is not too much to say that the political unity of the United States was preserved largely by the railways, which alone made communication between parts of so vast a Commonwealth practicable and convenient. Without them, people in some sections of the country might have found it more advantageous to trade with foreigners than at home; and in a continent where National lines were forming, allegiance well might have followed the course of commerce.

George Washington was much concerned about the remoteness and inaccessibility of the country lying west of the Allegheny Mountains, and to overcome the physical difficulties of communicating with the Atlantic seaboard he investigated the trade routes by which the Great Lakes and the Ohio and Mississippi Rivers could be reached most easily from the East. These routes were to be developed by improving the rivers, making them navigable as far up stream as possible, and then connecting the heads of navigation on the opposite sides of the mountains by highways. He mapped routes by way of the Hudson and Mohawk Valleys, and by the passes at the head-waters of the Potomac, the James, and the Juniata Fork of the Susquehanna. Each of these routes was occupied by an important railway line soon after the supremacy of the railway over other forms of transportation became recognized.

The anxiety of the Father of his Country would have been greatly relieved could he have known of the revolutionary changes in inland transportation to come within fifty years after his death, and that the railroads not only would carry the commerce between the western valleys and the Atlantic seaboard, but would be extended 2 000 miles beyond the westerly outposts of his time, crossing three major mountain ranges, knitting the political and commercial life of the nation from Atlantic to Pacific, and providing incidentally the long sought route to India over, rather than around or through, the continent.

Railways Essential

The railways to-day are as essential to the National and commercial life of the United States as ever, and anything that would jeopardize their success or efficiency should be avoided as a public menace. Other forms of transportation, however, are factors too, and it is well to consider them in their relationship to the railways and to the general transportation scheme.

In the development of transportation one form has succeeded another with astonishing rapidity, but not without a struggle; thus, we find operators of pack trains contesting with Conestoga wagon drivers, canal companies resisting railway projects, the graceful, yacht-like clipper ships yielding reluctantly to steamships, and steam railways competing with interurban electric lines for local passenger travel. Now, steam and electric lines, which had surpassed all others in the field of transportation, have encountered something that excels them both in certain particulars and under certain conditions. They find local traffic is taken from them by the most universal of all carriers, the motor car on the highway. As in former competitions between old and new means of transport, that which gives most of what the public wants will win. There must be speed, safety, dependability, comfort, convenience, and, in the case of public carriers, economy.

Automobile Industry

That most phenomenal of all industrial developments, the automobile industry, is the youngest, and now is said to be the largest, in the United

States. It is barely twenty-five years old. Its importance is so great, taken as a whole, that the railways gain much more from the freight traffic it gives them than they lose from the freight and passenger business it takes away.

Like all great developments, that of motor travel has been the result of a combination of favorable circumstances. Most important were the perfection of the gasoline engine and the paved highway, which latter depended largely on good, cheap cement. Added to these is the fact that in America there is a standard of living so high that luxuries are not beyond the reach of the many. Each of these conditions is partly the cause and partly the consequence of the others. Of all the automobiles in the world 83% are in this country, which has about 7% of the world's population. Even more are produced in the United States than are used, but it is a mistake to think that the automobile originated here, or that it always has been peculiarly American. Before the manufacture of automobiles was of any importance in the United States, they were in more or less common use in England and on the Continent, and had reached a much higher state of perfection there than here. It was not until about 1905 that the number of cars in the United States exceeded the number in Great Britain. There was comparatively little improved highway in this country then, but there were magnificent distances which afforded an opportunity for the automobile to attain its fullest capabilities. Moreover, the great individual purchasing power of the population constituted a potential demand which required only the encouragement of reasonably priced, reliable cars and better highways to burst into actuality. The volume of this demand made quantity production possible and brought the low priced car, together with a program of general highway improvement throughout the country. The almost universal ownership of the automobile which has resulted demonstrates the fact that when the public finds something it approves of and desires, its response is quick and emphatic. The new contenders for local freight and passenger traffic—the motor truck and bus—are outgrowths of the automobile.

Why the Motor Bus?

Probably the questions most commonly asked by railway men concerning the motor bus, are "What can its attraction be?" and "Is it not a fad which soon will lose its novelty and disappear?" Let us consider these questions. In many localities the bus does have some advantages over the railway train for local travel. Two of these are the greater frequency and the flexibility of its service. Compared with the railway train, the bus can give service at more frequent intervals, because each unit of service is small and may be operated cheaply in comparison with the cost of operating a train.

The ratio of cost of highway bus to steam train operation is about 1 to 5, which means that for the cost of one train in each direction, say, morning and evening, a bus can be run every 2 hours in each direction from 8.00 A. M. to 4.00 P. M., and this more frequent service better suits the needs of the average rural community. Owing to the extensive use of the private auto-

mobile there is scarcely enough travel even morning and evening on the average local run to justify one train, much less several trains, during the day; but the smaller and less expensive motor bus operating on the highway may pick up sufficient traffic to make it profitable. Besides greater frequency, there is the advantage of more convenient starting and stopping places. The motor bus is able to take on and discharge passengers at any street corner or at any house along the road. In other words, the motor bus is able to give a more flexible service than the train. People in the country can hardly use the railway for travel between neighboring stations, because, in proportion to the whole journey, the trips to and from the stations are so long. Not so with the bus. It gives continuous service all along the highway, while the railway gives it only at points 4 to 6 miles apart. Now, the amount of this strictly local business which railways cannot handle is considerable, and may be enough to insure the success of bus transportation.

Rail motor cars are being used rather extensively in lieu of steam passenger trains. They provide a unit of more suitable size, and economize by substituting the internal combustion engine for the steam locomotive, as well as in other ways. About five hundred such cars of various types are in service, and the cost per mile for operation is about one-third that of a passenger train. They are successful, therefore, to that extent, but are subject to the inherent limitations of any vehicle operating on railroad right of way. They cannot get as much "pick-up" business as buses, which run along the highways and streets, and stop at houses, stores, offices, hotels, and any other desired place. The special field for the rail motor car is to take the place of the steam train on light traffic runs, such as branches and local and suburban districts where, for various reasons, service must be provided.

At recent hearings before the Minnesota Railroad and Warehouse Commission, Edgar Zelle, President of the Jefferson Highway Transportation Company, presented an analysis of the train and bus schedules in the territory served by his line south of St. Paul and Minneapolis. The substance of what he said in respect to one community is quoted here:

"Owatonna is a town 77 miles from Minneapolis on two lines of railway. Seven daily trains give direct service to and from Minneapolis, but the schedules are such that service is concentrated morning and evening, without any trains during long intervening periods. For example, of the seven north-bound trains, three leave within one hour and seventeen minutes of each other, with a fourth trailing just an hour later, all four of these trains leaving before 7:30 A. M. After this there is no more morning train service, and only three more trains left for the balance of the day. One of these, a limited, leaves at 1:10 P. M., and then the other two locals keep each other company, both of them leaving around 4:00 P. M. within thirty-eight minutes of each other. Thus, six-sevenths, or 86%, of the north-bound rail passenger service at Owatonna is used to give service at but two periods of the day.

"South-bound service shows another abundance of rail service at two particular periods. A train arrives at 10:23 A. M. with another close behind at 11:30 A. M. Then everything is quiet until 5:20 P. M., when the first train

arrives, with another at 6:43 P. M., followed immediately at 6:59 P. M., with still another. On south-bound service the railroads thus concentrate five-sevenths of their passenger service at two periods of the day.

"The Jefferson Company, on the other hand, because it uses a type of equipment that can economically be distributed for local passenger service, gives Owatonna service from the north every two hours from eleven o'clock in the morning to eleven at night.

"That the public appreciates a frequency of service that is spread over the day at regular intervals is illustrated by the traffic records of the Jefferson Company. Over the twelve-month period ending August 31, 1925, there is a surprising uniformity of patronage, ranging from 27 to 38 passengers handled daily on each of these two hour scheduled south-bound runs. The north-bound records show a similar uniformity beginning with the first through run out of Mason City, leaving at 7:15 A.M., which carried 13 323 passengers, to the 5:15 P. M. run, which carried 15 123 over a period of twelve months, ranging from 31 to 41 passengers handled daily on each of these north-bound runs.

"The same uniformity is illustrated in the 19 831 passengers who used the outbound service at Owatonna. The pleasant month of June, with 1 342 outbound passengers, was the lightest month, while the cold month of January was the heaviest month, when 1 959 outbound passengers were taken out of Owatonna, averaging 45 per day in June to 63 per day in January.

"Owatonna, credited in the last census with a population of 7 252, furnished the Jefferson buses with a total of 37 928 in and out bound passengers in the twelve-month period.

"This two-hour bus service is not only patronized at small stations where the railroads restrict their service, but also at any point between stations. The cross-roads or any point on the highway is the stopping place of the bus."

While inapplicable to the territory adjacent to the largest cities or to sparsely settled regions, the condition described by Mr. Zelle is fairly typical of a great part of the United States.

The radius of travel of an individual multiplies many times when he becomes the owner of an automobile. His sense of independence and freedom, and his ability to give himself and his family enjoyment not otherwise obtainable, are sufficient reasons for sacrifices, if necessary, in other directions in order to have a car. For short-distance travel the most ideal way yet devised is by the private automobile. This is an important truth, because it accounts for most of the development in motor-bus transportation and most of the railways' loss of passenger traffic. For those who do not have their own automobiles, or having them, prefer occasionally not to drive, the motor bus affords a substitute.

The congestion of city streets has become a serious problem for the automobile user. In all cities, during the busiest hours of the day, much of the advantage of the automobile is lost for lack of parking space on the streets. This problem is having attention, and doubtless, to some extent, it will be solved by providing convenient places for parking cars near business centers. The cost of such parking, however, will influence some private car users to avoid the congested centers. In very large cities the bulk of commutation travel probably can be handled only by railway trains, subways, and elevated lines, but there seem to be many cities where the street congestion is not

too great for motor buses, yet is too great for private cars to operate conveniently, comfortably, and economically. In such places the motor bus has positive advantages.

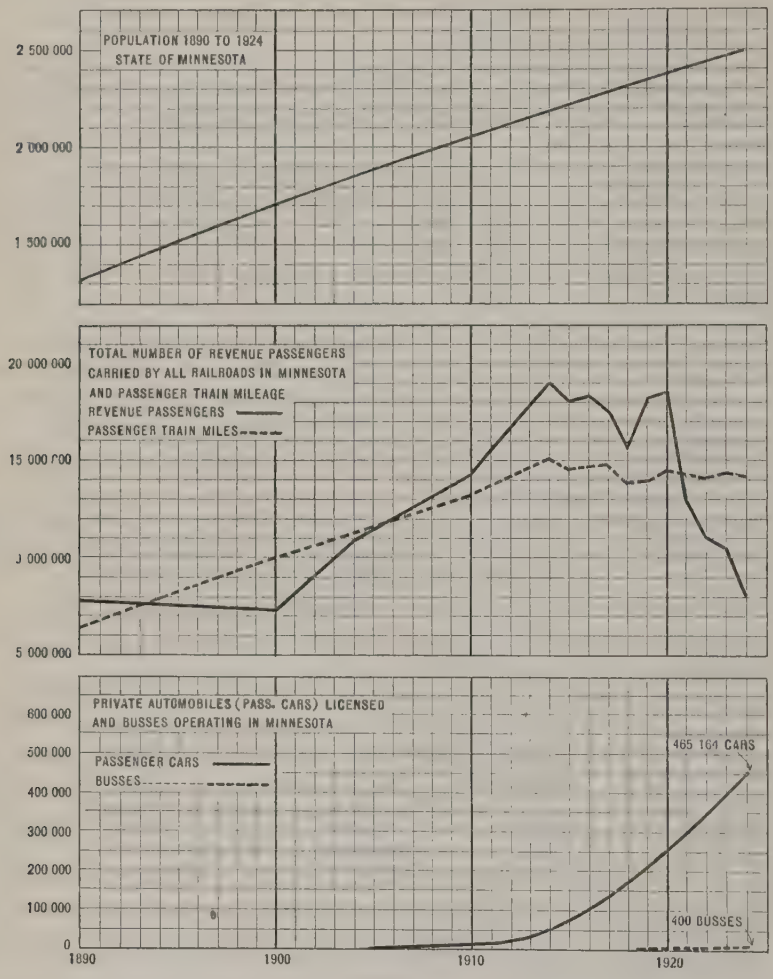

FIG. 1.

THE AUTOMOBILE AND LOCAL TRAVEL

In connection with these questions of frequency and flexibility of service, which are the main advantages of local highway over local railway passenger service, consider whether the railways really lost their business to motor buses or to private automobiles. Statements submitted to the Minnesota Railroad and Warehouse Commission recently indicate that the railways in Minnesota had lost a substantial part of their local passenger traffic before motor buses began operating to any extent, and that the number of

automobiles continued to increase as the number of passengers carried by railways declined; also that at stations where motor buses have been operating for some time, the loss of passenger business has not been materially greater than at stations where they never have operated.

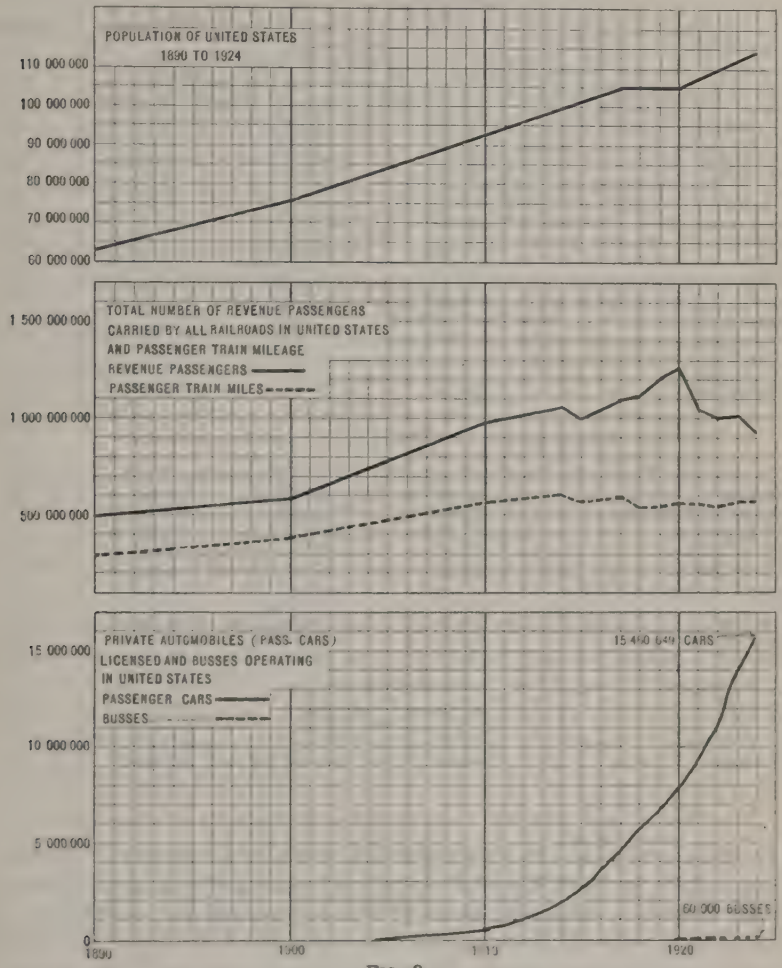

FIG. 2.

Fig. 1 shows the number of passengers handled by the railways in Minnesota since 1890, passenger-train miles, automobiles, and buses in Minnesota, and population; Fig. 2 gives similar information for the United States; and Table 1 shows the ticket sales at twenty-six railway stations in Minnesota. At fifteen stations, where there was no bus competition, the decrease in passenger tickets sold in 1924 as compared with 1920, was 49 to 76%, with an average of 64.6 per cent. At eleven others, where there was bus competition, the decrease was 55 to 74%, with an average of 63.7 per cent. The total number of tickets sold at the twenty-six stations in 1920 was 488 649,

and in 1924, it was 175 706, a decrease of 312 943, or 64 per cent. During the five years, 1919 to 1924, the total number of passengers handled by the railways in Minnesota decreased from 18 274 516 to 7 905 378, or 56.7%; while passenger-train miles on these railways increased from 14 052 547 to 14 223 456, or 1.2%; and the number of motor vehicles in the State increased from 259 741 to 503 437, or 93.8 per cent. Compared with 1919, the year 1921 shows a decrease of 4 902 444, or 26.8% in railway passengers; an increase of 535 584, or 3.8% in passenger-train miles; and an increase of about 60 000, or 25%, in automobiles, while buses had not yet become a factor. These and other data point to the conclusion that the private automobile has had a great deal more to do with the loss of railway passenger business in Minnesota than the motor bus. They also suggest, and railway statistics support, the suspicion that before bus operation began, the local passenger traffic of the railways in Minnesota had decreased to a point where much of it was being

done at a loss, largely because passenger-train miles had not been correspondingly reduced. Manifestly, the taking off of passenger trains in such instances is justified. Every train that is removed, however, serves to increase the advantage of the competitor on the highways; but if the business disappeared while the railway service was maintained, there is hardly reason for continuing such trains. Whatever may be the various reasons, local travel, to a very large extent, has left the railway train for the automobile and bus. This patronage of buses seems to establish beyond any doubt that they will continue, and probably will increase in number. From the foregoing it seems clear that the railways must recognize that public necessity and convenience require the development of transportation on the highways; that they should not attempt by arbitrary means to eliminate motor-vehicle competition, and should only insist that such competition be subject to proper public control; and, further, that they should seriously consider whether or not this new form of transportation, from the public as well as from their own point of view, cannot be more advantageously conducted under railway direction than otherwise.

Regulation

The rapid development of the common carrier motor vehicle, especially as embodied in the bus, has resulted in the enactment of regulatory measures by thirty-seven States. Similar measures are under consideration by legislative bodies of other States. The important and main provisions of these regulatory acts grant to the State the power to determine whether or not common carrier motor vehicles should be permitted to operate. If the State regulatory body is of the opinion that the public interests demand the operation of such motor-vehicle service, it issues a certificate therefor which is commonly called a "certificate of public convenience and necessity." No operation of common carrier motor vehicles can be carried on in these States without obtaining such a certificate. These laws,

1.—Require an adequate bond to protect the traveling public.
2.—Require State control of rates charged.
3.—Require State control of schedules of operation.
4.—Prohibit discrimination between individuals and communities.
5.—Require safety of operation with reference to the type of vehicle, and in other details affecting the safety of the traveling public.

These acts grant to the State regulatory boards the same control in general which these boards exercise over railway carriers. The regulatory board is required to give consideration to the effect the proposed service may have on other carriers, whether those carriers be railways or other motor-vehicle carriers.

These regulatory acts are wholesome and were necessary. Without such regulation the public had no protection from so-called "fly-by-night" operators, who had no capital and who were unable to furnish adequate service. These irresponsible operators would come and go as the seasonal business

might permit. That made it impossible for the legitimate operator to make reasonable profits and maintain adequate service. Sound regulation is building up in the several States a fixed and dependable service, and one which, in co-ordination with the railway service, gives to the public the best conceivable local transportation. The rates which the bus companies are permitted to charge in general bear a fair relation to the railway rates, and are generally only a fraction of a cent per passenger mile less than railway fares.*

The States have no power to forbid the operation of interstate carriers and have very little regulatory power over them. The Supreme Court of the United States has held that a State law which prohibits common carriers for hire from using the highways by motor vehicles between fixed termini or over regular routes without having obtained from the Director of Public Works a certificate declaring that public convenience and necessity require such operation, is primarily not a regulation to secure safety on highways, or to conserve them, but a prohibition of competition; and, as applied to one desirous of using the highways as a common carrier of passengers and express purely in interstate commerce, is a violation of the commerce clause, besides defeating the purposes expressed in Acts of Congress giving Federal aid for the construction of interstate highways. Prior to this decision, many of the States were regulating interstate carriers.

Truck and bus operators engaged in interstate commerce recognize that Federal regulation sooner or later is inevitable. The Federal Government, however, in regulating the interstate motor carriers, should leave that regulation, so far as the Constitution will permit, to the Commissions of the interested States. About 75% of the railway business is interstate, and, therefore, the regulatory power of the railways is properly vested in the Federal Government. The truck and bus business, by its nature, always will remain largely a local problem. Perhaps as much as 90% of the truck and bus transportation of the country always will be intrastate. Those vehicles travel highways which were built by the State, and are policed and maintained by the State. It is, therefore, most proper that the power that regulates be delegated to the several States as far as practicable.

Congress has under consideration a bill regulating interstate motor-vehicle transportation. Its main features are as follows:

No common carrier truck or bus can be operated in interstate commerce without obtaining a certificate of public convenience and necessity therefor.

This certificate is to be obtained from a Joint Board composed of representatives from the several States in which the applicant proposes to operate. An appeal from the decision of the Joint Board so created, lies to the Interstate Commerce Commission.

The Joint Board has complete power to regulate the service and rates and safety of operation of such motor vehicles. The bill as drawn is intended not to hinder or hamper the development of common carrier transportation upon the highways, but to protect the legitimate operator thereon. It recognizes as a fundamental principle that common carrier transportation service must be in the hands of a responsible operator and that he should be protected from the irresponsible and casual operator.

* A tabulation of the State Laws in force as of January 1, 1926, has been made by the National Automobile Chamber of Commerce.

The necessity of Federal regulation in the large States is not acute for the reason that nearly all such carriers are engaged in intrastate transportation and are subject to the regulation of the State. However, where these transportation companies are operating in the smaller States and it is possible to cross State lines in a normal day's operation, the necessity of Federal regulation is apparent. The public cannot be adequately protected unless the Federal Government enacts legislation that will require the operating company to furnish security for damage to persons or property, and unless the service and rates of such operators are fixed and determined through public authority.

The proponents of the bill have agreed that it should provide that operating companies, which were in operation on March 1, 1925, should, as a matter of course, without further proof of public convenience and necessity, receive a certificate.

Taxation

Every user of facilities furnished by the State should pay reasonable compensation for the use thereof, especially when such facilities are used for private gain. Common carrier motor vehicles should pay a fair and reasonable tax for the use of the highways, but regulation should not be attempted through taxation; that is, taxes should not influence the granting of permission to operate, and they should not be burdensome to the point of preventing low fares.

A highway is constructed for the benefit of society as a whole. Society, in the aggregate, benefits whether or not each individual may or may not use the highway. It has never been the policy of a State to charge the entire cost of upkeep of the highway to the users thereof. The highways are used by private individuals in the transaction of their private business for profit. They are used also by those who travel for pleasure, and they are used by common carrier transportation companies. Those individuals who choose not to drive their own cars, but to ride in common carrier motor vehicles, should not be asked to bear an unfair share of the burden of upkeep of the highways, nor should they be deprived of the advantage of cheap transport as inevitably must happen if public motor vehicles are taxed unduly, resulting in higher fares.

There are about as many different methods of taxing common carrier motor vehicles as there are States in the Union. Some States tax these vehicles solely on the basis of value or cost, some on a percentage of the gross revenue received, some on weight plus a fraction of a cent per passenger mile, and some on the seating capacity of the vehicle, or on the horse-power, or so much per hundred pounds of weight, or a combination of all. In addition to these forms of taxation, nearly every State has a per gallon gasoline tax. This tax amounts to about one-third of a cent per mile for the common carrier motor vehicle. Speaking generally, the taxes paid by buses are fair and just. In Minnesota, the tax is based on the value of the vehicle. The parlor-car type of bus in common use in Minnesota costs from $10 000 to $12 000. The

annual tax paid on each vehicle is 10% on the cost for the first year, decreasing 10% per annum to a minimum of $350. The average for the modern bus is about $750. The average annual tax paid on a Ford car is $12. It thus appears that the annual tax on a bus is about sixty times that on a Ford car. In addition, a tax of 2 cents is paid upon each gallon of gasoline used. The writer is advised that the tax paid by the bus companies in Minnesota is between 6 and 7% of the gross earnings of the operating companies. The tax on gross railway revenue in that State is 5 per cent.

The annual tax on a standard parlor car bus of a seating capacity of 30 passengers, weighing approximately 10 000 lb., and costing $10 000, would vary in the different States from $150 per bus per year to $1 000 per bus per year.

Commercial highway users themselves have taken an active part in forming an enlightened public opinion on the questions of regulation and taxation. In January, 1926, the Motor Vehicle Conference Committee published, among other articles, the following:

1.—Sound and Equitable Principles for Intra-State Regulation,
2.—Recommended Restrictions on Motor Vehicle Sizes, Weights, and Speeds,
3.—Sound and Equitable Principles to Control Special Taxation for Motor Vehicles.

These are attached as Appendices A, B, and C, respectively.*

One may not agree with the details of these recommendations, but it must be conceded that the free and unrestricted use of the highways by commercial vehicles in competition with the railways is a thing of the past, and that the operators themselves recognize the desirability of having their use of the highways controlled by appropriate laws rationally administered.

Whether a railway company itself should own and manage buses may depend on its willingness or unwillingness to take on additional obligations and responsibilities; but if no prejudice exists against bus operation, the deciding question probably will be whether, by such control, wasteful duplication can be eliminated and the service improved. There have been instances where, by co-ordinating the schedules, bus service has supplemented train service, to the end that for a lesser total expenditure a more complete and satisfactory service has been rendered. Each case is one for individual consideration. In many places throughout the United States electric lines have abandoned all or part of their tracks, and substituted bus service. In other cases, notably in New England, steam roads have substituted buses and trucks for branch lines.

The National Automobile Chamber of Commerce has compiled a census of bus operation as of January 1, 1926. Of 28 145 common carrier buses reported, 5 462, or 19.4%, were owned by steam or electric railways. The number of non-common carrier buses reported was 29 605. They are used by

* Pamphlets containing digest of State laws governing motor vehicles may be obtained without charge from the National Automobile Chamber of Commerce, 366 Madison Avenue, New York, N. Y.

hotels, industries, schools, and for sight-seeing and depot transfer. The geographical distribution of the buses reported is general. Of common carriers, the largest number in any State was 2 672 in New York, while Wyoming reported only 58. Ohio, with 2 454, had the most non-common carriers, while 11 for Rhode Island was the least reported.

Cost of Bus Operation

The question of cost of operating buses is vital for the future of that form of transportation, but reliable records have not been kept long enough to establish what might be called normal costs for certain routes or localities, as is the case with transportation costs on the different divisions of railway systems.

An article entitled "What Does it Cost to Operate Buses and Trucks?" has been published,* in which detailed estimates of the cost of operating a city type bus in New York are given. These costs vary from 23.6 to 30.6 cents per bus-mile, depending on whether the bus averages 200 or 100 miles per day. The details of these estimates have been compared with cost data, with which the writer is familiar, and he believes they are as reliable as can be made at this time, taking into account the fact that local conditions will determine several of the items in any such estimate. The cost of bus operation, however, should be at least 15% less than it is, and unless it is reduced that much, the business will not grow to its full possibilities.

The bus has come a long way from its origin in the motor truck, but it is not perfected yet. Lists of the different makes and types of motor-bus chassis designed exclusively for passenger transportation have also been published.† In this list are shown 96 types put out by 46 manufacturers. Standardization should result in substantial reduction in first cost, and the lessening of obsolescence would reduce the amortization or depreciation charges. The items of oil and gasoline and tires, of course, automatically would decrease if a car weighing 9 000 lb. could be substituted for one weighing 12 000 lb. Cost of insurance also will be less as the business is stabilized. With lower costs, rates can be reduced and travel increased. Many people living along bus routes would take buses to town instead of driving their own cars, especially if the fare was low enough. Here is an opportunity to render a service to rural communities, and it is a logical development in rural transportation for the bus to take the place of the private car on many occasions.

The Motor Truck

There are about 2 500 000 motor trucks in the United States. About 95% of them are non-common carriers, and are not subject to regulation as to rates or service. They are the successors of the horse-drawn warehouse, transfer, and delivery vehicles, and of the farm wagon, but the motor has given them radii of operation many times those of their predecessors. In freight, as in passenger, business the railway is supreme in the long-distance field.

* *The Railway Age*, March 27, 1926.

† *The Commercial Car Journal*, March 15, 1926.

It is also supreme in the handling of the great volume of bulk commodities, such as coal, ore, and grain. Indeed, there is nothing in the records of truck transportation to indicate that trucks are or can be contenders for any railway freight, except where the convenience of direct door-to-door delivery, together with the saving of terminal trucking and handling, outweigh the extra ton-mile cost of moving freight by truck on the highway over the ton-mile cost of railway line haul.

The principles governing the regulation and taxation of commercial freight carriers on highways are similar to those governing buses, but the handling of freight is so different from the handling of passengers that the truck bears a relationship to railroad freight service different from that of the bus to railroad passenger service. Freight shippers are interested solely in dependable, prompt, and cheap transport, whether the shipment be over a long or a short distance. The charge for freight service is important, but the question of economy does not enter into the vast bulk of local passenger travel which moves by private automobile. The flexibility and elasticity of truck operation, that is, its ability to make door-to-door delivery and to give radial service to both rural and urban communities, gives it a large field of activity. The elimination of one or two handlings and the consequent saving in time amounts to more than the excess cost of road haul by truck over that by rail up to some undetermined distance beyond the terminal. What that distance is no one knows. So many variables enter into the problem, such as the freight available on a given route, the character of the commodities, the relative importance of direct delivery to store doors, the extent to which return loading is obtainable, climatic conditions, the condition of the highways, etc., that only actual experience can determine how far beyond the city in each instance the truck can take the place of the box car. The horse-drawn truck excels the motor truck only for such freight as involves short movement and long delay in loading and unloading; the motor truck similarly excels the railway only where the distance involved is short enough so that the saving and convenience in terminal cost and handling offset the higher cost of transit by highway over railway, and only for comparatively small units of freight.

Common carrier trucks should not be permitted to operate in competition with railways except where there is a real public convenience or necessity. The convenience of a few in obtaining a quick delivery of property should not be controlling. It is most important that regulatory bodies, before granting a certificate for the operation of trucks, should carefully analyze what effect that operation will have on the essential rail carrier. The public cannot maintain two freight-transportation agencies without paying for both; and unless each performs a service which the other cannot do economically and efficiently, both should not be supported.

Railways are using trucks to assemble freight in cities in lieu of switch engines, and in some cases operate lines of trucks in lieu of local freight trains. Especially in large and congested terminals the use of trucks, whether by the railways or by others, is economical because local freight trains, due to the light tonnage, station work, and heavy switching cost incident thereto, may

be and often are unprofitable. Unlike the case of passenger traffic, freight train mileage may be reduced approximately in proportion when freight traffic declines.

Summary

The situation may be summarized as follows: The superiority of the railway for long-distance and bulk freight and passenger traffic is well established; motor-truck and bus competition is not a factor in those fields. Commercial users of highways should be subjected to reasonable regulation and taxation. Existing and proposed State and Federal legislation, generally speaking, will provide for this. The extensive ownership of automobiles and the large mileage of improved highways have resulted in the loss of most of the local passenger travel of the railways, except in the vicinity of the largest cities. The removal of local trains has left many communities with comparatively little railway passenger service. The small amount of local travel in many such instances does not warrant more railway service, but does warrant the operation of buses at comparatively frequent intervals. The station to station, and even shorter travel, which would not go by rail, makes up a considerable portion of the bus traffic. The bus business promises to increase if better service can be given and if the cost of operation can be reduced. The additional business which buses may expect will come largely from automobile users rather than from rail patrons. Buses may serve to supplement railway transportation more effectively in some localities, if managed by railways, than if operated independently. Street railway and interurban electric lines are making extensive use of buses. The field of the private carrier motor truck is wide, taking the place, as it does, of the horse-drawn vehicle both in the city and in the country. The common carrier truck has a much narrower field, because of the competition with the private truck on the one hand, and the common carrier railway on the other hand, the latter unquestionably being more economical for any but comparatively small lots and comparatively short haul. Motor trucks relieve railway terminal congestion by moving freight direct from door of consignor to door of consignee. In many cases, this does not represent a loss to the railway because at large centers, where trucks are most used, the terminal costs may absorb the profit of rail haul on local freight.

In considering public convenience and necessity—the *sine qua non* for any permit to operate a commercial vehicle on public streets or highways—due regard should be had for the existing modes and means of transport. When essential carriers are able to give service that is measurably similar to that proposed, or when the success or efficiency of the existing essential carrier would be seriously impaired without definite and distinct improvement in service to the public, then public necessity does not warrant the new facility, and it is in the true public interest to deny the application. The public must support whatever transportation agencies are maintained and should not undertake two where one will suffice. On the other hand, where such additional facility is in the public interest and, therefore, is permitted, it should

not be hampered by undue restriction or unfair taxation, but should be encouraged to operate as efficiently and cheaply as possible. Under the accepted plan of providing public transportation in this country, the service is rendered at cost; including in cost, however, a fair return on the value of the property used for transportation purposes. So long as this principle obtains, and for practical purposes that is so long as transportation is furnished by private rather than by Government agencies, it is in the true public interest to avoid unnecessary duplication of capital, and in every other reasonable way to help both old and new carriers keep down the cost of producing transportation. Cheap transportation of the highest quality is the key to much of the past and possibly more of the future prosperity.

APPENDIX A

Sound and Equitable Principles for Intrastate Regulation
(Recommended by the Motor Vehicle Conference Committee)

1.—Control over intrastate transportation of persons and property for hire, over regular routes or between fixed points, if adopted, should be exclusively in the hands of some agency of the State. No power, whatever, in the premises should be vested in the governing bodies of any political subdivision of the State.

2.—Such State control over motor vehicle common carriers should be placed in existing commissions, such as the Public Utility Commissions or other appropriate State regulatory bodies, of the various States.

3.—As a pre-requisite to the operation of the motor vehicle common carrier, the owner thereof should be obliged:

(*a*) To receive a Certificate of Public Convenience and Necessity, provided that lines in *bona fide* operation on the first calendar day of the legislative session at which the law is passed shall be presumed to be necessary to public convenience and necessity and such lines in the absence of evidence overcoming such presumption, shall receive a certificate for routes established by them.

(*b*) To take out liability insurance adequate to indemnify injuries to persons or damage to property resulting from negligent operation.

4.—The State regulatory bodies having control over motor vehicle common carriers should be vested with the powers they exercise in controlling other forms of public utilities.

5.—Taxes on motor vehicle common carriers should consist of:

(*a*) Those imposed in the particular State upon motor vehicles, the proceeds from such taxes being first applied to the maintenance, and any surplus thereof to all other costs of highways of general motor use.

(*b*) Proper and equitable taxes in exchange for franchise rights, provided that if such taxes are adopted, an amount equivalent to those paid under (*a*) should be deducted.

6.—Legislation should be enacted enabling steam railroads, trolleys, shipping companies, and other public utilities to acquire, own, and operate motor vehicles in conjunction with the regular lines of business.

APPENDIX B

Recommended Restrictions on Motor Vehicle Sizes, Weights, and Speeds (Recommended by the Motor Vehicle Conference Committee)

Size Restrictions

1.—Width, including load, 96 in. (Traction engines 108 in.)
2.—Height, including load, 12 ft. 6 in.
3.—Length, including load:
(*a*) Single vehicle, 30 ft.
(*b*) Combination of vehicles, 85 ft.

Note.—From the foregoing it is apparent that in order to admit of the safe passage of two vehicles each of which with its load is 96 in. wide, a highway at least 20 ft. in width is desirable.

Weight Restrictions

1.—Single vehicular unit of four wheels or less (tractors and semi-trailers to be regarded as separate units), 28 000 lb.

2.—Any one axle of the vehicle or any additional axles of semi-trailers or trailers, 22 400 lb.

3.—Per inch width of tire measured between flanges of the rim in case of solid rubber tires:

Size of Tire	Load per Inch (Maximum)
3 in.	400 lb.
3½ "	400 "
4 "	500 "
5 "	600 "
6 "	700 "
7 "	750 "
8 "	800 "
10 "	800 "
12 "	800 "
14 "	800 "

4.—Minimum thickness of rubber for solid rubber tires:

3; 3½; 4; 5-in. tires	⅞ in.
6; 7; 8-in. tires	1 "
10; 12; 14-in. tires	1⅛ "

Speed Restrictions

In the matter of speed restrictions no motor vehicle should be operated upon a public highway at a rate of speed greater than is reasonable and proper, having regard to the traffic and use of the highway, or so as to endanger the life or limb of any person or the safety of any property, and should not in any event, while upon an urban street, run at a rate of speed greater than 15 miles per hour; upon a suburban street at a rate of speed greater than 20 miles per hour; or upon any other street or highway at a speed greater than 30 miles per hour.

Note.—The laws of many States prescribe for the three types of thoroughfares indicated a graduated schedule of speed limits based on the kind of tire equipment of the vehicle and its gross weight. Such elaborate and detailed schedules, however, are very difficult to enforce.

Special Permits to Raise Restrictions

There are, of course, times when it is imperative on certain highways or portions thereof that the movement of vehicles bigger and heavier than those allowed by law be permitted.

To meet such situations—which should be the rare exception rather than the rule—the State, county, or municipality exercising jurisdiction over roads and bridges should be empowered under definite limitations to grant written permits for the movement of restricted vehicles to meet emergency conditions.

Special Permits to Lower Restrictions

To deal with bad frost or other similar conditions where it is essential to lower the weight or speed restrictions ordinarily enforced, the power of the State, as centralized in its highway departments or the county or local highway authorities, after consultation with and permission from the State highway department, should have power to reduce the weight or speed restrictions to points deemed essential to the preservation of highways or the safeguarding of travel.

In all such cases, however, there should be public hearings on the subject; due notice of the reduced restrictions should be given to the traveling public and the highways or portions thereof affected should be properly posted.

From the nature of the case, size restrictions on the vehicle, of course, can never be reduced.

Local Powers

Except as indicated, the subordinate political sub-divisions of the State, such as counties, cities, towns, boroughs, townships, etc., should have absolutely no power to prescribe size, weight, or speed restrictions at variance with those allowed for the State as a whole. The need for such limitations on local governing bodies is too obvious to require discussion.

APPENDIX C

Sound and Equitable Principles to Control Special Taxation for Motor Vehicles

(Recommended by the Motor Vehicle Conference Committee)

1.—The State should be the sole special taxing agency—Federal, County, and Municipal Governments should be excluded from the field.

2.—The motor vehicle tax should be simple in form and distributed in equitable and just proportion between the different types of motor vehicles.

3.—No highway should be improved by expenditure of public funds in excess of its earning capacity. The return to the public in the form of economic transportation is the sole measure of the justification for the degree of improvement.

4.—All money raised by such special taxes should be placed in the State Motor Vehicle Highway Fund and to secure the best results should be expended under the direction of the State Highway Department.

5.—The cost of building and maintaining adequate systems of highways should be distributed in an equitable relation to the benefits derived. These may be summarized as follows:

(*a*) Benefits to society in general, such as influence on education, recreation, health, fire prevention, police protection, the National defense, the postal service, living and distribution costs.

(*b*) Benefits to definite groups, such as agriculture, manufacture, labor, railroads, mining, forestry, and waterways.

(*c*) Benefits to property served.

(*d*) Benefits to the road user.

6.—For the purpose of apportioning costs in relation to benefits received, all highways may be divided into two classes: First, those used by the general motoring public; and, second, those which perform a purely local service function.

7.—Special motor vehicle taxes should be levied and used only for the improvement and maintenance of highways used by the general public, *i. e.*, for general highway traffic flow lines.

8.—The wide variance in valuations, tax burdens, number of motor vehicles in use, and the status of highway development in the several States prevent the adoption of any fixed formula as to the proportion of the total cost of highways of general use which should be paid for from motor vehicle funds. Generally speaking, however, these principles may be set forth:

(*a*) In States where the income from motor vehicles is insufficient to meet all of the maintenance costs of highways of general motor use without undue burden to the individual motorist, such funds should be applied first to the maintenance of interstate and State highway systems.

(*b*) In States where the income from motor vehicles is sufficient to meet all maintenance costs of highways of general motor use without undue burden to the individual motorist, any surplus should be used for this class of highway reconstruction and administration costs.

(*c*) In States where the number of motor vehicles will bring in large sums in excess of maintenance without placing undue burdens upon the individual motorist, such surplus should be used to defray all the costs of maintenance and a substantial share of all of the other costs of highways of general motor use.

(*d*) In those States where the motor vehicle income is more than sufficient to meet maintenance costs of highways of general motor use without undue burden to the individual motorist, it may be found advisable to use such surplus for the purpose of defraying all or part of the costs of bond issues to expedite construction of economically desirable motor highways.

9.—Roads of a purely local interest, serving only local needs, should be financed out of local revenues obtained from local general taxes. Special assessments on adjoining land to defray a portion of the costs of such roads may be justified.

10.—Where extraordinary improvements are undertaken in the vicinity of or serving congested areas of population the increment, if any, in property valuation following the improvement should be drawn upon to defray an equitable portion of the cost.

11.—Irrespective of the particular form of special tax of the motor vehicle, whether registration fees or motor fuel taxes, the aggregate amount of these taxes in any one year should not be so great as to impose an undue burden on the individual motorist.

DISCUSSION

JOHN V. HANNA,* M. AM. SOC. C. E.—It may be said, as a matter of economics, that the traveling and shipping public is going to make use of any new instrument of transportation which offers better service than it has had heretofore. Consequently, when motor cars, buses, and trucks can perform service economically they will enter the field, driving out less attractive or less economical agencies. Efforts to do away with this form of competition, by characterizing it as unfair, and attempting to prevent the issuance of certificates of necessity and convenience, are not likely to meet with success as long as the traveling public shows a preference for such service.

The passenger motor car, it is generally agreed, has caused loss of business to the steam railroads. If it does not always afford cheaper transportation than the railroad, it offers an attractive form of touring, unrestricted by schedules dictated by considerations other than the wishes or convenience of a particular traveler. The motor car has also a distinctly business application, as in the case of the traveling salesman, who can make his trips to suit his convenience, avoiding considerable loss of time waiting for scheduled trains. Many other instances might be cited.

As far as the tourist is concerned, most railroad officers regard the loss from this cause as permanent. The same is true of short business trips. Bus transportation is in a somewhat different category. The bus usually offers to the man who formerly used the railroad train a trip in greater comfort, more frequent schedules, and greater convenience in beginning and ending his journey. It would appear that this is a field, heretofore occupied by the steam and electric interurban railroads, which such roads might legitimately consider their own and continue to occupy, abandoning the old equipment and route for the new.

It does not appear likely that the bus will take any considerable part of the railroad's long-distance travel. The item of comfort disappears in long journeys, particularly those extending over night, and the frequent stops by buses for local passengers slow up their average speed to a point below that of the express train. There appears to be a logical place for the bus for short daylight runs, and these are more likely than not to parallel the line of the railroad.

There is little doubt that the service now rendered by the accommodation train, traveling 75 to 150 miles, and made up entirely of day coaches, would, for most passengers, be more acceptably rendered by a line of buses with more frequent service, but carrying smaller numbers in each unit. There is a proper use of the bus as a feeder for a line of railroad, also for branch-line service, now given by train. Such cases can only be determined by thorough examination. This has been done by a number of the steam roads and bus service has been inaugurated.

One feature of such service that should appeal to the public is the existence of regulation, both State and National. Bus transportation to-day is

* Chf. Engr., Kansas City Terminal Ry., Kansas City, Mo.

frequently in the hands of men with small financial resources. The sentiment that all public transportation agencies or common carriers should be held responsible for their acts of omission and commission has taken firm root. The responsibility of steam railroads for personal injuries, and loss and damage to property is well established, and it seems reasonable that the traveling public should expect and demand the same responsibility on the part of all general transportation agencies. While public demand will undoubtedly call for regulation of bus transportation, whether in the hands of steam railroads or independent agencies, the machinery of regulation of steam railroads is already in existence, is well understood, and can readily be extended to any other means of transportation the railroad may use.

An important consideration in bus and truck transportation, one that appeals particularly to all users of the public roads, is the question of taxes for the construction and maintenance of those roads. Instances have been known of electric interurban lines, the business of which has been seriously injured, if not destroyed, by motor travel on parallel public roads, having been highly taxed for the construction of those same roads. The public road not infrequently has been parallel with and adjacent to the interurban line. The injustice of a tax on the interurban's right of way is apparent and needs no argument. It is not clear, however, that there is an application of this argument to the case of the steam railroad which uses the bus as a feeder, to replace an accommodation train, a self-propelled unit, or in branch-line service. Where train service is replaced by bus service on public roads paralleling the railroads, it may be said that the permanent way is provided for the railroad at public expense in the same manner and to the same extent as it is furnished to other users; and it is equitable that the property of the railroad should be taxed in the same manner as the property of others. There is danger, however, in a direct property tax, such as some States apply, of an assessment out of proportion to the benefit the railroad receives.

The improved country road is often the means of affording readier access to the railroad on the part of the people along its lines who receive their supplies and ship their crops or merchandise over the railroad. Improved roads, offering encouragement to development of the country and the increase of its population, may prove to be a source of revenue to the rail line. To the extent that improved highways promote the growth and prosperity of the country, they promote the prosperity of the railroad serving that country.

Construction of the State Road System of Missouri is being carried out with funds obtained from the sale of bonds, together with portions of the motor vehicle and gasoline taxes. Where the motor vehicle license is proportional, or roughly so, to the horse-power of the vehicle, there is no gross inequity in that license or the gas tax. It is not true that damage to public roads is directly proportional to weight of vehicle and consumption of gasoline; but on the whole there is some approach to fairness in this general proposition, and its simplicity commends it for use in the place of more complicated methods, which attempt to take into account the destructive effects of particular types of vehicles.

The present policy of Missouri is to construct and maintain State roads without a direct property tax or benefit assessment. The motor vehicle and gasoline taxes, it is now estimated by the State Highway Commission, will yield an amount large enough to supply a sinking fund for retirement of road bonds, to pay maintenance costs, and, later, to provide money for new construction. By this means it is expected that the entire system of State highways, more than 7 000 miles, will be completed without a bond issue other than that of $60 000 000 now authorized.

The use of trucks in making a part of the complete movement of merchandise, from shipper to consignee, has obtained for many years, first, in the shape of the horse-drawn vehicle and, later, the motor truck. The movement between the freight house has not been handled by the rail company until a comparatively recent date and even now is not commonly so handled. The cost of the trucking part of the complete movement has always been paid ultimately by the consignee or consumer as a necessary part of the whole transportation charge. Except for the reluctance of railroad managements to add to their machinery for the transaction of business, there appears to be no sound reason why the rail company should not handle the entire goods movement from origin to destination.

The truck movement, particularly in large cities, has been handled by the shipper or consignee himself, or by trucking companies organized for that purpose, or by individuals. It would be manifestly a convenience, both to the shipper and consignee, if store-door pick-up and delivery were the general practice; the entire movement made under one bill of lading and the collection of charges made by one agency. There should be no increase in total costs. There might be a slight decrease in cost if all trucking to and from the freight house were performed by one agency instead of a number of unrelated concerns. It is evident, upon a little reflection, that once this trucking unit is organized, its operation can be extended to road haul, as long as the distance traveled is kept within economical limits.

A less than car load movement of, say, 30 miles by rail requires that (1) the merchandise be loaded into a truck; (2) be taken to the freight house; (3) be unloaded and placed in a car; (4) the car switched into a local freight train; (5) be hauled the 30 miles; (6) be set at the freight house or unloaded by the crew of a local freight train; (7) the goods be loaded into a truck; (8) the truck be drawn to the place of business of the consignee; and (9) the goods be unloaded. If this movement were made entirely by truck, six of these operations would be eliminated. The movement in the truck would undoubtedly mean a higher ton-mile cost than the rail haul considered alone; but a point must exist where the total of all costs for the combined rail and truck movement would exceed the total cost of the truck movement. Beyond this point the transfer from truck to car and *vice versa* would be justified by the lower cost of the rail haul. Short of this point the all-truck haul would be cheaper. Without analysis of cost, the length of profitable truck haul cannot be determined—it will vary with local conditions and type of equipment used.

As in the case of buses for passenger movement, convenience to the public is a feature likely to meet favorable reception. There appears to be no good reason why tariffs should not be fixed to give appropriate rates for points within limits of economical truck haul. Again, it is feasible to handle the truck movement by contract with independent agencies, or by the rail company under its own ownership and direction with a separate department. The advantages to the public would be in eliminating some of the agencies with which the shipper and consignee must now deal and in placing the entire movement in the hands of a financially responsible concern subject to regulation by existing State and National bodies.

E. A. HADLEY,* M. AM. SOC. C. E.—The author has well stated that transportation always has been a controlling factor in the commercial expansion of a country. One of the highest types of ancient civilization was that of the Roman Empire. Its road construction and maintenance was such that certain of its highways have survived to the present time and have set an example of what constitutes permanent highway construction.

When and how a line of highway should depart from its general course to pass through a small city or town, or to give service to an agricultural or industrial community, is a problem which cannot be settled by any predetermined rule, nor is it likely to be settled to the satisfaction of all parties concerned. The question of deciding locations for highways where only natural physical conditions are involved, causes less trouble to the engineer than where features of ultimate development of the territory must also be considered. A highway located so that it serves as a direct feeder to other transportation lines is a distinct asset to the community as a whole. In the construction of such highways the railroad company finds itself most favorably interested.

During the early periods of American history, the Government, by means of Congressional appropriations, from time to time aided in the construction of certain toll roads and canals, as well as inland waterway projects and railroads. These appropriations were spasmodic and followed no definite plan, nor were they equalized among the several States. Probably they were governed largely by immediate military necessity or political influence rather than for any definite purpose of development of the country as a whole.

Norway has records of legislation more than 1 000 years old, providing for the building and upkeep of roads and bridges. In 1274 a rather complete code of highway laws was enacted, which was replaced by a new code in 1604. In 1824 there was another revision and from that time dates Norway's modern road system. Highway legislation in England also dates back many hundreds of years.

In the United States, the interest of the Federal Government began to take definite form when a small department was originated in Washington, D. C., in 1893, called the "Office of Road Survey", the function of which was to collect data on highway conditions. This department was later designated as the "Office of Public Roads", and the scope and volume of its work and

* Chf. Engr., Mo. Pac. R. R., St. Louis, Mo.

its personnel was largely increased until it finally developed into that branch of the Department of Agriculture, now known as the "Bureau of Public Roads."

The Bureau has played an important part in the development of the highway movement, although prior to 1916 it took little active part in local or State affairs, other than in research and investigation work. Largely through its recommendations a provision was inserted in the original Federal Aid Road Act requiring that as a condition prior to receipt of Federal Aid, an adequate State Highway Department must be created and maintained. Beginning with 1916 when the Federal Government appropriated $75 000 000 to be allotted to the States annually over a 5-year period, on a graduated scale, the Government has increased such appropriations from time to time so that the total made for the years 1917 to 1926, inclusive, has amounted to $615 000 000.

It is to be presumed that these funds of the Federal Government have been accumulated by taxation under which the railroad companies have at least paid their proper proportion. As property owners and taxpayers in the several States, they are, therefore, entitled to their proper share in the distribution of Federal Aid to the States in highway construction. Unfortunately, this view does not seem to prevail in certain States, and those in authority fail to consider the railroad company's interests in the application of such Federal aid as is secured.

In other words, Federal aid has been applied to projects which have not involved separation of grades from the tracks of a railroad company, and the cost of such separations has been divided between the State and the railroad, eliminating any consideration of Federal aid funds allotted to the State for highway work. This is not entirely fair to the railroads. They are setting up the claim that Federal aid should be prorated in such manner that the railroad companies will benefit in the same proportion as other property owners and taxpayers in the community.

The theory of highway taxes for maintenance of roadways is quite ancient. As early as 1661, during the reign of King Charles II in England, four hundred hacks were licensed for operation in London, Westminster, and vicinity, and within a radius of six miles. The revenues from these licenses were used for paving the roadways.

The gasoline tax, as mentioned by Mr. Budd, is an efficient device for making those using the highways pay for such use in somewhat the same manner as toll-gates once required such payments. Thirty-nine States and the District of Columbia now tax gasoline sales, revenue from which is used for the benefit of the highways of those States. According to report the Republic of Mexico has imposed a gasoline tax for the purpose of raising funds for improving highways.

It has been estimated that in 1925 about 20 000 gal. of gasoline were consumed in the United States during every minute. The domestic consumption of gasoline has increased from 4 474 000 000 gal. in 1921 to 8 950 000 000 gal. in 1925, or almost exactly 100% in 5 years. Records indicate that there are

in excess of 20 000 000 motor vehicles in the United States, or 1 for every 6 people (which exceeds the number of telephones). Under such conditions the gasoline tax is widely distributed and seems to be the most logical method of raising funds for the construction and maintenance of highways.

A uniform bill for motor vehicle regulation by the several States has been proposed by the American Electrical Railway Association (it also has the support of the American Short Line Railroad Association). The Association has gone so far as to prepare a complete bill which it recommends be passed, vesting authority in the Railroad Commission of the State for the regulation of highway traffic. This bill proposed a tax of 1 cent per ton-mile for pneumatic tired vehicles, and 1½ cents per ton-mile for hard tired vehicles, which figures were arrived at by a committee of the Association after extensive studies. The Committee admits that the information on which the amount of the taxes was based was incomplete, but believes that any change which may be necessary in the future will be in the form of an upward, rather than a downward, revision.

The railway companies have complained because of the general and special taxes they are obliged to pay to help construct and maintain highways, on which motor vehicles compete with them. Spokesmen of the motor industry have replied by showing that the total taxes paid on motor vehicles are larger than on railroads and by referring to the large amount of freight business that the motor manufacturing industries give the railways.

The fact, however, must not be lost sight of that part of the taxes collected from the railways are used to pay for the highways on which motor vehicles operate, whereas none of the taxes paid on motor vehicles is used to help provide highways for the railroad trains. Many taxes assessed against motor vehicles are against private passenger automobiles; therefore, the total amount paid is no indication as to whether or not the taxes now being levied on motor buses and trucks are adequate. The railways operate on roadways which they themselves construct and maintain, while buses and trucks operate over highways which the public has constructed and maintains. Eventually, they must pay in some form their *pro rata* of this cost if an equal balance is to prevail.

Regulation of buses and trucks operating as common carriers appears to have the unanimous approval of virtually all interests. The principle of taxation has similar approval; however, the amount of the taxes which would be fair and just is a point on which there is sharp controversy. It appears to be generally agreed that taxation should not be adopted for the purpose of strangling highway transportation, and the conservative elements on both sides of the question advocate a tax schedule that would impose a fair share of the cost of construction and maintenance of highways on trucks and buses without unduly burdening them or restricting the development of this form of transportation.

F. G. Jonah,* M. Am. Soc. C. E.—Transportation is one of the distinguishing characteristics of civilization. Savages and barbarians had none,

* Chf. Engr., St. L. & S. F. Ry., St. Louis, Mo.

or, at best, very crude methods. Primitive man traveled very little. The first migrations that he made were probably in following game and for spoliation or conquest of neighboring tribes. In the earliest forms of transportation man himself was the vehicle, burdens being carried by women and slaves. After a time he learned to domesticate and harness animals, and thereupon transferred the burden of transportation from his own shoulders to the backs of four-footed creatures.

All transportation is founded on the use of the wheel, also much of the industrial development. At a very early age when the wheel was invented, transportation took an immeasurable stride forward. The first development of the vehicle on wheels was the chariot of the ancients, harnessed to horses, and used largely in military operations. The necessity of furnishing some path on which these vehicles could travel gave birth to the good roads idea.

The Romans built the great roads of antiquity as a basis for military, rather than commercial, operations. However, they substantially formed the basis of the vast network of highways which became of great use in the development of Central Europe.

There was little change in transportation methods for a period of almost 2 000 years, the only difference being that vehicles became more ornate, more commodious and more substantial, and that the roads on which they traveled became better. It was not until 100 years ago that anything was evolved that could be termed "rapid transportation" and that possibly only after mechanical means were utilized for propulsion.

In 1925 England celebrated the one-hundredth anniversary of the founding of the steam railway. Railway development in the United States began about 90 years ago. It was far more rapid, efficient, and economical than anything the world had previously enjoyed, so it is not surprising that on its introduction all other forms of transportation quickly fell into disuse. The stage coach, pony express, river steamer, and canal-boat became almost obsolete in the United States, and the fact that railway transportation was developed so quickly and so efficiently led for a time to the neglect of the highways. In this respect America was entirely different from the European countries because their highways had been established and well developed before the steam locomotive was invented.

In the Eighties, electricity was introduced as a motive power for transportation. At once the interurban car became exceedingly popular for the simple reason that it could traverse the streets of cities and villages, could be boarded at almost any street corner, and made frequent trips between various parts of the cities and adjacent country districts. Then the railroad companies were faced with a new competitive factor, one with which they could not wholly compete for short-line hauls.

A few years later, or about 1900, the automobile became a reality, and its use, with the motor trucks, has become so general that an entirely new situation has developed in transportation. About the first important result of the widespread ownership of automobiles was an insistent demand for

the construction of good roads, and the various States undertook to supply this deficiency with characteristic American haste and waste.

Good roads have been, and are now being, developed along previously established routes of communication; that is, generally they are parallel with the trunk lines of the railway companies. It is not at all improbable that many expenditures thus made were unnecessary, and that more good would result to the country eventually if the roads had been built into remote districts, making them accessible and tributary to the existing railways.

The centers of population were built along the railroad lines, which usually represented the shortest distance from one flourishing community to the next. As the object of the highway systems was to link up important towns, it was natural that the railroads would be paralleled to a great extent.

On the completion of these highways, bus lines were introduced, in close competition with the railways—in some instances, with the electric lines. Being more flexible and mobile in their movements, they have become a highly competitive instrument in transportation, so that in many cases railway companies have been obliged to curtail their local passenger service. To the present time they have not entered the field of freight carrying to any great extent, although that is coming. Certain companies in the East have put on freight-carrying buses to handle their local freight traffic within certain territories. This has one distinct advantage—it makes store-door delivery possible within a certain radius.

In the early days of railroad development it was regarded as very essential to have freight and passenger stations as near the heart of the city as possible. This was in the days of the horse-drawn vehicle when the haul was of particular moment; but nowadays, with well-paved streets and quick-moving motor vehicles, it is not so essential, and cheaper sites on the outskirts of the cities can be obtained. The moving of these freight terminals probably will lessen congestion on the business streets of the city to a great extent, so that eventually the railroad companies may be able to make substantial savings. In many instances the railroad companies own extremely valuable properties in the hearts of cities, which may be dismantled and the ground sold for more than enough to erect modern and commodious terminals on the outskirts.

The question arises as to what is the railroad company to do to meet the bus competition? To some extent it can, and does, put motor-driven cars on its rails, as for local passenger service; but this does not fully meet the situation because the car is still confined to the rails, and is not as mobile as the bus, which can gather up its passengers around the street corners of the cities.

As to less than carload freight, the time is undoubtedly coming when manufacturers in cities will distribute goods from their factory doors to their customers within a radius of many miles by their own motor trucks; or the service may be performed by truck companies, the goods being only handled twice—once from the factory into the truck, and again from the truck to the store. Evidently, there is some economy in this handling as

compared with methods pursued in the past. Just as the railroad companies performed a more efficient service than had hitherto been enjoyed, so the motor bus and motor truck, with the possibility of cheaper transportation, will undoubtedly secure a part of the business, and the railroad companies will have to adjust their operations accordingly.

There is a widespread movement for American railroads to enter into motor-bus and motor-truck transportation.* Railroad companies are applying to the Interstate Commerce Commission for permission to publish joint through-passenger fares covering transportation partly by train and partly by motor bus. Several companies are adding greatly to the buses already in service.

The Chicago and Alton Railroad Company has announced that it will put on motor buses to travel the highways between certain important points on its lines. On no other railroad in the Middle West could this experiment be tried with as good prospects of success, nor would the experiment be so well justified. Situated as it is across the populous State of Illinois, extending from Chicago to St. Louis, Mo., and having many large and important towns only a few miles apart over its entire distance, and paralleled practically the entire way with an electric line on one side and a concrete highway on the other, this railroad seems to be ideally fitted to try out a system of motor transportation under railroad management. One result of the developments of the last few years has been that local passenger trains have become much less generally used, and the chances are that in the next few years many local freight trains also will disappear.

The good roads have been and are being established, and the motor bus and motor truck are being more efficiently developed from year to year. All three are fixed parts of the transportation plan, and the railroad company will have to utilize these and add them to its established facilities as another arm of its service.

It is not at all unlikely that the railroad companies, with their skilled shop forces, whereby repairs to motor equipment can be maintained more cheaply than by private companies, will be in a position to render this service perhaps cheaper than any other agency. It can be set down as a certainty that the cheapest and quickest method of transportation will, in the end, be the most used. There is no possibility that for long hauls any method can supplant the railroad for the movement of either passengers or freight.

The increasing use of the automobile, motor bus, and motor truck is having a pronounced effect on rural life. The growth of small country towns as business centers has been arrested. The country store, country school, country church, country doctor, and country newspaper are passing, and business activities and population are being centralized. The local business of the railroad companies is being affected by this tendency.

Years ago, when railways were first built, and in the days of horse-drawn vehicles when highways were generally in bad condition, it was thought necessary to have stations about seven miles apart. Now, when communica-

* *The Railway Age*, March 27, 1926.

tion is so much more rapid and easy, business will seek better markets, and there is a strong likelihood that in many instances the local stations of the railways can be abandoned, and possibly the railway companies may be able to effect some savings by reducing service where it is no longer needed.

The railroad companies have not always been treated fairly by State Commissions in respect to the curtailment of their passenger service. It has been clearly shown in many hearings that the introduction of bus lines has taken away the necessity for the operation of local passenger trains and yet the Commissions refuse to allow the companies to change their schedules. The time is at hand when a comprehensive plan of regulation must be worked out, governing the operation of buses and trucks engaged for hire on the public highways; and the interests of the railroad companies must be taken into account by the regulatory bodies. The aim should be adequate service without wasteful duplication.

W. W. Crosby,* M. Am. Soc. C. E. (by letter).—"The Relation of Highway Transportation to the Railway", as set forth by Mr. Budd, seems to be the fairest statement of fact that has been printed on this subject. It seems refreshingly frank, lacking in prejudice, thoughtful, and even prophetic; with a calmly judicial atmosphere permeating it which adds to its convincing quality.

Perhaps one might wish that brevity had been sacrificed for the sake of greater clarity in some cases. For instance, in his "Inventory", it is not apparent just how the "investment" figures are reached. Do they include land or right-of-way values in any or all cases? "Cost" figures always suggest detailed explanation and scrutiny before acceptance. Just what is meant by the statement that "twenty-five years ago the inventory would have been blank so far as modern highway transportation is concerned"? Were not the rights of way existent and valuable? And are not some of the important highways of to-day in the main the same highways of twenty-five years ago?

The essentiality of the railways is well set forth by Mr. Budd, and the writer is glad to see it emphasized contemporaneously with the recognition accorded by the author to the importance and supplemental abilities of the newer means and forms of transportation. In these days of "consumptionism" there is certainly a need of brakes on the apparently growing tendency to throw away the old for the sake of something new. The arguments for economy in transportation for the sake of public welfare seem soundly, if briefly, stated.

Mr. Budd points out correctly that the automobile is not of American origin, but there may be some argument—of the "hen or the egg" variety—with his statements as to the relation of automobiles and highway improvement. From his own observation and experience, the writer would be inclined to put the highway before the automobile.

Arguing most convincingly in the matter of motor-bus competition with, or in addition to, railway transportation, the author reaches conclusions that, with perhaps one exception, appeal strongly. As to the conclusion that, "the

* Cons. Engr., Coronado, Calif.

public must support whatever transportation agencies are maintained and should not undertake two where one will suffice", he may be correct theoretically, but at the same time give a wrong impression.

Is not a reasonable amount of competition needed in transportation now, as well as in trade, to insure the proper economic "life"? If railway officials were always able to act as calmly and fairly as Mr. Budd has written, there might be less need for competition; but even with the belief that,

"—the days are hastening on
By Prophet-Bards foretold,"

it still seems advisable to allow reasonable competition in many lines of activity, including transportation; not putting into the "one basket" of "railway direction" all the "eggs" of the "new form of transportation"; nor, indeed, in that basket until that railway direction shall have substantially recovered from its past handicaps of "public damnation", Government control, etc. Mr. Budd's last sentence is a mildly expressed, pithy summary of the whole matter.

William T. Lyle,* M. Am. Soc. C. E. (by letter).—The fundamental economic principle governing the relations between railway and highway transportation should be co-ordination. The public cannot afford superfluous and overlapping service, but requires, and should demand, a smooth-running and efficient transportation system. Without it the National commercial and industrial structure will disintegrate.

The following information, collected by the Interstate Commerce Commission, is based on replies received from 164 out of 176, Class I line-haul steam railways, including all the larger companies; 377 out of 635 Class II and Class III steam railways; and 118 out of 260 unclassified electric railways.†

Steam Railways.—Buses.—No buses are operated by subsidiaries in terminal service as compared to 506 in line service. Leading Class I railroads have reported subsidiary bus lines operating buses for service in connection with their own operations, as follows: The New York, New Haven and Hartford, 118; the New York Central, 81; and the Union Pacific System, 39; all in line service. In addition, the Great Northern reported 74 in competition with its own operations and 83 in competition with other railroads. The railroads of Class I owned 225 of the buses in operation and those in Class II and Class III, owned 23.

Motor transport companies and individuals operate 1 511 buses in terminal service to Class I railways and 19 in terminal service to Class II and Class III railways. Only one of these is engaged in interstate traffic. The buses operated by motor transport companies and individuals in line service competing with Class II and Class III railways, number nearly 600.

The New York Central reports 473 buses; the Chicago and Eastern Illinois, 246; the "Big Four", 349; the Pennsylvania, 292; and others, 170; to a total of 1 530 buses operated by motor transportation companies and private individuals in competition with Class I railroads in terminal service. On line

* Prof. of Civ. Eng., Washington and Lee Univ., Lexington, Va.
† Docket No. 18 300.

service the Pennsylvania reports 2 463 buses competing; the Baltimore and Ohio, 838; Chicago, Milwaukee, and St. Paul, 1 234; Atchison, Topeka, and Santa Fé, 1 079; the Southern Pacific lines 1 891; and other Class I roads, 11 594; making a total of 19 099 competing buses. There are also 1 253 independently operated buses that do not compete, but supplement the service of the steam roads. Of the combined total of 20 352, 2 848 are engaged in interstate traffic, 14 193 in intrastate traffic, and 3 311 in traffic of both kinds.

Steam Railways.—Motor Trucks.—Steam railways of all classes report somewhat similar conditions with respect to motor trucks. Only 27 trucks are operated directly by first, second, and third-class railroads in terminal and line service and only 57 trucks by subsidiaries.

The railroads own 56 of the motor trucks in operation, and the motor transportation companies subsidized by them do not own any. The New York Central declares that 526 trucks are operated by motor transportation companies and private individuals in terminal service along their lines; the Pennsylvania, 603; the "Big Four", 381; and all others, 407; making a total of 1 917 trucks. Of this number only 13 affect the service of Class II and Class III railroads, the remainder being reported by Class I roads.

In line service, the reports are: New York, New Haven and Hartford, 2 229; New York Central, 2 648; Pennsylvania, 6 564; Chicago, Milwaukee, and St. Paul, 1 978; Atchison, Topeka, and Santa Fé, 3 662; the Union Pacific System, 3 531; and all other Class I roads, 22 595; or a total of 43 207 trucks in competitive service. These roads report, likewise, that there are 225 privately owned trucks operating in connection with their own lines.

In line service, Class II and Class III railroads are affected by only 545 private motor trucks, while railroads in Class I have 43 207 competing against them. Of this last number, about one-half are engaged in intrastate traffic and the remainder in interstate traffic, or a combination of both kinds.

A similar analysis of tabulated data obtained from operators of electric railways reveals the following facts.

Electric Railways.—Buses.—There are 401 buses in terminal service, practically all in intrastate traffic. In line service, working within State lines, there are 350 buses; 751 in all. Of this total, 300 are competing with the railroad reporting; 100 are competing with other roads; and 351 are not competing with any railroad.

Subsidiaries operate 190 buses in terminal service, chiefly in intrastate traffic; and 406 in line service of which 59 are engaged in interstate traffic, 178 in intrastate traffic, and 169 in traffic otherwise unclassified. Subdividing further, 339 of the total operate in connection with the electric roads reporting; 226 compete with them; and 31 compete with other railroads.

There are 955 buses owned by electric railway companies from the eight National regions, with the Southern region listing none. There are only 75 buses owned by subsidiaries.

Motor transport companies and individuals operate 75 buses in terminal traffic, all of an intrastate character; and 1 356 in line service, of which 170

are distinctly in interstate service, 586 in intrastate service, and 600 not classified. In the line service, only 1 040 buses compete with electric lines.

Electric Railways.—Motor Trucks.—Railroad companies report that they operate 30 trucks and their subsidiaries 19, both being of negligible significance. They state that they own 36 of the trucks, the subsidiaries owning none.

Motor transport companies and individuals operate 27 trucks in terminal service and 2 394 trucks in line service. Of the 2 394 trucks in line service, 77 operate in interstate service; 1 297 in intrastate service; and 1 020 in service common to both.

Of these same 2 394 trucks, 43 are run in connection with electric railway operations and 2 351 in competition with them. Of the 2 351 trucks, the large number of 1 340 are operated by the Pacific Electric.

Comment.—This investigation shows that a comparatively small percentage of buses and a large but undetermined percentage of motor trucks are operated in interstate traffic.

The information presented reveals a very large degree of competition in transportation service, which should be closely investigated in each individual case. The principle laid down by the author that common carrier motor trucks should not be permitted to operate in competition with railways, except when they are a real public convenience or necessity, appears to be thoroughly sound. His view that the railways must recognize that public convenience and necessity require the development of transportation on the highways, and that they should not attempt to eliminate motor-vehicle competition by arbitrary means, appears to be liberal. Such competition should be subject to proper control. Consideration should be given to the question whether or not highway passenger transportation can be conducted more advantageously under railway direction. The importance of National, State, and joint board regulation is apparent and, for the present, each case should be carefully determined on its own individual merits.

M. H. Gerry, Jr.,* M. Am. Soc. C. E. (by letter).—American railway transportation is undoubtedly the best and cheapest in the world, nevertheless, it has reached a point where it is too slow, too inflexible, and too costly to meet the requirements of expanding business in this country. The motorized highways have very greatly relieved the situation, and to an increasing extent will continue to do so; but a satisfactory general solution is not likely of attainment save through a re-organization of the railways, and their operation in combination with other facilities now available for public transportation. Perhaps the most important matter confronting industry to-day is that of providing quicker and cheaper means of moving freight and passengers over the great distances separating sections of this country.

The United States presents the largest and the most diversified market for goods and products, and it has also an abundant supply of raw materials, power, and virgin soil. Foreign competition at home can develop only as permitted by insufficient means of domestic distribution.

* Cons. Engr., San Francisco, Calif.

There is no known limit to the amount of transportation that may ultimately be utilized if made sufficiently rapid and proportionately cheap. The tremendous development of the highways has demonstrated this fact, and furthermore it has shown that speed and convenience both draw and create traffic and that the public appreciates the saving in time and will pay accordingly.

It must be quite apparent to any one who has given the matter serious thought, that there must be continual improvement, betterment, and much new construction in connection with the railroads, or National transportation will be seriously impaired within the next decade. For a considerable period there has been no general expansion of the railways, at a time when highway development has been the greatest in history. Nevertheless, the rails are still the back-bone of public transportation and are likely to remain so, as no other facilities on land, when properly operated, are their equal for moving dense passenger or freight traffic over material distances.

In recent times the railways have represented about the only great business in the United States that has not shown material expansion. This can be illustrated by Mr. Budd's figures on equipment in use, invested capital, and annual cost of transportation during the past five years (1900-1925). However, there has been substantial progress in other directions. The railroads have handled more freight than ever before and have reduced the time in transit; operating conditions have been bettered and efficiency has been increased; their financial position has been improved, and their securities are now relatively attractive as investments. On the other hand they have added but little to their facilities or their capital.

Since 1922 the electric and gas public utilities of the United States have placed about $8 000 000 000 of new securities, while the industrials gained about $10 000 000 000. For the same period the railways issued only about $3 000 000 000. There is a reason for this situation, and it can hardly be found in a lack of public demand for the kind of transportation which the railways can best provide; nor can it be found in the impossibility of financing any well-considered development. It may have arisen in part from conservatism in railroad management, or it may be due to Government restrictions; but it is probably the result, in no small degree, of reliance on the fallacy that the total amount of traffic was a fixed entity, controlled only by population and industrial conditions, and not susceptible of material increase by betterment of its own characteristics of speed, convenience, and cost. It has now been proved, however, by experience with motorized highways that traffic, like the demand for electrical power or for merchandise, responds in volume to improved service at lower cost.

There are large sections in the interior of the United States that would profit immensely by quicker and less expensive transportation, and if this can be attained in any way, a great increase in the volume of traffic may be expected, with profit alike to the region served and to the carrier companies. It is probable, therefore, that very soon "public convenience and necessity" will demand much more expeditious and efficient mass-distance transportation,

coupled with some form of collection and delivery system operating under one contract. To accomplish these results, new facilities must be used and new methods employed. Thus, the problems involved, to a material degree are those of engineering and a discussion by the profession is, therefore, opportune.

Time in Transportation.—Of all the elements of transportation, except costs, time is the most important. It bears directly on the value of the service and it enters materially into the cost. Most things of importance in the business world run with time: Interest, depreciation, taxes, labor costs, life itself, are measured in its terms. Every advance in transportation has been based primarily on time. The quickest movement at equal cost will always win, be it for a letter, a passenger, or 1 000 000 tons of coal. The public will pay more for fast service because it is of greater value.

The motorized highways have provided a very much quicker movement of passengers and freight under a great variety of conditions, and, therefore, they have not only taken over from the railways their slow-moving local traffic, but they have created a fast volume of business not heretofore existing. Time enters, not only as speed in transit, but as the full interval required, from readiness to move to arrival at final destination. Therefore, frequent service, regular schedules, convenient terminals, and expeditious gathering and delivery of merchandise, all accelerate transportation and increase its value.

In the movement of passengers, comfort and safety are important factors, but they control the volume of business only when co-ordinated with time. The railroads now provide a high degree of safety and reasonable comfort on most of their trains. It is true, of course, that some "locals" hardly compare in comfort with the best motor coaches, but it is doubtful whether much traffic has been lost on that score alone. The automobile and the motor-bus have diverted traffic from the railroads because they take the passenger over more territory, where he wants to go, with less expenditure of his time, when he is ready to move; and for him this is cheaper transportation. Mr. Budd points out that the buses gain traffic by making frequent stops along the highways, but after all this is only another way of providing a quicker movement of the passenger from the point of origin to destination. Moreover, in California, there are fast bus lines that operate only from depots, make fewer stops than the trains, and better time in transit. With frequent schedules, this service has created for itself a very large volume of business without materially affecting railway traffic in the same territory.

The question is frequently asked, to what extent can the rails compete with the highways for passenger business? The answer is that they can compete wherever the volume of traffic is sufficient to justify a faster over-all service than that possible on the highways, at substantially the same fare. For every distance, there is a certain volume that meets this condition, modified, of course, by local situations.

The motor truck has succeeded also largely because it saves time. Shippers realize that there is value in time and will pay for it. The truck is faster than the rails for short hauls, and in many cases for hauls of con-

siderable distance, due to saving in time otherwise required in transferring to and from terminals and in waiting for train movements. For example, a certain freight shipment in California required 2 days, including the terminal transfers and loadings. The same movement is made by truck in 5 hours, with one loading and one unloading. The truck haul costs more, but it is worth more to the shippers. For short hauls the truck is not only a time-saver, but it is less expensive to operate. However, as in the case of passengers, if the volume of freight be increased sufficiently, a point is finally reached for every distance, except the very shortest, where the rails can move the traffic in less time and at smaller cost than is possible with trucks on the highways.

In the last analysis, time is the controlling factor in transportation. To industry, speedy delivery of materials and products means a reduction of waste in large measure, due to the lesser amount of equipment and capital required in the business. To the carrier companies, faster movements mean greater volume of traffic handled with substantially the same facilities and labor.

It is said that, by good management since the World War, the railways have accelerated the movement of freight on an average by 25 per cent. This is an excellent showing, but it is not enough to meet the future requirements of American business. However, with equipment and facilities which can now be made available, it is believed feasible to further reduce the time required for completed movements of freight and passengers by at least 50% for average conditions in the United States. This improvement, nevertheless, is not possible without a change of motive power and a re-arrangement of the main railway lines, co-ordinated with motorized facilities on the highways.

Arterial Railways.—Highway development is producing great arterial thoroughfares extending from the Atlantic to the Pacific and from Canada to Mexico and the Gulf. These main traffic lanes are contributing largely to the extent and popularity of highway transportation.

The railways, on the other hand, have provided no such arterial ways, although in their case the need is more urgent. This situation has been caused, in part, by diversity of ownership, by competition for business, or by Governmental restrictions, but, in a larger sense, it is the result of lack of vision in connection with the requirements of continental transportation.

All the principal railway companies are operating main-line through services over their own rails and in various combinations with others, but these arrangements do not qualify as arterial trafficways in the sense here intended. To be truly "arterial" they should drain the territory served and fully utilize other rails, buses, trucks, and all available means, as gathering, forwarding, and distributing agencies. The routes followed of course should be the most direct, regardless of present ownership, and, in the end, the rail companies will find a way, by merger or otherwise, to accomplish this result with full protection to all vested interests.

The arterial railways must be equipped, of necessity, for rapid and expeditious movement of passengers and freight over long distances, leaving to the other rails and the highways the task of collecting and distributing the traffic.

Such a service would meet with public favor, and it should reduce the time as well as the cost of long-distance transportation.

Electric Traction.—This subject is introduced here because of its material bearing on the future relation of highway to rail transportation. As previously stressed in this discussion, it is believed that speed is a far greater factor in controlling the volume of traffic than the carriers or the public have ever fully realized. For a long period the railways were supreme in this direction, but now, under many conditions, they provide slower transportation than that furnished by the highways, or even in some cases by the waterways.

It is well known that there are many existing limitations to speed on rails, but their removal does not involve difficulties, either physical or financial, as great as those which have been overcome in the development of motorized highways since 1900. Some will say that the track and roadbed cannot be further improved economically, and that this will limit speed. However, only a few engineers will agree with this view. Others will cite many real or supposed obstacles, but most men will agree that improved motive power and train control are essential if any great increase in speed is attained.

The application of electric traction to trunk railroads has been discussed from many angles for a number of years, but mainly from the one of cost of operation under existing railway conditions. The general conclusion among railway men has been that a change in motive power was not justified, and, viewed solely from the standpoint of arrested development, they are probably right. For special reasons, however, electric power has been applied to heavy railroading in a number of cases, under a wide variety of conditions, and the results obtained are ample to establish its possibilities in connection with any great increase of speed in railway operation. The modern steam locomotive is a wonderful power plant, considering its limitations of space and weight, but it is fundamentally unsuited for supplying mechanical energy at the rate necessary for moving trains at materially higher speeds.

It is recognized that there must soon be further material improvements in long-distance transportation. The basic requirements are more speed with less cost, and electric traction offers greater promise of aiding in these directions than any other known agency. There are sound engineering reasons for this statement, based on the highest technical authorities, and fully substantiated by wide experience in both the electrical power and railway fields.

The thought is therefore expressed that the main rail lines should be electrified and highly improved so as to adapt them for very fast and heavy traffic; that the less important rail routes and branch lines should be equipped with rail-motor cars, or Diesel electric locomotives; and, finally, that all gathering, transfer, delivery, and short-haul business should be handled by fleets of trucks and buses operating on the highways.

Summary.—Ample, fast, and cheap public transportation is the most essential of all factors in establishing and maintaining American prosperity.

The movement of freight and passengers is inherently a universal public service and ought to be conducted by corporations or other agencies of National character, functioning under one form of Governmental supervision.

The railroad corporations should extend the scope of their operations to include the highways, the waterways, and the airways.

Arterial railways, electrified and fully equipped for heavy traffic at high speeds, are an essential part of any continental transportation system adequate for future industrial needs.

With improved and unified methods of operation, by utilizing facilities now available, it is commercially feasible to reduce materially the cost of conducting transportation and to expedite the movement of traffic in the United States.

RALPH BUDD,* M. AM. SOC. C. E. (by letter).—Mr. Crosby properly questions the writer's "Inventory". Values for highway right of way were not included and to that extent the figures given for investment in highway transportation were too low.

He also questions whether competition should not be permitted between different carriers even though such competition would add to the total cost of producing the transportation by the competing carriers. The writer does not believe in eliminating all competition, but, in the case of commercial highway transportation, the theory of regulated monopoly has much to commend it. Just how far this can go in practice is, of course, a question of judgment to be determined by the circumstances in each instance.

Mr. Gerry's plea for quicker and cheaper transportation is in line with the ever-increasing need for efficiency. As far as passenger travel is concerned, the operation of through sleeping cars from the East to the West Coast, and *vice versa*, is practically all that the writer can think of that would eliminate delay and inconvenience in long-distance railway travel on the present-day fine, through trains. It is true that freight movement by rail can be expedited still more than it has been during the years since the World War, but most of the saving in time will come from avoiding terminal delays rather than from operating freight trains at higher speeds.

By some further consolidation of railways, transfer of cars and the incident inspection will be unnecessary, and the cars may be kept moving more of the time.

The problem of taxation was discussed by Messrs. Hanna and Hadley. It seems a most difficult one to solve. The principles stated in the paper still seem to be correct.

The obvious injustice of taxing the railways to provide highways for competitors should be removed, but not by imposing an unjust tax on other transportation agencies. The fairer method is to transfer the burden of taxation from the users of the railways to the users of the highways and to tax each of the latter on the basis of the proportion that its use bears to the total use made of the highways.

The trend of local passenger travel from the railways to the highways of the country, due to the increasing number of automobiles and highway motor buses and the improvement of roads, has continued uninterruptedly through 1926 and 1927. The decrease in railway passenger revenue in 1927

* Pres., G. N. Ry., St. Paul, Minn.

compared with 1925 was $78 800 000, and the decrease in the number of passengers handled was 51 000 000, or 5.8 per cent.

The astonishing thing is that many railway men thought and said in 1925 that the bottom had been reached in the decline of railway passenger travel. The conclusion seems inescapable that the railways have lost irretrievably the short-haul passenger business. The common sense course open to them is to substitute smaller, lower cost, gas or oil-electric units for steam-operated passenger trains, where trains are essential, and to eliminate unprofitable trains wherever they are not necessary. The latter process may be advanced by the operation of high-class, convenient motor-bus service on highways adjacent to and often parallel with the railways.

Probably the most striking statistics concerning the operation of the railways of the United States for recent years are those which show a decline in passenger revenues from $1 290 000 000 in 1920 to $980 000 000 in 1927, with practically no reduction in passenger train-miles during that period. The effect of this loss in passenger revenue is, therefore, a loss in net railway operating income of approximately $310 000 000 in 1927 compared with 1920, or the equivalent of 1% on $31 000 000 000. This is more than the total investment in the railways of the United States.

It is the 20 600 000 private automobiles, and not the 90 000 highway buses, that are responsible for this continuing decline in railway passenger revenue, although the total travel by bus is increasing, as is also the average length of ride per passenger. No one can say how much more railway travel will decline, but it is evident that the long-haul passenger business is going to remain with the railways just as the long-haul bulk freight will. To keep as much travel on railway trains as possible, the railways are justified in providing extra fine through trains and small economical units for short runs and branch-line operation. In many places highway buses can be substituted for unprofitable trains by co-operating with bus operators, or by the railways controlling the bus companies themselves.

Regulation of buses by the same commissions that regulate railway operation seems essential for complete correlation of rail and highway service. There is pending in Congress a bill to provide some Federal control of common carriers on highways and that bill very wisely leaves most of such regulation to the State authorities. Beyond the issuance of certificates of public convenience and necessity authorizing interstate operation, there does not seem to be any real need for Federal jurisdiction.

During the last two years there has been substantial improvement in bus transportation. The capacity of buses has been enlarged, until the newest types carry thirty-eight passengers. Luxuries have been added in the way of air-cushioned seats, interior baggage racks, hot-water heaters, storm windows, and ventilators. Chassis also have been improved in riding qualities and motors of greater reliability and economy have been produced. The interiors of the latest buses are painted in pleasing colors giving a decorative effect comparable with the treatment of the fine transcontinental trains. Now, the use of aluminum alloy is proposed to lessen their weight by 3 000 lb., or more.

There is in active progress a series of consolidations of small bus companies into a lesser number of stronger and more efficient systems. In this respect, the bus situation, to-day, resembles the railway situation in the Fifties when amalgamation of many short lines into systems like the New York Central; New York, New Haven and Hartford; Pennsylvania; Baltimore and Ohio; and others was beginning. There is no doubt that larger and stronger bus companies will be able to improve upon the service of the small weak companies and to operate much more economically, just as the larger railway systems were able to improve upon the service of the many small railway lines operating independently. How far consolidation of bus lines will enable highway buses to compete more effectively with the railways for long-haul travel, is one of the most important transportation problems of the day.

URBAN AND INTERURBAN BUSES*

By Britton I. Budd,† Esq.

With Discussion by Messrs. Robert P. Woods, Fred G. Buffe, B. H. Piepmeier, C. E. Smith, Winters Haydock, John W. Reid, Lucius S. Storrs, Anson Marston, and Britton I. Budd.

Rapid development of the bus, or as some prefer—the motor coach—in urban and interurban transportation, has given railway operators a new problem; that is, to find the best and most economical use to which the motor coach can be put, and then to fit it into its proper place in the transportation system.

The demand for motor-coach service in recent years has come directly from the traveling public. We have been living in an era of great prosperity in which the number of private automobiles averages almost one for every family in the country. The comfort and convenience of the automobile has created a demand for de luxe travel, and the motor coach has appeared to meet that demand, regardless of economic law which, under less prosperous conditions, would be a determining factor.

It is the business of transportation companies to supply the public with the character of service it demands. If the public prefers to ride on rubber tires at increased cost, the transportation company must supply that service, even if it may not be the most economical.

Co-ordination of all transportation facilities so that each may be assigned to the kind of work it is best fitted to perform is the problem which must be solved before the future of the motor coach can be forecast with any degree of accuracy. The public must look to the operators of the steam and electric

* Presented at the Spring Meeting, Kansas City, Mo., April 14, 1926.
† Pres., Chic., North Shore & Milwaukee R. R., Chicago, Ill.

railways for the solution. They are the men who by training and experience are qualified to perform this service.

That rapid strides are being made in the co-ordination of facilities is seen in the manner in which steam and electric railway companies have adopted the motor coach.

A survey made by the National Automobile Chamber of Commerce shows about 20 steam railroads operating motor coaches as a part of their regular passenger service at the end of 1925 and that 18 others are now (1926) considering similar service. The same survey shows that 51 steam railroads in the United States and Canada are using motor trucks to supplement their freight service.

The adoption of the motor coach by the electric railways of the country is much more marked. In 1920 there were only 16 such companies using motor coaches as a part of their service, whereas, at the end of 1925, 280 companies were using them.

This great increase has come in the last two years. In January, 1924, only 14% of the electric railway companies of the country were operating motor coaches. In January, 1926, the percentage had risen to 35. These companies are operating 13 000 miles of motor-coach routes.

That most of this traffic is new business is seen in the fact that electric railways in the same period carried more passengers than ever before in their history. The steam railroads carried more freight in 1925 than in any previous year and materially reduced the time lost in transit.

As the adoption of the motor coach and the motor truck by the electric and steam railroads goes on, it is probable that in the near future the existing transportation agencies will handle all this traffic as a properly co-ordinated part of their systems. The problem is one of adjustment.

Some of the electric railway companies of the country have gone into the motor-coach business on an extensive scale. The largest is the Public Service Company of New Jersey which is operating more than 800 motor coaches in connection with its rail lines. Many other companies on a less extensive scale have fleets of 50 to 100 motor coaches in service, while some operate only a few from the end of their rail lines.

This extensive use of the motor coach and the motor truck by the railway companies is only a small phase of the industry. The number of independent motor-coach operators has increased until there is a network of routes all over the United States. On January 1, 1926, 6 455 companies were operating motor coaches over routes aggregating 232 341 miles. The latest figures indicate an increase of 15% in the number of coaches and 8% in miles of route. It it probable that by the end of 1926 the miles of route will be in excess of 250 000, a mileage almost equal to that of Class I steam railroads, and the number of motor coaches will exceed 75 000.

Although the experience of the last few years has demonstrated the usefulness of the motor coach as a transportation agent, it has shown as clearly that it has certain definite limitations. The experience in some instances has been a costly one to the public and to private investors. The public suffered

because of inadequate service and the independent motor-coach operator lost all or part of his investment.

In the urban field it has been shown by the experience of Akron, Ohio, and Des Moines, Iowa (to mention only two of the number of cities which tried the experiment) that the motor coach is not suited for mass transportation. It cannot substitute for the electric railway.

In the interurban field the experience of Indiana is a strong argument for co-ordination of the motor coach with the electric railway.

Comparison of the relative speeds and carrying capacity of the motor coach, the street car, and the rapid transit line (elevated or subway) under heavy traffic conditions, tends to place each agency in its proper place in urban transportation.

Under average conditions in the large city during the hours of heaviest travel, the speed of the motor coach is 8 to 9 miles per hour and the utmost capacity of double-deck buses in a one-way movement under the most favorable conditions is from 5 000 to 6 000 passengers.

The average speed of the surface electric car is 9 to 11 miles per hour and its carrying capacity from 14 000 to 16 000 passengers.

The rapid transit lines (subway or elevated), operating trains instead of single cars, have an average speed per hour of 14 to 15 miles in local service and 18 to 25 miles in express service. The maximum capacity is from 35 000 to 50 000 passengers per hour.

In a city like Chicago, Ill., where the rapid transit elevated lines are called on to carry 80 000 to 90 000 passengers into the "Loop" each morning in the space of an hour and an almost equal number out in the same time in the evening, it will be seen at once that this service could not be rendered by gasoline-driven vehicles which occupy relatively much greater space per passenger carried.

What has been said of Chicago applies in degree to every large city in the country in the traffic peak hours. There has been considerable loose talk that the motor coach is destined to supplant the electric railway in city and interurban transportation, but there is no substantial basis on which to rest such claims. Neither are such claims made by those qualified to speak on transportation subjects.

Reference was made to the experience in Indiana. Probably no State can furnish a better example of the results of competition between motor-coach and interurban railroad routes. The fact that the motor-coach company controlling the larger number of bus routes is now in a receivership does not prove that the motor coach is not a useful medium of transportation. It proves that in Indiana it was used in the wrong way; that is, in competition with the interurban railroads for long-haul traffic. Both the rail and motor-coach lines suffered while the competitive war was on. The motor-coach lines could not compete successfully with the interurban lines on long hauls, and the electric lines could not compete with the motor coach in local traffic.

In a recent public statement Fred I. Jones, Receiver for the motor-coach lines, was quoted as follows:

"It is becoming apparent, it seems to me, that the operation of motor buses be co-ordinated with existent steam and electric forms of transportation. This is particularly true in Indiana, which is covered by such a network of steam and interurban railways serving the population fairly satisfactorily. The buses find it impossible to stand alone, but are logically indispensable in rounding out a complete and unified transportation system".

Certain definite conclusions may be drawn from the Indiana experience. It proves that competition between two transportation systems serving the same communities, prevents either system from giving the public the best service. It proves that rates of fare that do not provide a reasonable rate of return on the capital investment lead to bankruptcy.

The Indiana experience has shown that the motor coach is neither more popular nor more economical than the electric railroad for long-distance travel. It has shown that the motor coach is not a medium around which any great system of interconnecting transportation can be built, but that there is a profitable field for its operation co-ordinate with other agencies.

Courts and regulatory commissions are now generally agreed that competition between utilities giving the same kind of service is not to the best interest of the public. In a rate-cutting "war" what the public gains temporarily in lower rates it loses in quality of service; in the long run it pays higher rates when the competing companies combine or one is forced out of business. The company that remains must recoup its losses sustained during the "war".

Many motor-coach operators made the mistake of establishing rates of fare on a competitive basis with electric railways. Motor-coach service costs more to produce than electric railway service and it probably always will; but the public demands this special service which more nearly approaches the comfort and convenience of the private automobile. That the public has shown its willingness to pay a higher rate of fare, is seen in the patronage given the motor coach in New York, N. Y., Chicago, St. Louis, Mo., and other large cities, where higher fares are charged than on the electric railways.

Although no general rule can be laid down for every situation, either with respect to motor-coach operation or the rate of fare to be charged, experience indicates that in city service the rate necessary to maintain motor-coach service should be approximately twice that paid on electric railways. In interurban service, the rate should be from 30% to 50% more than the railroad rate. The future of motor-coach industry depends on its being made self-supporting.

California was one of the first States to adopt the motor coach on an extensive scale. At first, the industry was entirely unregulated, but afterward the motor bus was brought under the regulation of the State Railroad Commission which prescribes the system of keeping accounts. An incomplete report issued by the Commission covering motor-coach operation for the year 1924 brings up the question whether the rate structure is sound.

An analysis of the report made by the Chief Statistician of the American Electric Railway Association shows that, although the California motor-bus operators carried 1.5% more passengers in 1924 than they did in 1923 and that

their total revenues increased 8%, their net revenue from operations showed a decrease of 7.6 per cent. Operating expenses, exclusive of taxes, increased 10% over the previous year. Taxes were increased 165% during the year, and when they are deducted the net income showed a decrease of 42.5 per cent.

The motor vehicle operators of California have had more experience than those of any other State. Nearly all of them operate independently of electric railways. If, as the report shows, they are finding it necessary to increase their operating ratio in spite of an increase in business, it indicates that the rate structure is not on a sound economic basis.

Electric railway companies which have gone into the motor-coach business have generally adapted a rate structure from their railway practice. Experience so far tends to show that railway rates applied to motor-coach transportation will not cover the cost of operation.

The largest item of expense in the upkeep of the private automobile is depreciation, an item that escapes the attention of many users. That item alone exceeds all other expenses of upkeep, including gasoline and tires, garage rent, insurance, and repairs. One large manufacturer of automobiles who has made a study of depreciation finds that the average automobile is traded in for a new model after being run 16 000 miles. The constant demand for the latest model runs depreciation charges up to a high figure.

In a measure the same applies to the motor coach. Manufacturers are constantly making improvements in motor coaches as they learn by experience. The public must have the latest or patronage will decrease. Just as the owner of the private automobile will exchange his car long before it is worn out to obtain a newer model, so must the motor-coach operator keep up with the latest styles.

With greater experience no doubt the depreciation costs on the motor coach will be materially reduced. Not enough attention has been paid to this phase of operation. Railway companies which exercise the utmost care in seeing that their railway equipment is maintained at the highest efficiency, provide few facilities for maintaining their motor coaches in the same way. They will employ only the most highly skilled workmen to inspect and repair their railway equipment, yet they will entrust their motor coaches to the care of inexperienced and unskilled men. There is no doubt that operating costs are often made higher than necessary from this cause.

If motor-coach operation is to be made successful more attention must be given to garage facilities and to proper maintenance. Careful studies must be made of tire costs and gas consumption. The motor coach must now be considered as much a part of a transportation system as the electric car, and the costs of operation must be studied as closely.

City motor-coach operation and interurban or inter-city operation are separate and distinct propositions. The type of equipment that might prove satisfactory in city operation where the haul is comparatively short, would not meet the requirements in inter-city service. Motor coaches engaged in long-haul operation must be attractive in type and comfortable. Where they are in constant service on regular routes, it may not be necessary that they

should be quite as luxurious in furnishings as the types used for special tours, but they must be greatly superior to the ordinary type used in city service.

In interurban and inter-city service motor-coach schedules must be arranged with great care. They must provide for convenient rest stops and public comfort facilities. These conveniences must be counted in the capital investment and in the cost of operation and maintenance, items which many independent operators do not consider.

One phase of motor-coach operation that is proving attractive to the traveling public and profitable to the operators is the chartered coach business. To a large extent this is pleasure riding. A small organization plans an outing. It may be for a single day, for a week, or a month. The motor coach is the convenient agent for such travel because of its flexibility. The time spent on the road is not a factor as in the ordinary business trip. More opportunities are afforded the traveler to see the country through which he passes. The rate which such parties are willing to pay makes the operation profitable for the carrier as the travelers are more interested in getting the kind of service they wish than in what it costs them. If the parties are of sufficient numbers to equal the number of seats, or nearly so, the rate charge can be made quite reasonable and still give the carrier a fair profit. The writer knows of instances where such chartered motor-coach operation has proved sufficiently profitable to offset the losses sustained in operating non-paying regular routes, so that the business of a company as a whole showed a margin of profit.

In summing up the motor-coach situation in the urban and interurban service, some fairly definite conclusions may be drawn:

1.—In city service the motor coach has its greatest economic value when operated in conjunction with electric railways. It is a most convenient agent to give transportation service along boulevards and parks and to serve as a feeder to electric lines in territory not otherwise served.

2.—In the suburban and interurban fields the motor coach is most useful for comparatively short hauls of 20 miles or less. In long-haul traffic it is not as useful nor as economical as the high-speed electric railroad and should not be operated in territory served by rail. As an auxiliary to the railroad the motor coach has its greatest usefulness in the interurban service, as it can be used to serve territory contiguous to the railroad for a distance of 25 miles or more.

3.—The cost of operating motor-coach service is greater than that of rail service and is always likely to be so.

4.—Railway operators with their special training and experience are best qualified to operate motor coaches and co-ordinate them with the railways.

5.—In the near future, under a properly co-ordinated transportation system, the motor-coach business will be placed on a sound economic basis. Where motor coaches can be operated economically they will be run, and where it is found that the public will be better and more economically served by rail lines, the latter will carry the traffic.

DISCUSSION

ROBERT P. WOODS,* M. AM. SOC. C. E.—Motor coach operation between cities and towns as a unit of transportation has grown rapidly since 1924. Included in this interurban service are the necessary and the unnecessary, the desirable and the undesirable. Vehicles ranging from the luxurious 30-passenger, high-powered, $12 000 coach to the well-worn touring car are in use. Here and there the business is standardized to a certain extent, but, on the whole, the situation, due to the quick growth and misapplication to existing necessities, is far from being stabilized. The character of equipment, amount of service, rates of fare, and ownership of lines and companies are changing rapidly and new routes are opening. The lines of the routes vary from a few miles to several hundred, and the rates of fare from 1.5 to 5 cents or more per mile. The higher rates apply more particularly where infrequent service with light patronage is given. The average rate is low. The schedules range from one or two trips per day to regular hourly and half-hourly service.

Thirty-eight States have passed laws controlling interurban coach service, but not Missouri. A number of the States made changes in their laws at the Legislative Sessions of 1925-26. An intensive move is under way for interstate regulation by the Federal Government.

The motor-coach service is welcome and popular with many people. Helpful in this direction has been the development and great use of the automobile, of which there are now (1926) 20 000 000 in the United States, a sufficient number to enable practically the entire population to ride at the same time. Few, therefore, are immune to its pleasures, its readiness to serve, its speed, and its accessibility. The number justifies the statement that the people have formed the riding habit.

Another help has been the extension of improved hard-surfaced roads. Motor-coach manufacturers have developed a high-grade equipment and this, in contrast with the present character of many interurban electric railways, has been favorable to the motor-coach patronage. Interurban electric railways, however, generally have been handicapped financially because they suffered a loss in net earnings, due to the low rates of fare and the increased operating expenses. Motor-coach carriers may encounter the same handicap. The tremendous use of the private automobile has created a restless spirit that will brook no delays, and it is to this more than to any other factor that the growth of motor coaches may be attributed.

The motor coach as a carrier is expensive in initial cost, operation, and maintenance, more so than the public realizes—in fact, more so than many of the newer operators believe, because the maintenance and renewal expenses will come as a future revelation.

The cost of owning, operating, and maintaining a private automobile is no small item, but when a person rides or drives in the family car the feeling of pleasure and personal interest discounts the expenses, and if a similar spirit is felt in riding in the public motor coaches, sufficient revenues may be

* Pres. and Gen. Mgr., Kansas City, Clay County & St. Joseph Ry., Kansas City, Mo.

expected to sustain good service. It should be remembered, however, that the present status as a carrier has been built up during a period of low fares.

Motor coaches are in operation where formerly there was no transportation. They are used as feeders to steam and electric railways, and for special trips, both long and short; also, where the service was deemed inadequate, as along steam railroads with only one round-trip train each day, the stations of which are somewhat remote from the center of the retail business districts.

Opinions as to the future of interurban motor-coach transportation will be varied, depending on familiarity, knowledge, experience, and personal interest. In part, at least, it will hinge upon "whose ox is gored". Among those looking at the subject from this angle will be the coach manufacturer, the coach owner, steam and electric railway officials, the coach salesman, the accessories representative, those receiving special benefits from its operation, and, lastly, the public.

The speaker will try to be as free of bias as possible. As an independent unit of transportation in the interurban field the success of the motor coach as a carrier will be spotted. In progressing it will meet the same measure of regulation as that given to the regular transportation carriers as soon as it emerges from the swaddling clothes of newness. If the volume of traffic becomes heavy, it, like the electric interurban roads, will probably be forced to secure private right of way in such sections. This the coach line would require for safety and to maintain its speed; and the authorities would require it on account of traffic congestion and extra wear and tear on highways. The steam and electric railways are getting into the field more and more and, in time, will probably control the greater number of parallel coach lines.

Much has been said of the "co-ordination" of coaches with other carriers, but the word seems not to have the meaning given in the dictionary. The intent in many places is rather to parallel and "cut under" the regular carriers. Proper co-ordination, however, is needful for the public good. In time, it will prevail, but when it does the operation of the motor coaches will be on a different basis from that prevailing to-day. Duplication of service is an economic loss, first, underwritten by the interests involved, and, later, paid for by the public, whose portion is not always earmarked, but who finally settles for it in one way or another. Excess service, especially when unprofitable, produces bad after effects; the equipment deteriorates and then recovery brings higher rates for the public to pay—in short, the public pays "going and coming".

It must not be inferred that the interurban motor coach carrier will be banished—far from it; it will fit into the transportation picture nicely, but not as operated at present. Its development has been remarkable and in these days of enterprise and keen competition it may be that the industry could not have attained the wide recognition it has by any other introductory means than have been used. The justice of the means in some instances, however, is at least questionable.

A tabulation of the various coach lines throughout the country, showing the complete character of service, local conditions, volume of traffic, com-

petition, and other pertinent facts, would disclose interesting information from which a reliable estimate, rather than a guess, could be made of the future tendency of the industry; but such a summary would be voluminous and hardly worth the effort, for before it could be compiled and studied the situation would be changed. However, a short review of the interurban motor-coach service in and out of Kansas City, Mo., will supply definite knowledge that is applicable to the conditions found in a large part of the industry as a whole.

Interurban motor coaches are operated between Kansas City and seventeen other terminals. Twenty separate coach lines are operated and competition extends over three, and a part of a fourth, of these seventeen routes. Three of the routes practically parallel electric railways and all cover territory served by steam railroads. The total length of highways traversed (not doubling where competing lines exist) is 1 773 lin. miles. The twenty coach lines run 250 total trips daily into and out of Kansas City, covering, all told, 12 419 coach-miles, or a distance equal to half way around the earth. On sixteen of the twenty coach lines the vehicles seat twelve or more persons, and, on the remaining four lines, touring cars are used. These various routes with their length are given in Table 1.

TABLE 1.—Various Motor Coach Routes and Their Distances Into and Out of Kansas City, Missouri.

Place.	Miles.	Place.	Miles.
Topeka, Kans.	75	Higginsville, Mo.	58
Leavenworth, Kans.	33	Sweet Springs, Mo.	62
Excelsior Springs, Mo.	32*	Warrensburg, Mo.	60
St. Joseph, Mo.	60†	Harrisonville, Mo.	41
Parkville, Mo.	10	Lees Summit, Mo.	20
Plattsburg, Mo.	38	Osawatomie, Mo.	62
Lexington, Mo.	47	Denver, Colo.	677*
Booneville, Mo.	104	St. Louis, Mo.	267*
Columbia, Mo.	130		

* Two separate companies.
† Part-way competition.

The rates of fare vary from 1 to 0.7 cent per coach-mile, as in the case of the two lines to Denver, to 3.9 cents per mile. The rate from Kansas City to St. Louis, on both lines, is 2.6 cents per mile on a single-trip basis, or 2.3 cents on a round-trip basis. The numerical average rate of fare for all routes is 3 cents per mile one way and 2.9 cents per mile on a round-trip basis.

The net earnings of these lines are not known, but as they are dependent on volume of business, kind and amount of service given, depreciation provisions, and rates of fare, it is believed that, taken as a whole, there has been no profit. Recently,* much to the surprise of many, seven or eight of the large interurban motor coach lines operating out from Indianapolis, Ind., have failed. Time is bringing adjustments to the coach industry throughout the country, and the Kansas City field will show modifications from time to time

* Between March and April, 1926.

due to the foregoing factors and such regulation as may be added by legislation.

An example of operation in competition with long-established steam and electric transportation is the line along the Kansas City, Clay County and St. Joseph Railway. This railway, situated entirely in Missouri and one of the outstanding interurban electric railways of America, has been in continuous operation since early in 1913. It is a high-speed, heavy-type, electric road, with a 1 200-volt catenary trolley, all steel passenger cars, automatic block signals, and all on private right of way, with a dozen or more grade separations. The train service is hourly, with half-hourly service at rush periods. Many of the trains are of two cars. The rate of fare is 2.5 cents per mile.

On February 15, 1924, the new, hard-surfaced highway between Kansas City and Excelsior Springs was opened to traffic, at which time a motor coach company (Yellow Line) began operation between the two terminals, paralleling the Electric Railway with large high-type motor coaches on a 2-hour service, which by June 1 was increased to hourly service. At rush-hour periods it was necessary for the company to send out two coaches seating twenty-six persons each. The Yellow Line is still operating and as a competitor of the Electric Railway.

On August 7, 1924, the Kansas City, Clay County and St. Joseph Auto Transit Company (Blue Line) owned by stockholders of the Electric Railway and managed by the latter's officers and heads of departments, inaugurated a 2-hour service between Kansas City and Excelsior Springs, with large de luxe motor coaches, thus paralleling the Electric Railway and the Yellow Line. This service being too infrequent to draw patronage, it was changed to hourly service, with extras during the rush-hour movement. The combined heavy service of both coach companies, amounting much of the time to about ninety coach trips per day, continued until May, 1925. During this period the passenger cars of Electric Railway showed a heavy decrease of patronage, yet it maintained and still maintains its former schedule of hourly service, with a half-hourly rush-period schedule. Beginning with May, 1925, by agreement, each coach company reduced its service to an hourly schedule, thereby eliminating the extra service that had developed.

Three reasons may be given for the attitude of the Electric Railway Company: One was a spirit to give to the public coach service to the extent it desired; another was to protect ultimately the $5 125 000 invested in the property; and the other was to indicate to those contemplating further paralleling of the line that they would have competition in kind. For considerably more than a year the Blue Coach Line (ally of the Electric Railway Company) has operated from Kansas City to St. Joseph, 60 miles, and from Kansas City to Parkville, 10 miles. It has no bus competition between the terminals at Kansas City and St. Joseph. The line to Parkville has no competition; it partly parallels the Electric Railway, but also acts as a feeder.

Notwithstanding the frequent and high-grade motor-coach service given by the two companies between Kansas City and Excelsior Springs, patronage has been steadily falling off recently (1925-26) on both and that on the Electric

Railway has been increasing. Previously, the combined coach service was twice that of the Electric Railway. From March 31 to April 6, 1926, there was no motor-coach service on the coach lines, due to a heavy fall of snow. Upon resumption, the Yellow and Blue Lines, on account of the falling off in business, agreed to operate coaches every two hours instead of hourly, with some modifications, such as an extra coach for the short haul at 6:00 P. M. and the partial elimination of the last or theatre run. A few figures will show the change in the flow of patronage from the coaches to the Electric Railway between Kansas City and Excelsior Springs.

During the calendar year 1925 the railway, with about one-third the combined service of the Electric Railway and two coach lines, carried twice as many passengers as both the coach lines and during the last five months of 1925 it carried two and one-third times as many, showing the increasing tendency to switch to the Electric Railway.

For the first three months of 1926 the number of coach passengers on both coach lines has decreased about 32%, and the number of passengers on the Electric Railway has increased about 33%, to a number 2.94 times as large as both motor coach lines. During this period the coaches curtailed their mileage, while that of the Electric Railway was increased, the railway supplying 38% of the total mileage.

Therefore, with rates of fare practically the same on all lines, the combined motor-coach patronage with its extensive service decreased, as compared with the year previous, with the rate of decrease greater during the last three months. Whether or not this tendency will hold is problematical. The motor coach is here to stay. Adjustments and modifications will be made from time to time and gradually there will be a real co-ordination with the other long-established and more reliable transportation carriers.

FRED G. BUFFE,* ESQ.—It seems indicative of a better era in business to find thinking men actively engaged in constructive work in their communities, seriously studying transportation, and by so doing helping those in the business to solve their problems.

The bus has been, and still is, a problem. To the unthinking it may not seem so. It is easy to say, "We like this new method of riding—the smell of gasoline and a ride on rubber—and if the street railways, the interurbans, and the railroads will not furnish such rides, three cheers for the fellow who will." Such was the attitude that existed when competing street railways were built; when competing railroads were invited; when gas and electric franchises were had for the asking, on the theory that competition is the life of trade, and "the more the merrier." It took many years of loss and efficiency before this mistake was generally recognized and before the public accepted *in toto* the theory that certain services, chief of which is transportation, are natural monopolies, and that regulation and not competition is the proper check against abuse.

Therefore, the bus must be considered not only as a vehicle capable of carrying people, but in its relation to the transportation situation as a

* Vice-Pres. in Chg. of Operations, Kansas City Public Service Co., Kansas City, Mo.

whole. In the last analysis the problem and its proper solution becomes that of the public. There is danger of magnifying the importance of the motor coach and of giving it a disproportionate place in transportation. This is natural with a new development, especially one that has enjoyed the advertising and propaganda given to the bus. People are prone to like new toys.

A bus system is a valuable agency in urban transportation when it can be built carefully and properly, with due regard to other facilities. If, because of too much propaganda or threatened competition, or without due regard to its effect on transportation, it is used improperly, it will in the end work a real public harm where there is an apparent public gain. It is valuable because of its flexibility. It can be used anywhere—routes can be changed, detours made, and delays avoided. It requires a lower investment per seat furnished. It affords an easy and less costly method of making extensions, of serving undeveloped territory, and of instituting cross-town lines. It readily lends itself to park and boulevard service that have grown away from car lines. It fills a gap between the street car and the taxicab, and gives the street railway operator a vehicle that appeals to his former patrons who have deserted his service for the private automobile.

The bus is not, and very evidently never can be, a substitute for the electric railway in moving large numbers of persons during the rush hours. The street railway is here to stay, and its usefulness will increase as the vehicle for mass transportation at the lowest possible fare. The street car is more reliable; its rides can be furnished at less cost; it takes up less pavement space per passenger moved; it moves on a fixed track and congests traffic the least, considering the number carried. The street car is the backbone of urban transportation, the great servant of the masses, the foundation on which rests the superstructure of real estate and business prosperity, furnishing the maximum service for the minimum fare. The bus is primarily a "seat-for-every-passenger" vehicle offering a preferential service at a higher fare.

As confirmation of this statement, it is only necessary to call attention to the present-day electric railway activity. There is a great awakening in every city; new equipment is being bought; tracks are being rebuilt; higher standards of service are being maintained; the more important street railway securities are no longer a drug in financial centers. These things are not by chance. Bankers of long experience would not advise or permit such programs if these properties were going out of business over night.

The competing bus is a pirate in its very nature. Instead of rendering a public service as it seems, it is in reality working a great public injury. It is a backward step in urban transportation, and at some future date the bill must be paid. It will be paid in lack of capital for improvements, in impaired service—often in forced consolidation by which the promoters collect their profit and the street railway as a public agent pays the loss, which, in turn, becomes that of the public. Such competition exists only because it is permitted to serve a preferred territory having great traffic density and a high load factor. It does not assume the burden and the obligation of city-wide service,

of undeveloped lines and districts, but leaves these to the street railway while it takes the business the railway must have to support its service obligations. With its system of flat fares and universal transfers, city-wide transportation is properly a municipal problem, and certain sections can be served only because the better lines support the entire structure. Unwise bus competition has often been most unfair, in not being given the advantage of short hauls and profitable territory, but rather in being relieved of paving, street cleaning, and tax burdens, with which its older competitor has been laden.

The proper place for the bus is as an integral part of the co-ordinated transportation plan. Webster says, "to co-ordinate" is "to adjust, to harmonize". With this adjustment, this harmony, transportation may be developed along proper and natural lines. Co-ordinated transportation contemplates a complete service, using both bus and street car, not making one subordinate to the other, but fitting each vehicle to its proper field to avoid duplication and to render a more efficient and desirable public service.

The bus when used as a feeder, as a server of undeveloped territories, such as cross-town facilities and on lines where track must be rebuilt and where there is no rush-hour problem, plainly meets a real need. It can also be used as a main or through-line carrier, serving districts heavily built up away from car lines and along boulevards and parks where car lines would not be permitted.

On the other hand the bus should not be used half-heartedly and confined to the outskirts. The public desires bus transportation, and transportation agencies must meet this public desire. The down-town bus can be used to advantage. It offers a different service, makes an appeal to a certain class of riders who are willing to pay a higher fare on a "seat-for-every-passenger" basis. There is also in many cities opportunity for a limited-stop express service from distant residential districts at a 25-cent fare.

Kansas City, Mo., operates 69 buses on four down-town routes, one express route, one cross-town route, and four feeder routes, a total of 44 route-miles. The fare is 10 cents without transfer except on feeder and cross-town routes, where transfers are given from bus to street car and from street car to bus on payment of a 3-cent differential. The express fare is 25 cents. In all, 200 000 bus-miles per month are run and 540 000 passengers carried.

This bus installation is a good example of co-ordination and of a proper public attitude. Kansas City desired buses. There was an extended investigation by merchants' associations and others, and the general public opinion was that such service should be available. A franchise was submitted by promoters financially able to carry out their commitments. Had this competition been successful in Kansas City, it would have wrecked The Kansas City Railways and postponed the lifting of the receivership indefinitely. Incidentally, it may be said that jitney competition in 1918 and 1919, taking $3 000 per day in revenue, was a large contributing factor to the receivership.

The public, the press, and the city authorities took the position that in providing the desired bus service, the first opportunity should be given The Railways, and that competition should not be permitted. As a result, after

careful analysis and planning, The Railways have co-ordinated bus transportation so as to furnish a maximum of service and not compete directly with existing facilities.

The bus, properly developed and co-ordinated, has a future as a transportation agency. It will be further perfected and refined. New uses for it will be found. It will develop its own clientele. It will do its part to solve the traffic and parking problems. It offers new opportunities to serve as well as new problems to solve, and in the end its proper development will mean a distinct public gain.

B. H. Piepmeier,* M. Am. Soc. C. E.—Urban and interurban transportation in its various stages of development has been confronting civilization since the beginning of time. The rapid development of different kinds of transportation has been watched with interest. Many have predicted that the truck and bus could not compete with the electrical car and train, but since their inception, the truck and urban and interurban buses have continued to increase in size, speed, and number. The growth of this form of transportation shows that it is increasing in public favor.

The flexibility and convenience of motor-bus transportation have made it very popular. In the congested centers it is being more extensively used, as it provides a means of transportation at a faster rate of speed and with less congestion than perhaps any other form that has been developed to date. The business man who in the past has been driving his private car to the office and parking it at or near his place of business, is now forced off the street by congestion and parking regulations, and has substituted the use of urban buses.

Every one will concede that the motor car and bus have afforded a means for rapid growth and development of suburban communities. It would be difficult for any one, at this time, to predict the future development of this form of transportation, or just what effect it may have on the future growth of suburban communities. At present, in nearly all parts of the United States, urban and interurban bus traffic is developing by leaps and bounds. During the last five years the vehicles themselves have become almost the last word in convenience and pleasure. Some may raise the question that they are developing faster than they should, or beyond the point of economic transportation.

The maintenance of the road-bed for both steam and electric railroads has been one of the chief expenses imposed on transportation companies, and the public is just beginning to realize that it is shouldering this tremendous upkeep due to urban and interurban bus transportation. It is perhaps impossible, at this time, to estimate just how much of this expense should be assigned to the companies. Modern highways and streets are being designed to withstand the present-day motor bus. It is evident, however, that roads built ten years ago (1916) were not, as a general rule, designed to meet the requirements of modern use. One of the big problems, therefore, confronting the engineer and business man of to-day, is to work out an equitable tax which

* Care, Diversified Investments, Incorporated, Kansas City, Mo.

should be charged against urban and interurban buses, so that they may pay their share toward road construction and maintenance costs.

If the public were entirely dependent on buses for transportation, the question of taxing commercial vehicles would not be so serious; but public highways are designed, built, and maintained primarily for individual use. The commercial use, therefore, presents a problem of taxation that has not yet been solved. The public should not pay an indirect obligation from which it will receive no benefit, and yet the bus should be able to continue to serve and aid in the development of community life.

It is a matter of experience that all roads wear out or deteriorate with use, thereby impairing their function in the transportation system. To overcome this, constant maintenance must be provided and replacements must be made at intervals. The traffic is responsible for the deterioration, and, hence, should pay sufficient fees and taxes to meet the annual cost of maintenance and of periodic replacements. In Missouri, all motor vehicles pay a part of this obligation through license fees, based on the horse-power of the engine, and through a gasoline tax, based on the number of gallons used. There is, however, another condition peculiar to motor buses operating for profit—they are using a roadway built at the expense of the motor-vehicle owners at large, and are making a profit out of such use; they are getting a benefit from investments in roadways out of proportion to their contribution to such investments. In addition to the regular license fees and gas tax, they should pay such proportion of the interest charge as the motor-bus traffic bears to the total traffic.

To illustrate this principle, consider as an assumed case—a road 20 miles long, costing $35 000 per mile, and carrying 1 500 tons of traffic per day; over this road motor buses having a gross weight of 4 tons make 14 trips per day, or an equivalent of 56 tons of traffic. The motor buses, therefore, produce $\frac{56}{1\,500}$ of the traffic, and should pay interest at $4\frac{1}{2}\%$ on $\frac{56}{1\,500}$ of the cost of constructing the road, or about $1 200 per annum.

Motor buses may be able to pay such fees if properly regulated. If they are allowed to operate promiscuously on the streets or highways, they may cause unnecessary damage and encounter such competition that they will not be able to pay their proportionate part of the construction and maintenance expenses. All motor buses, therefore, should be granted permits on the basis of a public necessity and be regulated and controlled by public service commissions.

Engineers should also give more time and study to the design of highways with reference to the economical movement of traffic. Railroads and electric lines have, in general, received much more study than the highway. The outstanding reason is that they have developed gradually over a period of years and this has given engineers a chance to study their needs and to establish economic principles, whereas the motor vehicle has developed so rapidly that engineers have been forced to overlook, in many instances, the economic location and design of roads, in order to keep traffic out of the mud.

Much has been done during the past few years in developing a type of pavement that more nearly meets the requirements of modern transportation. The heavy bus and the speed with which it is driven over the highways has done untold damage. This condition, however, is no cause for complaint against the bus or the engineer who has been directing the work of building roads. The bus has developed so rapidly that time or money would not permit the building or rebuilding of roads to meet the new requirements. It is encouraging to know, however, that the newer types of roads will withstand this modern type of transportation.

There must be developed, however, a sentiment for more uniform regulation of all modern traffic to insure economy in the design of pavements and the proper development of urban and interurban buses. The carelessness of the operator, in many instances, has developed a sentiment against the bus. While it is generally admitted that this form of transportation will continue to develop, it is also agreed that it must be regulated and properly controlled to insure its greatest usefulness.

The question of additional width of highways should be considered very seriously, especially since buses travel at a rate of 45 to 50 miles per hour. It is apparent that either the buses must be narrowed; the main roads widened; or additional routes built to meet all the requirements of modern traffic.

The answer is to build additional routes in the suburban territory rather than wider routes. The highway between Kansas City and St. Louis, which is known as the air-line route, is 26 miles shorter than the shortest railroad between these two points; it is, however, only 18 ft. in width on a 60-ft. right of way. When the system is completed these two main terminal cities will be joined by two or three other routes across the State, which will serve not only the two main terminals but all intermediate points. It is very evident, therefore, that additional routes render greater service to the public than the building of wider roads or super-highways. This does not generally apply to congested districts such as exist around Kansas City, St. Louis, and Detroit.

C. E. Smith,* M. Am. Soc. C. E.—The extent to which the local urban and interurban motor-bus and electric-railway situation has been misunderstood is well illustrated by the statement of L. F. Loree, M. Am. Soc. C. E., before the St. Louis Chamber of Commerce to the effect that an investment of about $6 000 000 000 in street and electric railways in the United States should be written off the books because the automobile has thrown these systems into the discard just as clearly as the steam railroad has superseded the stage coach of olden days. His words created quite a sensation; but few transportation experts will agree with him. They are true of some street railway tracks in the congested centers of large cities where the transportation is furnished by rapid transit lines on upper and lower levels, and of many interurban lines; but the street railway will remain the backbone of the transportation system in all other large cities.

* Vice-Pres., N. Y., N. H. & H. R. R., New Haven, Conn.

There is a big field for the motor bus. Its principal use will be for service beyond the ends of steam railroad and interurban lines into territories where it has not been economical in the past, and would not be in the future, to build and operate rail lines. This is particularly true of the suburban districts surrounding large cities.

In the past the radii of residential areas were pretty well-defined and limited by rail lines because there was no other means of mass transportation; but with the coming of the automobile those limits have been extended. With cities spread over much larger areas the density of population has been reduced. Whereas railway lines have been serving districts in which the population has been more dense, outlying residence areas to-day have from 2 to 6 people per acre. Yet these people need transportation. It will not pay to build rail lines for them, because the density of population will not support such lines.

In city service, there is need for motor-bus transportation only in coordination with established rail routes; in competition it would mean duplication of service, costing more in the long run. It is uneconomical to operate cars and trailers during the crowded hour, carrying 250 people on each train, for local service in an intermediate area; each time the car and trailer stop for one passenger the whole train is delayed. This has been necessary in the past because it has not been feasible to provide both local and express service on street car lines, but now it is possible to supplement the rail service by motor buses which will take care of the local traffic—the street to street traffic within the intermediate area—while the street cars run express, stopping only at cross-town streets.

On the whole street car traffic appears to give indications that it is "coming back"; as a matter of fact it never got very far away except in particular instances. Statistics issued by the American Electric Railway Association show that street cars to-day, and for several years past, have carried about 17 000 000 000 cash-fare passengers each year. That has not increased very much, but it has not decreased to any appreciable extent. Automobiles and motor buses have taken away the normal increase that would otherwise have used the rail lines. The future is yet uncertain. In Greater New York the rapid transit lines carry about 1 500 000 000 cash passengers per year, the street cars about 1 000 000 000, and the motor buses only about 100 000 000.

St. Louis, Mo., gives a good example of competitive systems. Its large street railway system is laid out with radial and circumferential lines on good engineering principles. There is also a motor-bus system that the promoters tried to lay out as a radial system with cross-town lines, to compete with the street railways. The street cars carry 90% of the riding public, the motor buses, 10 per cent. First the buses were put on the principal streets and took the "cream" of the traffic. They were quite profitable. Later, the bus company secured permits to operate on additional streets into territory where the street car company could not afford to put lines. With this additional service the motor buses are not paying, although the fare is 10 cents. The car fare is 7 cents, but by reason of motor-bus competition and

diversion of business to automobiles the car company is taking steps to increase its fares. It is paying about 11% of its gross revenues in all sorts of public charges; the motor-bus company pays about 4%, which does not reimburse the city for the pavements the motor buses wear out. The buses do not carry their share of the peak load. The peak load on the street railway is six to eight times the base load during the day, whereas the buses provide very little more service during the peak than during the day, when there are sufficient empty seats on the cars to carry all the passengers using the buses.

The failure of the motor buses to provide peak-load service increases the peak load on the street railway line. In bad weather the uncovered double-deck motor buses have their loads cut in two, the half lost being thrown on the street railway—a bad condition during rush hours. This is being corrected gradually by the enclosure of the upper decks of the motor buses.

Street railway fares in St. Louis amount to about $1 500 000 per month. If it were possible to take off all street cars and put on enough motor buses to carry the whole load, the transportation bill would increase another $1 000 000 per month. It may be that the psychology of gas and rubber has led to the point where the public is willing to pay that much more for motor-bus transportation, but it does seem that eventually when money is not so plentiful people will look a little closer at this material difference. The same relation applies to other large cities.

One reason why the public has welcomed competitive motor-bus transportation even at higher cost, is the dissatisfaction with street railway service and strap-hanging. People have been educated by the automobile to get around more quickly. All other means of transportation have improved, while the street car, which, in St. Louis carries nearly 1 500 000 cash and transfer passengers per day—about 75% of the traveling public—does not move any faster than it did before.

Motor buses performing local service in large cities have proved a disappointment as far as speed of transit is concerned, but many people prefer them, when standing passengers are not carried and for other reasons, real or fancied. In large cities, street cars run at an average speed of about 10 miles per hour. The motor buses run about 1 mile per hour slower than the street cars in St. Louis; unless some means are found for speeding up street car and motor-bus service, people will find ways of getting around faster, and the value of street railway property will decrease as traffic is deflected.

Before it becomes necessary to provide rapid transit on other levels than the surface, frequently street car service may be accelerated. In many cities streets are being widened from 50 to 60 ft. to 100 ft. At the time a street is widened, it does not cost much more to make the width 120 or 150 ft. In streets more than 100 ft. wide cars can be operated at much higher speeds notwithstanding the crossing of other streets at grade.

A 100-ft. highway, paved the full width, is dangerous for people to cross; but if it is made wider and is divided into three parts, a roadway for traffic in each direction and a reservation in the center for street-car tracks, the danger is largely eliminated. On the other hand, where the track reservations

are in streets only 100 ft. wide the side roadways—less than 30 ft.—are so narrow that other users, particularly the Fire Department, object.

The motor bus will be useful as a feeder and distributor of traffic for rapid transit lines. This combined service can be furnished in some instances at greater speed than by street cars, and unless street railway fares are kept low, the cost of rapid transit, motor-bus service will not exceed street railway service in the larger cities and, of course, will be more satisfactory in congested districts.

WINTERS HAYDOCK,* M. AM. SOC. C. E.—There is a very direct relationship between the rapidly increasing importance of bus transportation on highways and the design of those highways as traffic carriers. The large size of the bus and the high speed which it must maintain in order to fulfill its proper mission bring into prominence this relationship between inter-city bus transportation and the capacity and efficiency of the highways which the buses must use.

It is probably true that the most urgent duty of State highway departments at the present time is to obtain the greatest possible mileage of well-paved highways for the money available. However, it is obvious to any one who observes the present trend of traffic conditions on important trunk highways, and even on some of less importance, that within a short time the most important work of the engineer will be the improvement of these highways as to their traffic-carrying efficiency.

A fundamental principle of highway design, to which sufficient attention perhaps has not been given, is that no highway can be an efficient carrier of traffic in large volume if there is provision for only one lane of moving traffic in each direction. This is true because the various vehicles using any highway will necessarily and properly operate at various speeds, and if there is only one lane the slowest vehicle will set the pace or compel the faster vehicles to pass it only through the dangerous expedient of dodging into the lane of traffic moving in the opposite direction. If, however, there are two or more lanes for traffic in each direction, all vehicles may be required to keep to the right-hand lane except when passing slower vehicles. Thus, each vehicle may travel at the speed which is individually appropriate for it and the flow of traffic is made flexible and fluid through the constant ability of vehicles to weave in and out from one lane to another without ever trespassing on the part of the roadway assigned to traffic in the opposite direction.

Evidently to insure two unobstructed lanes for moving traffic on a heavily loaded highway there must be provision for stationary vehicles off the traveled section. It is not possible to prevent the stopping of vehicles. Property owners also have rights to the use of their frontage, and this often means that space along this frontage must be available for standing vehicles. Therefore, the minimum requirement for efficiency as a traffic carrier is that a highway should have not less than two lanes for unobstructed moving traffic

* Directing Engr., Dept. of City Transit, Pittsburgh, Pa.

in each direction, with provision for standing vehicles on each side and pedestrian ways.

This principle of highway design for traffic-carrying efficiency is so simple and obvious that it would scarcely seem necessary to dwell on it were it not that its importance is insufficiently realized. Highway engineers are giving only scant attention to the problem of securing sufficient right of way for trunk-line highways to permit their proper amplification at such time in the future as it becomes financially possible. They are even building long stretches of new highway on newly acquired rights of way which are too narrow for this future amplification, although they pass through open country where the increased width could be obtained at only a moderate additional expense. Along these new highways, and also along the now open parts of the old highways, new improvements and new villages will be built, which will make the future acquisition of right of way exceedingly expensive. The sooner it is realized by highway engineers that the biggest problem they will have to face in the future will be the amplification of present highways, and the sooner they undertake intensive study of the means of meeting this problem, the less will be the inevitably enormous expense involved.

JOHN W. REID,* M. AM. SOC. C. E.—The City of Detroit, Mich., is one of the very few of the major cities which own and operate street railway systems serving their entire cities. The Detroit City Charter, adopted in June, 1918, authorized the ownership and operation of a street railway system and the creation of a commission for that purpose.

In 1920 and 1921, the Department of Street Railways built a system consisting of 61 miles of track and 30 miles of trackage, and operated it privately under a "day to day" permit. In accordance with the terms and conditions of this permit, the Commission has taken over this system and has built some new trackage in territories annexed to the city subsequent to the city's purchase in 1922 of the properties, power plant, car houses, yards, and 273 miles of track of the privately owned street railway company. The total trackage is 400 miles with 1 590 cars operating. The fare is 6 cents with a 1-cent transfer charge.

Supplementing this service is a privately and very largely locally owned bus company, operating eight routes, with a total of 350 buses, of which 145 are of a double, and 205 of a single-deck type. The company operates on a day to day permit from the city. A 10-cent fare is charged. Many of the company's lines parallel important street railway lines. This condition has brought rather sharply to the fore the question, "Since the City is in the transportation business, should it not control and operate all types and thus eliminate competition?"

As a partial answer to this question, and also as a practical means of meeting demands for some degree of transportation in newly developed and rapidly developing areas, the Street Railway Department has established a number of bus lines. Several lines have been placed in streets having street railway service. These are operated in an effort to furnish both express and

* Commr., Dept. of Public Works, Detroit, Mich.

local service and to eliminate the "jitney." The buses are well patronized, but the "jitney" persists and in increased numbers. The question of the city's right to effect its order of more than a year ago, banishing the "jitney" from its streets, is now (1926) before the Supreme Court of the United States.

The matter of adequate highways has been very carefully worked out in connection with the Rapid Transit Commission's studies for a complete rapid transportation system. The Commission's plans contemplate subways within the 6-mile circle from the center of the city. Outside this area a system of super-highways, having a width of 204 ft. is projected, the center 84 ft. being reserved for 4-track rapid transit on the surface. On each side is 60 ft. for pedestrian and vehicle traffic. The intersecting highways, at approximately ½-mile intervals, will pass under the super-highway, thus allowing uninterrupted movement to high-speed through-traffic vehicles. Woodward Avenue, from the north city limit of Detroit to the City of Pontiac, a distance of approximately 18 miles, has been developed in this fashion during the past three years, except that intersecting highways are not separated.

Super-highways are proposed every 3 miles at right angles to one another. Intermediate 120-ft. highways will be located on each mile line and 86-ft. highways on each half mile, local service streets (so-called) being 60 ft. wide. This general plan has been adopted by the Common Council of the City of Detroit and the Wayne County Board of Supervisors as the plan toward which to work. At its 1925 session, the Michigan Legislature passed a law authorizing adjoining counties, through their Boards of Supervisors and Road Commissions, to join for the purpose of securing rights of way by dedication, purchase, or condemnation. The Counties of Wayne, Oakland and Macomb have, under this authority, acquired a very considerable mileage of such right of way by dedications.

In connection with its subway route studies, within the Six Mile Circle, the Rapid Transit Commission also developed an interior thoroughfare plan, so-called, which is a very valuable contribution to the solution of Detroit's street problem in the older and densely settled areas of the city. The older part of the city is laid out over old ribbon-like French farms, which extended back from the Detroit River from 1 to 3 miles. Uncontrolled platting of these by the original and successive owners accounts in large measure for many of the street openings, widenings, and straightenings necessary to afford a reasonably good arterial system for both transportation and traffic.

The problem of the parking of automobiles, particularly that falling in the "storage" classification, in the streets of the city, is a most serious one. It is a matter of tremendous import to both trade and traffic. The city is spending approximately $3 000 000 annually in widening existing street pavements to provide greater freedom and safety in traffic movements, but the new pavement areas thus obtained are quickly seized upon as "storage" space for automobiles. Notwithstanding this, the traffic capacity has been materially increased; but the "parking" problem is yet to be solved in Detroit, the center of the automobile industry.

LUCIUS S. STORRS,* ESQ. (by letter).—The status of the automotive vehicle in public transportation service has been thoroughly and convincingly presented by Mr. Budd. Its true economic position will not be determined until a full realization is had of the fundamentals expressed in his conclusions.

The rapid expansion of American cities has been primarily because public transportation is available to every resident of the community. Maximum convenience and efficiency of such public transportation can be accomplished only when all such agencies are under the direct control of one able transportation group whereby the maximum efficiency of each unit can be planned with direct relation to all other such units.

The automotive vehicle presents an exceedingly valuable aid in expanding public transportation throughout an entire urban area. It performs a higher grade of service than is rendered by rail units—a kind that will attract a large portion of the public accustomed to using private means of transportation. In this way the motor bus or motor coach will serve the communities themselves by making possible a reduction in the number of private automobiles utilizing the public ways.

ANSON MARSTON,† M. AM. SOC. C. E.—The speaker began his professional life in railway location and construction, and his memory extends back to a period when "wild cat" railways were still being promoted and sometimes constructed. Those who have never worked on a "wild cat" railway, uncertain of ever getting their pay, have missed a wonderful experience.

The railway system of the United States was not laid out originally as a National system, carefully planned. It was developed by a method of "trial and error". Roads were built in numerous instances because localities could be found that would offer attractive bonuses. Later, many such lines, or parts of lines, have had to be abandoned.

The speaker has been a member of the State Highway Commission of Iowa for 22 years and wishes to discuss motor truck and bus transportation from the standpoint of the State Highway Commission. The highways of the United States are passing through a period similar in some respects to the early stage of railway development, referred to previously. No sufficiently scientific study has yet been made of the proper design of an adequate National highway transportation system for the United States. Development of highways and of highway transportation has been, and still is, proceeding to a considerable extent by a method of trial and error. The speaker does not feel that such a method is wholly objectionable. Scientific research should, in general, proceed by a method that permits variation of technique, and even of immediate objective, from time to time, as the facts developed in the investigation may indicate to be wise.

From the standpoint of State highway departments, the present situation as to the development of motor-truck and bus transportation on the highways

* Managing Director, Am. Elec. Ry. Assoc., New York, N. Y.
† Dean of Eng., Iowa State Coll., Ames, Iowa

is unsatisfactory. Such traffic has developed unsought, and its present chaotic condition constitutes an almost impossible situation, very much as if the electric or steam railways had to build bridges and roadbeds without knowing the kind of rolling stock or the amount of traffic to be anticipated. Even in States that have adequate legal restrictions on motor-truck and bus transportation, there is in most cases little effective enforcement of the law.

Nevertheless, the speaker adheres to the general belief that motor-truck and bus transportation is here to stay. State highway departments are intensely interested in the early development of adequate regulatory measures. Immense sums of money are being spent on the construction of permanent highways. The interests of the public require the early adoption of measures by which these costly structures can be protected against excessive damage by what, after all, constitutes only a small percentage of total highway traffic.

A study of transportation needs in Iowa indicates that there are important sections that are likely to be entirely dependent on truck and motor-bus transportation for passenger and freight traffic. Some railway branch lines have already been abandoned. In fact, in more than one instance, a State highway has been built in part upon the abandoned roadbed of a former railroad. The speaker believes that the railroads are finding it unprofitable to operate several other branch lines not yet abandoned. The longest interurban railway in Iowa is already operating motor buses for passenger transportation between different points on its line. The speaker believes that this practice is likely to extend to the steam railways in some instances.

Nevertheless, there may be a reaction in favor of street cars and railway cars, showing that they are preferred from the standpoint of convenience and safety. It may be that the present preference for motor-bus transportation is to some extent a temporary fad.

The speaker has had the opportunity, as a bystander, to observe two interesting instances of experience with motor-bus transportation as a substitute for street railway service. The first was in the case of a town of 10 000 population, where for a time a motor-bus system operated in competition with the street railways. The bus operation continued until the buses were worn out, when the company went into bankruptcy. A serious accident occurred shortly before the bankruptcy in which, by a gasoline explosion during the filling of the tank, some people were injured, and one injured passenger died. The bus company was so irresponsible that no damage suit was filed against it, but suit was brought against the gasoline filling station. After the bankruptcy of this system the street railway company secured a franchise and is operating a bus system of its own, and the combination is giving satisfaction to date.

The second instance was in the case of the City of Des Moines, which had a population of 141 441 in 1925. On account of a controversy between the electric railway company and the citizens over a franchise, the street railway entirely suspended operation, and the city was left entirely dependent on motor buses. After a comparatively short period of this experience, the franchise was voted as demanded by the street car company.

Britton I. Budd,* Esq. (by letter).—The discussion emphasizes the chief points brought out by the paper, namely, the necessity of co-ordinating motor-coach with rail service, placing the operation of buses in the hands of skilled bus transportation men, and eliminating wasteful and uneconomic duplication of service.

Developments since the paper was written have increased, rather than diminished, the evil effects of unrestricted competition and unregulated motor-coach operation. This is particularly true in interstate traffic which at this time is wholly unregulated. Regulation of a sort obtains in most States in intrastate business, but irresponsible bus operators can easily escape such regulation by laying out routes that cross State lines.

This condition presents the most serious problem to-day in interurban and interstate motor-coach transportation. Eventually, irresponsible bus companies will be forced to the wall, thus relieving a situation here and there, but others will arise to enter into competition with responsible transportation companies that are giving the public dependable service, unless regulative measures are adopted.

Several of the discussors have pointed to the damage being done to highways by buses, which do not pay their proportionate share of taxes. That is unquestionably true and is a condition likely to continue until a sane and uniform system of regulation is adopted.

* Presented at the Summer Meeting, Seattle, Wash., July 14, 1926.

THE ENGINEER IN THE LUMBER INDUSTRY

By J. J. Donovan,* M. Am. Soc. C. E.

Sawing boards seems a simple task. It was in the old days of the single circular saw which replaced the primitive whip-saw and when the market was usually within the radius of one day's journey by horse from the mill. Those days are gone. Now turbines generate electricity which drives the great band-saws and the many varieties of special machines with a speed and accuracy unknown a few years ago. With the old machines went the long hours, and the mills and camps of the Northwest have had the eight-hour day for more than eight years.

Problems of Production

Lumbering is the great industry of the Pacific Northwest. The forests of Washington will last for fifty years and those of Oregon for one hundred years at the present rate of cutting, allowing nothing for new growth. The industry is here to stay—if the common sense of the engineer is applied to the problems before it is too late. What are the problems?

First.—Cutting the trees, hauling them to the mills, and sawing them into lumber without unnecessary expense or waste.

Second.—Explaining to distant markets the special value and practical use of different species and grades of lumber.

Third.—Shipping and delivering lumber from the mill to the ultimate distributor with the utmost economy.

Fourth.—Protecting the young forests in order that future generations may have fuel, implements, shelter, and clothing, such as have served man from the earliest ages.

There are many subdivisions of these four major theses, but only a few will be discussed in this paper.

Modern lumbering requires the trained mind of the civil, mechanical, electrical, and steam engineer, with skilled mechanics of many kinds, with salesmanship that grasps the need of both buyer and seller, with knowledge of the strength and life of materials. Finally, future foresters must have knowledge of silviculture and some ability to deal with the ever-present political factor.

Methods—Old and New

Until 1890 the logging on Puget Sound and along the Columbia River was almost entirely over skid-roads made by embedding maple, alder, or hemlock logs, 8 ft. long, spaced 8 ft. or less, from the shore to the forest. The logs to be hauled were barked to give a smooth riding surface; the "greaser" swabbed his skids; and six to ten pair of oxen with much straining and a wealth of picturesque language on the driver's part moved the log to the water.

* Vice-Pres., Bloedel Donovan Lumber Mills, Bellingham, Wash.

Two miles was the ordinary limit for such roads. Horses occasionally replaced the patient ox (Fig. 1), but were less reliable in mud and swamp.

Following the use of horses in logging came the small single-drum donkey engines with a "line horse" struggling through the brush from the skid-road to the log. The "line horse" hauled the line from the engine drum through an almost impassable tangle to the log that was to be hauled in. The maximum range was 300 ft. The adoption of double drums and the increased use of railways (Fig. 2) came thirty years ago (1896); but it is only ten years since a revolutionary change occurred in the handling of logs. This was the use of trees as masts (Fig. 3) with great blocks, some weighing 1 200 lb. and hung 180 ft. from the ground. The engine is run up against the tree, the main line runs through the roof to the block, and thence off to the logs. The tree or mast itself is guyed with ten or more heavy steel cables and the whole trimmed, rigged, and made ready for work with phenomenal speed by a small crew of highly skilled men.

The most picturesque figure in the woods is the "high rigger" who, with life-belt, spurs, and axe, climbs a tree to a point nearly 200 ft. from the ground, trims it, cuts off the top, hauls up blocks and lines, and ultimately rigs the tree as shown in Fig. 2. This method, used with a radius of 600 ft., immediately brought a lifting strain on the end of the log, and it came in at twice the speed of the old ground-yarding method.

Steam Is Main Power

The modern unit consists of an oil-burning boiler mounted on a heavy steel railroad car supplying steam for a duplex loading engine and a yarding engine with one main and three auxiliary drums. Each engine is arranged to run independently, yarding and loading going on simultaneously.

A good logging outfit thirty years ago cost $25 000; to-day, it costs $500 000. Most camps use steam generated by oil as their main power. A few use electricity. Diesel engines are in the experimental stage. Many auxiliaries are gasoline or gasoline and electric.

The latest development in logging is the heavy skidder (Fig. 4) with an articulated steel mast 100 ft. high, which, with yarding and loading engines, blocks, and lines, complete on three cars, represents an investment of $75 000.

Such a unit can be installed with remarkable speed, the steel mast replacing the tree of the high-lead system. A tail tree, carrying the outer end of the trolley line at a distance of 1 500 to 2 000 ft., marks the radius of action. In rough ground a unit of this kind will effect a saving of about $1 per 1 000 board-ft. over the high-lead system. This saving is due to a reduction of about 50% in railroad branches and the ability to reach into and across gulches at higher speed. This skidder system lifts the log by one end to a trolley line and then drags it to the railway.

Railway Development

Logging railways were scarce thirty years ago, and such as existed were poorly built, with 30 to 35-lb. rail. Locomotives weighed 30 to 40 tons.

To-day, the railway is the most necessary and usually the most expensive factor in logging operations. The weight of steel rail has more than doubled and that of equipment, tripled. The modern logging railway has 60 to 70-lb. steel rails, heavy geared and compound Mallet locomotives, and high-class special cars with all modern safety appliances. Special types of locomotives and cars have been developed to carry the increasing loads over the longer distances with economy and safety. On no trans-continental railway is more care used on grades and curves than on the logging railways. Fig. 5 shows a Baldwin Mallet locomotive for main-line work, which handles 24 loaded cars up a 1.5% grade. Its weight on the drivers is 90 tons.

Another type is the Climax geared locomotive (see Fig. 2) which works successfully on grades up to 8 per cent. Both engines have superheaters, which reduce the fuel consumption one-third. A typical development of a mountain side is a main line using a 6% sustained grade from the valley, a distance of more than 6 miles. Branch lines are extended from the main line on approximately parallel lines 1 200 ft. apart horizontally and from 200 to 300 ft. vertically. Thirty-six spar-trees were used on this development of 1 200 acres. Two high-lead machines and one skidder worked on this location with an average monthly output of 7 000 000 board-ft. and a cost exclusive of stumpage, taxes, overhead, and depreciation of $8 per 1 000 ft. of logs.

Primitive Bridges

To illustrate the work of the engineer in logging operations a view of the Cavanaugh Creek Bridge is submitted (Fig. 6). This structure is notable for three things:

(*a*) It is built almost entirely of timber cut on the site.
(*b*) The piling is all single length, and in some of the falsework it is 140 ft. long.
(*c*) The Howe truss is made of four single fir trees, 108 ft. long, braced properly, and was swung into place with an ordinary pile-driver. The height from rail to the water is 130 ft. The span was constructed to insure against slides up the canyon and sudden rushes of water, such as wrecked a locomotive and cost four lives only 10 miles away. The length is 1 000 ft., and the cost was $30 000.

The civil engineer has made his mark in the woods and his mechanical brother has kept pace at the mills and docks. Labor-saving devices of many kinds—package handling, conveyors, steam and electric cranes—all do their share to give the men of the Northwest the best pay and the shortest hours of any lumbermen in the world.

The necessity for application of engineering principles to the proper utilization of wood was never greater. Obsolete and expensive specifications are still used on many contracts. Much progress has been made in the standardization of certain sizes, varieties, and grades under the lead of the U. S. Department of Commerce.

With it all is the effort to eliminate waste and to use the right size and the right grade of lumber in the proper place. The testing laboratories at

Madison, Wis., under Government engineers, have rendered service of great value in proving strength, fire-resisting power, and other qualities under varying conditions. Likewise, the National Committee on Wood Utilization has done notable work in bringing together the various interests and agencies dealing with wood.

There is much ill-informed talk of a timber famine. There is more of fire dangers in wood construction which do not exist and a determined, well financed, and specious propaganda for wood substitutes. The fact remains that there is plenty of wood at prices which make it the building material for nine-tenths of the homes, and for most of the granaries, warehouses, and miscellaneous buildings of the country.

All the railway ties, a considerable amount of car, bridge, and building material of the railways, is wood and will continue to be, because it gives the best service for the money. There is no substitute for wooden ties. Close and intelligent studies of methods of logging, milling, selling, shipping, and using are being made.

Reforestation

Reforestation is largely a matter of protecting Nature in its work. The National Government set aside great areas thirty years ago. It owns more forest area in Washington than is in private hands, and nearly as much stumpage. The State also has great forest areas in trust for the schools and about $20 000 000 has been realized from sales that have been made. Washington is slowly developing a forest policy, but it still has far to go. It has more logged-off lands than any other owner. It cannot sell them because of the minimum price of $10 per acre fixed by law. These lands are usually Sections 16 and 36 in each township. They are often surrounded by private logged-off lands, some of which are reverting to the State for taxes.

Private reforestation is impossible economically under the existing law. Even with better laws the inducement is small. The State should survey and grade its logged-off lands, sell all that will bring the minimum price of $10 per acre for agriculture and grazing, and buy adjacent lands more suitable for forests for a maximum price of, say $5 per acre, and develop and protect the young forests which fifty years hence will have value. Some exchanges with private owners may be possible as has already been effected by the State with the National Government.

Co-Operate for Forest Protection

There is need of close co-operation between National, State, and private owners of timber for fire protection and reforestation. There is better understanding to-day than ever before and fire protection is especially good. The proper building up of State forests has only begun, not only in Washington, but in many other States. Private forests cannot survive in many States under the existing laws and are capable of giving financial return at present only as pulp producers in conjunction with paper mills.

It is well to remember that in 1907 the country produced and used 45 000 000 000 board-ft. of lumber; that in 1925 this fell to 35 000 000 000, and that per capita consumption fell from more than 500 to 300 board-ft. Further, it is significant that all the soft woods exist in great abundance and at low prices, and that engineers who produce and sell these woods ask their brethren in the Engineering Profession to remember that wood is economically available for many classes of construction and often has special advantages worthy of careful consideration.

LOGGING RAILROADS

By Walter J. Ryan,* M. Am. Soc. C. E.

This paper gives a brief description of the location, construction, and operation of logging railroads, in comparison with standard railway practice, and shows the relationship between the railroad and the logging operation that it serves. It tells of the work of the engineer in connection with logging railroads and points out a field for further usefulness.

The primary function of a logging railroad is the transportation of logs from woods to saw-mill. This service was originally performed by teams of oxen that dragged the logs over poles laid across the roads as shown in Fig. 7. The modern logging railroad has progressed a long way toward standard railway practice, but it still bears some of the characteristics of this ancestor, the "skid-road".

Logging Engineering

The first logging railroads were built without any technical engineering. This is well illustrated by Fig. 8, which shows an early type of crib bridge. It was part of the duty of the logging superintendent to locate his railroads, and he had little time or opportunity to plan further ahead than the section in which he was working. These roads were extended from year to year, until the easy country was logged off or some serious obstacle to further progress was encountered. About this time, locating engineers were called in to solve the difficulties, and the original lines had to be abandoned and new lines built to reach the tracts of timber farther back. These engineers were given no opportunity to learn the requirements of the logger and many times the results were not satisfactory. There finally came a realization of the fact that an engineer was required who understood logging. The Pacific Logging Congress, in 1912, began an active campaign for "the creation of the profession of Logging Engineering as a distinct branch of mechanical science". As a result of this effort, the Western universities have established courses and are graduating classes each year with a degree in Logging Engineering.

The larger companies now maintain Engineering Departments, and there are a number of engineering firms that do all such work for their clients, usually the smaller operators who do not feel justified in maintaining an engineer in continuous employment. There are many parts of the logging operation in which an engineer is called upon to assist, but the principal part of his duty consists in the location of railroads.

Relationship of Railroads to Logging

The object of logging railroad location is not to provide a route through a territory or to connect two definite points, but to serve a given area with a

* Civ. Engr., Weyerhaeuser Timber Co., Tacoma, Wash.

network of rails. Any part of a tract of timber that is not within "yarding distance" of a railroad is in the same position as a piece of land above the ditch on an irrigation project. This "yarding distance" is the distance that it is economical to bring logs from the stump to the "landing" where they are loaded on cars. It varies from 600 to 3 000 ft. with different types of logging equipment in use. Thus, the spacing of the railroads will vary from ¼ mile to 1 mile.

It is the relationship between the cost of logging by different methods and the cost of the railroad, that determines the type of logging equipment best suited to each situation. As railroad construction becomes more difficult, more expense is justified for logging equipment and labor to give longer yarding.

Every phase of railroad construction and operation is intimately connected with the logging which it is to serve, and a reconnaissance for a railroad is incomplete unless it covers a study of the area from the point of view of logging as well as of railroading. The modern timber cruiser, after examining a tract of timber land, makes a detailed report of the timber that he finds, by species and grade, and prepares a contour map of the area. These cruisers' maps are made by pacing distances and by measuring elevations with an aneroid barometer. The maps are usually on a scale of about 6 in. to the mile, with contour intervals of from 25 to 100 ft. The U. S. Geological Survey has mapped part of the timbered area of the Western States, but there are some districts of which there are no maps worthy of the name.

The maps available are made the basis of preliminary study, but most operators recognize the value of an accurate contour map so that the reconnaissance survey usually takes the form of a mapping party. Well made maps, with accurate cruises of the timber, allow the operation to be planned so that the railroads can be built in the proper location for economical logging, with the minimum of cost.

Logging Railroad Location

When the logging railroad leaves the timber and is built for some distance to a log dump at the mill or rafting ground, the selection of a route does not differ from that for standard railway or highway practice, except that controlling rates of grade and curvature may have been determined by conditions in the timber (Fig. 9). This route to the timber and one or more lines through the tract make up the main line over which full trains are handled. Grades as high as 4% and curves as sharp as 24° are used on these main lines, and the construction cost runs as high as $50 000 per mile.

Branches and spurs serve the logging, and from these the loaded cars are switched by lighter locomotives. Geared locomotives permit the use of curvature as sharp as 40° and grades of 6% on these spurs. Where timber is still out of reach, inclines are used.

The field work of location is usually done with small parties of from three to six men. A transit or compass preliminary line is run, often with an axeman, a chainman, and an instrumentman, using a 500-ft. tape and setting

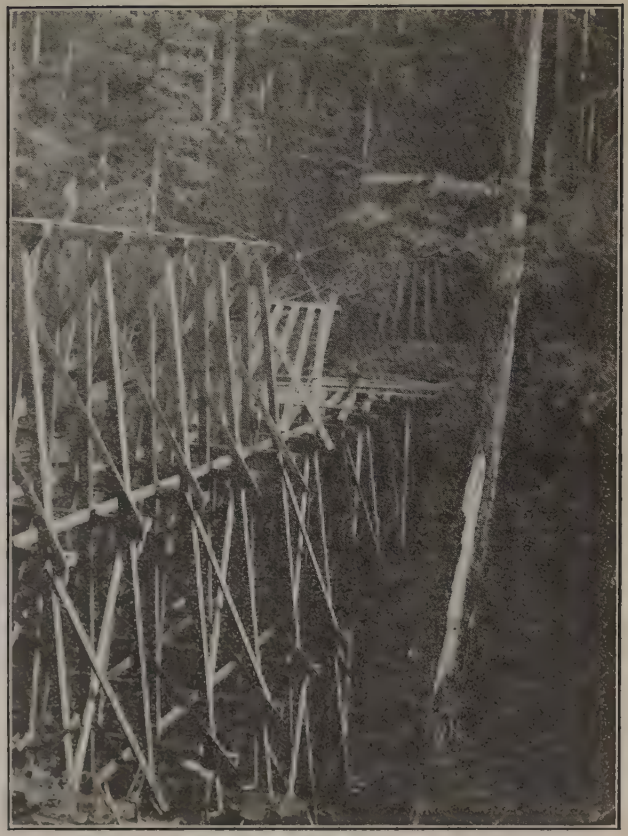

FIG. 10.—FRAME TRESTLE OF LOGGING RAILROAD ERECTED BY "SKY LINE."

stakes at 100-ft. stations. The same party runs levels and takes topography. A center line projected from this preliminary line may be run in the field or simply staked by offsets. A small party can do the locating and look after the construction of 10 or 15 miles of road per year. This proves more satisfactory than employing a larger party on intermittent work.

Logging Railroad Construction

Clearing the right of way is often the most expensive part of the railroad construction. Much road has been built with no other power than dynamite, where stumps and logs up to 10 ft. in diameter were to be removed. Horses and steam-logging "donkey" engines have been used for the clearing. Recently, gasoline "donkeys" and tractors have come into use. If power shovels or drag-lines are used for the grading, the same machine often does the "chunking out".

Culverts are usually built of logs. Where long life is required, Western red cedar or redwood is used, as these woods resist decay almost completely under the conditions found in most culverts.

Until recently, the grading was done largely by hand. The only power commonly used was a drag scraper pulled by a logging engine. A limited use is made of large steam shovels. Nowadays, the small revolving power shovel or dragline, on crawler treads, is doing a large portion of the work. If the range of the machine is sufficient it is common practice to waste the material from the cuts and to borrow for the fills. The shovel runner and his helper may constitute the entire grading crew and the finishing may be left for the crew that lays the track. Where it is necessary to haul the excavated material, it is customary to use car and track, although auto-trucks are used to some extent.

The construction of bridges has shown more variation from standard railway practice than any other feature of logging railroads. The bridges that were built on the skid-roads of "bull-team" days were cribs of logs with a solid deck. The first railroads were laid over this same type of bridge (Fig. 8) with ballast under the ties. The logs in these bridges were seldom salvaged; this fact made the cost excessive when timber became of greater value. Framed trestles (Fig. 10) and pile trestles, as now used, show wide variations in design.

Pile trestles 100 ft. or more in height are frequently built. Where the ground allows little or no penetration for piling, the sticks are set, butt down, on the rock or hardpan and held in place by the driver until capped and braced. Piling as long as 100 ft., with a top diameter of 14 in., has been used in this manner.

The trestle over Cedar River Canyon (Fig. 11) is a good example of a high pile structure. This was built in two decks with Douglas fir timbers of 120 ft. and 80 ft. in length. In all, more than 500 pieces of piling and 400 000 board-ft. of sawed lumber were used, all obtained near-by. The height of 203 ft. is claimed to be the record for high timber trestles.

Pile trestles are built of material cut at the site, when it is available in suitable sizes; the caps and stringers are hewn to size and small poles are used for bracing. Fig. 12 shows such a trestle, with a log span near the center. In many stands of timber, there are no trees suitable for bridge material, and it is necessary to haul timber in by rail from the saw-mill or another part of the operation. Pile trestles are very cheaply constructed when suitable material is available on the ground. For many years, some companies built spurs entirely on trestle as they found it to cost less than grading and ballast.

Sawn timbers with depths of as much as 48 in. are available and are suitable for spans up to 40 ft. Logs are used as girders for spans as long as 50 ft., without any form of truss. Spans of 100 ft. have been built by placing a solid deck of logs on falsework and laying ties about 20 ft. in length on top of this deck. Two additional large logs are placed on top of the ties, one on each side of the bridge. The cap of the falsework is bolted through the logs above and below the ties to act as a floor-beam, and the whole structure is laced together with wire cable. On high trestles, these log spans may be used to give channel clearance and to support frame bents (Fig. 10) to carry the deck.

An overhead cableway is often used in the erection of high trestles as shown in Fig. 10. The cable is stretched above the site of the structure and on or near the center line. The cableway is used to deliver material and, in case of a framed structure, to raise the bents. Wire rope up to 2 in. in diameter is usually available around a logging operation. With the use of a logging "donkey" for power, it is possible to design such a cableway for very heavy loads. Wooden Howe trusses, steel girders, and steel trusses are in use. Their design and construction conform to standard railroad practice.

Tunnels have been built on some logging railroads and are usually timber-lined. The only variation from standard practice has been the wider section sometimes adopted to provide clearance for wide loads, due to knots or limbs on the logs. Some standard roads have refused to accept logs for haul over lines with tunnels, but there have been few accidents reported from this cause.

Track

Track laying is usually done from a push-car or from cars handled by a locomotive. A car is arranged so that the rails may be placed on the floor or bunks and the ties piled on the same car, on timbers, to hold them clear of the rail. The ties are rolled off the end of the car and the rail pulled out and placed by hand. Track-laying machines are used by some companies. These are built with an overhead trolley supported on a truss and extending about 20 ft. in front and 50 ft. behind the car on which the machine is built. The rails are piled on the floor under the machine, and two cars of ties follow behind. The ties are handled in bundles and delivered in the center of the grade ahead of the machine. When they are in place, the

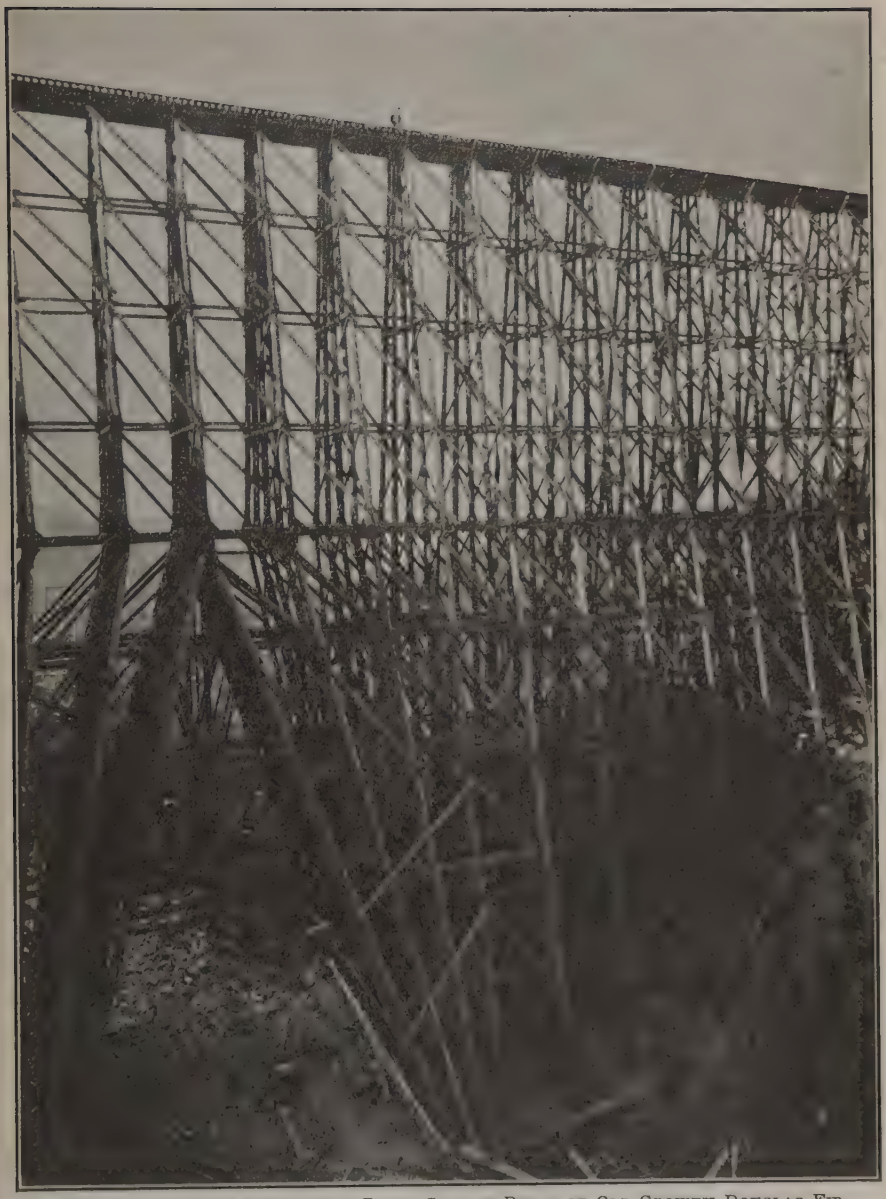

FIG. 11.—TRESTLE OVER CEDAR RIVER CANYON BUILT OF OLD GROWTH DOUGLAS FIR.

Fig. 12.—View Showing Pile Trestle with Log Span, for Logging Railroad.

Fig. 13.—Logging Railroad: View Showing Skeleton Log Cars Loaded with Fir Timber.

rail is delivered and held by tongs until swung into position. The rails are held by bridles until the train has gone ahead. Spiking is done by a crew in the rear.

The ties are usually from local timber, hewn in the woods to the thickness of 6 in. If the work is directly connected with a saw-mill, sawn ties are frequently used in sections from 6 by 8 in. to 7 by 9 in.

Good ballast is almost an essential along the west slope of the Cascades. Gravel is used where available. Sometimes it is purchased on cars and delivered by the standard railroads. Most companies have ballast pits at one or more places on their properties and load into center-dump cars. The cars are loaded by shovels, draglines, scrapers, grab buckets, and other devices.

The most common weight of rail is 60 lb. per yd.; some of lighter section is in use and a few roads are adopting a heavier type. Re-lay rail, purchased from the standard railroads, has been used almost entirely, although some foreign rail and a little American-rolled new rail have been laid.

The sharp curves usually make necessary some lateral support for the track. Rail-braces are used for this purpose, and, on some roads, tie-plates alone hold the rail. When it is necessary to put locomotives with unflanged drivers around the very sharp curves, five rails are used, two inner guard-rails and a rail outside the track rail on the inside of the curve.

Creeping rail presents a serious problem to logging railroads. The loaded traffic is all in one direction, usually down grade. The common practice has been to allow the rail to creep and to place "points" in the track to prevent buckling. The gaps that occur are filled with "Dutchmen", and the broken angle-bars replaced. Some effort has been made to hold the track by driving piling in front of long ties and by tying the track to stumps with pieces of cable. Rail anchors have proved successful in some instances and are coming into more general use.

Train Equipment

The cars originally used for hauling logs were separate trucks equipped with log bunks. The ends of the log are placed on a pair of these disconnected trucks and these loads connected into trains. With light logs, the load is sometimes fastened to the bunk with chains, but in the fir district there is seldom anything to hold the trucks together except the weight of the logs on the bunk. Hand brakes are provided on each truck.

In order to allow the use of the air brakes, these trucks are connected into skeleton cars (Fig. 13) by means of a center sill that carries the air cylinder and brake equipment. These skeleton cars are built in lengths up to 70 ft. The standard railroads are building some skeleton cars, although most of the logs that they haul are loaded on standard "flats", provided with log bunks on the deck.

All the Western States have safety requirements governing the construction and operation of logging railroads, but these requirements are not as stringent as those for common carrier roads and allow the operation of trains

without air on the cars. A skeleton car for common carrier roads is built with platforms on the ends and a wider walkway from end to end.

A geared locomotive is commonly used for short hauls and switching. These machines are built in weights of 40 to 90 tons, all on the drivers. For longer haul, a direct-connected locomotive is used, the most popular type being the Mikado 2-8-2. For service on heavy grades, these locomotives are built with tanks for oil and water on the locomotive. The Mallet type is becoming popular and gives the advantage of a heavier unit with light wheel loads (see Fig. 5). The Mallet type locomotives in use in the woods are much lighter than those built for standard service and are frequently built with saddle tanks.

Train Operation

Oil is the fuel most favored. The fire risk is much less with an oil-burning locomotive and this, with the saving in time and labor in handling, justifies its use, although the cost is higher than for coal or wood. Gasoline locomotives are built for light service, but are seldom used for hauling logs. Some logs are being handled by electric lines, and one logging railroad has adopted Diesel electric power.

The train length is usually limited to about 30 cars. The speed seldom exceeds 20 miles per hour with loads; but due to the short hauls and the facility with which cars are loaded and unloaded, it is not unusual to have a record of daily car loading in excess of the number of cars in use. The service is very severe on cars. Logs often drop from the tongs on to the cars, and rough track and frequent derailments make car repairs a large element in the cost of operation. This cost is much less with the log trucks and skeleton cars than it is with standard flat cars.

Train despatching is conducted by telephone and is usually very simple. Most companies have a man who gives all, or part of, his time to keeping the position of trains and directing their movements. Train crews are smaller than on common carrier roads and the labor cost of hauling is less.

All these factors combine to make the operation of the logging railroads cheaper than that of common carriers. The rates on common carrier roads have recently been increased in the State of Washington to a point where many of the loggers feel that they can build and operate their own roads more cheaply than they can pay freight. This is resulting in the extension of some roads to the mills or to tide-water. The logging roads are always being extended into more remote territory as the timber is cut. Of the track of a logging railroad, from 20 to 60%, is laid on temporary spurs that are in use only a few months and then removed.

The Field for Logging Engineering

In the Pacific Coast District, there are more than 6 000 miles of logging railroad in operation. The total is increasing about 5% per year. The annual replacement of spurs probably amounts to more than 25% of the total

mileage. This makes the total length of railroad built annually about 2 000 miles, which is about one-half as much as the average annual construction of all the Class I railroads for additional main lines, yards, and sidings, during the decade, 1915-25.

The railroad cost is often as much as 40% of the total logging cost and probably totals more than $30 000 000 per year in the Pacific Coast District, yet there is very little either in construction, operation, or maintenance that can be called standard practice.

The economics of railroad location, as applied to logging railroads, has received no study that is entitled to be called scientific. The problem is difficult, but the increasing magnitude of the industry would justify the expenditure of a large amount of effort in its solution. Accurate cost data on every part of the cost of logging, as well as of railroading, are the first requisite of such a study.

The wide variation in natural conditions and operating methods makes it difficult to formulate rules, and the rapid progress in the development of new equipment and logging methods soon renders old data obsolete. The principles that will cover all conditions must be basic and will require time studies of many features of the work.

Conclusion

The practice that now prevails is remarkably efficient. It has been the survival of the fittest and is a result of the good judgment and experience of a group of men who are typical of the best that American industry has produced. With such a background, there is every incentive for the engineer to carry on, and the next few years should see Logging Engineering entitled to a high rank in the profession.

SKYLINE METHODS USED FOR LOGGING

By K. Berger,* Esq.

The logging industry as a whole, not only employs a great number of engineers, but develops men faster along engineering lines than any other business. It does not necessarily follow that all engineers may become successful loggers or that all loggers are engineers, but it is necessary for the logger, in order to be successful, to develop quick and sound judgment along engineering lines, whether trained in the Engineering Profession or not. It is interesting to note the ingenious ways and means devised, in order to get results with the least amount of equipment which is always inaccessible and often inadequate, except wire rope, which is one of the most important requirements. The ever-present wire rope in the woods is no doubt responsible for the varied methods utilized for the transportation of logs, the most important of which are briefly explained.

North Bend System

Of the various skyline systems now used for logging purposes, the North Bend system is the best known. The chief reason for its extensive use even up to the present is its simplicity (both as regards rigging and machinery for operation), and its usefulness for yarding, as well as for swing, that is, hauling loads of logs between two definite points.

With this system any double-drum machine may be used, as there are only two operating lines, the main or hauling line and the haulback line. A tight skyline is used, that is, a track cable is put up permanently for that particular setting. The simple carriage is equipped with double-track sheaves and a sheave in the bottom of the carriage. The hauling line is fastened and a fall-block is used to run on it. The chokers are fastened to the lower part of the carriage to this block, as is also the haulback line which runs out and through the haulback block. The haulback block is placed where the turn (the load of logs brought in) is to to be hooked on, then in and on to the haulback drum. The main or hauling line leads from the carriage through the fall-block and on to the hauling drum on the engine. The idea of the skyline is to lift the end of the turn to clear all obstructions or to carry the turn entirely suspended in the air while it is being hauled in, as well as to guide it and make inhaul easier.

The North Bend system is suitable only on even up-hill ground, as the lifting of the turn is dependent on the retarding strain on the haulback line, which, of course, must be paid out as fast as the turn is hauled in (Fig. 14). On a down-hill setting, the retarding strain on the haulback line would generate too much heat on the brake in order to lift the turn sufficiently to clear obstructions (Fig. 15). For that reason, in yarding down hill, the hauling line is fastened in the block and is led over the lower sheave in the carriage

* Chf. Engr., Washington Iron Works, Seattle, Wash.

and then through the fall-block, thus giving block purchase for lifting the load and correspondingly decreasing the strain on the haulback brake.

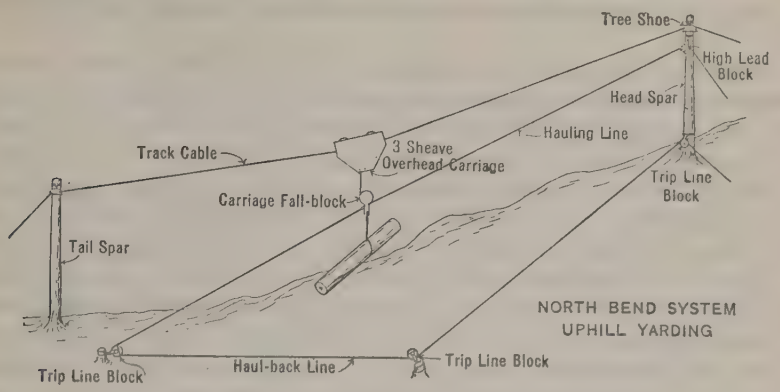

FIG. 14.

Modifications of rigging include fastening the end of the hauling line in the carriage, then leading it through the fall-block and through the lower sheave in the carriage. To keep the carriage in position while unloading, some sort of latch is utilized which serves to engage the carriage and hold it in place while slack is paid out for releasing the load.

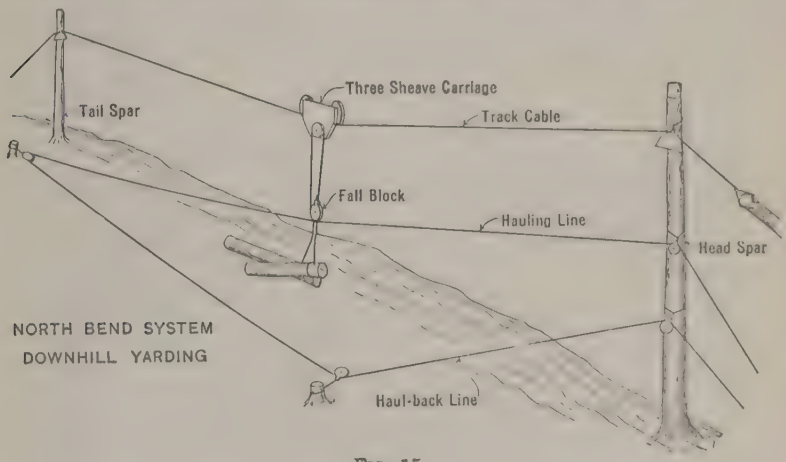

FIG. 15.

SLACK LINE SYSTEM

Until recently this system, first developed and operated in 1908, has not been used as extensively as the North Bend system. Although it is quite simple, as regards the number of lines used, it requires a somewhat larger and more complete special engine. With present-day machinery, it is one of the fastest logging systems in use, both for yarding and swinging. The skyline, instead of being permanently tightened, as in the North Bend system, is raised and lowered with each turn by a separate engine. Hauling and haul-

back lines control the travel of the carriage with its load. The chokers (pieces of wire rope with eye-splices on one end and hooks on the other end which are used for attaching the logs to the main cable) are attached to the carriage direct.

In operation, the haulback line, which is fastened to the carriage, hauls the carriage with chokers out along the raised skyline to the point where the turn is to be hooked on, then the skyline is slacked off, permitting the chokers to drop directly over the logs to be hauled, either directly under the skyline, or by placing the haulback block to the side (side-blocking) and bringing the carriage and skyline both to the side as far as practicable (Fig. 16). The skyline is raised and the turn is then brought in by the hauling line. In the early days of the slack line a simple engine or two engines were used, which did not demonstrate the advantages of this system because of certain operating characteristics. It was not until the introduction of the "Duplex Flyer" that the slack line system became successful. The duplex flyer, as now made, is the largest single-unit logging machine built, weighing, stripped of lines and water, as much as 130 000 lb. Two sets of engines take steam from a common boiler and are built on a common base. One set is used for operating the skyline, the other set for hauling, haulback, straw line, that is, a light line used for handling changes of haulback line block, and sometimes a transfer line, a heavy line for handling changes of track cable or hauling line. The engines as built are controlled entirely by air.

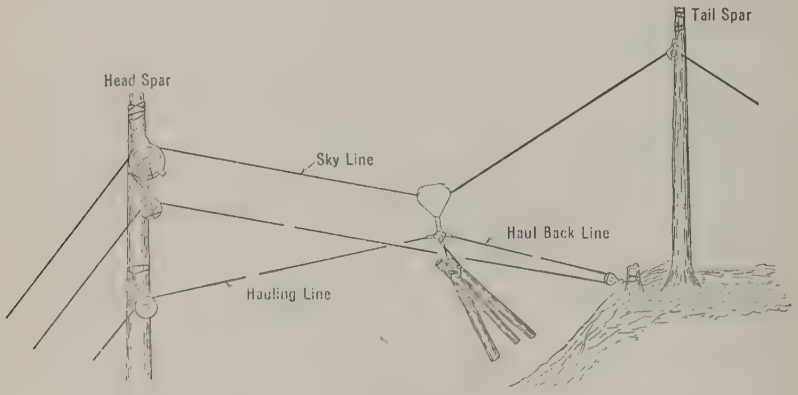

Fig. 16.—Slack-Line System.

Double Slack-Line System

This method (Fig. 17), in operation and rigging, is similar to the single slack-line system, only as regards hauling and haulback lines. The skyline, instead of being fastened at the tail spar-tree, used at the outer end of the track cable, as in the single slack-line system, is led through a block at the tail spar-tree, and each end is wound on a separate drum on the engine. This permits the use of a lighter skyline and gives two speeds on the skyline inhaul. One drum may be held under brake while the other is engaged for winding in the line. This gives one speed. If both skyline drums are engaged at the

same time, the speed will be doubled and, consequently, the pull halved. This system has been used successfully for spans more than a mile in length.

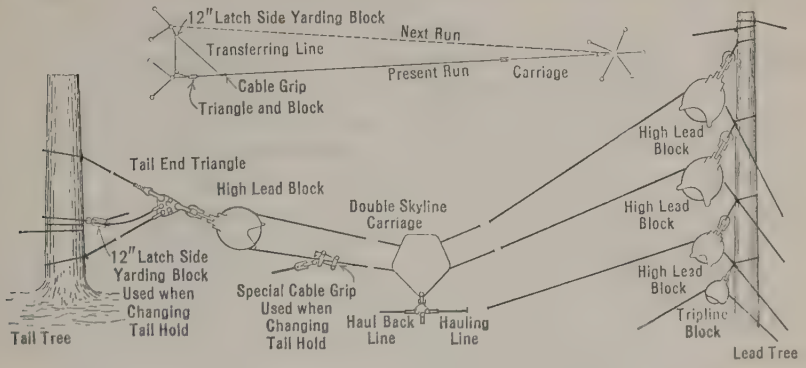

FIG. 17.—DOUBLE SLACK-LINE SYSTEM.

INTERLOCKING SKIDDER SYSTEM

This is one of the oldest systems. A tight skyline and a carriage equipped with two track sheaves, one slack-puller sheave, and a block known as the depending block (fall-block), are used (Fig. 18). The skidding line leading from the skidding drum on the engine is run through a block in the spar-tree and then through the depending block on the carriage. Another line, the

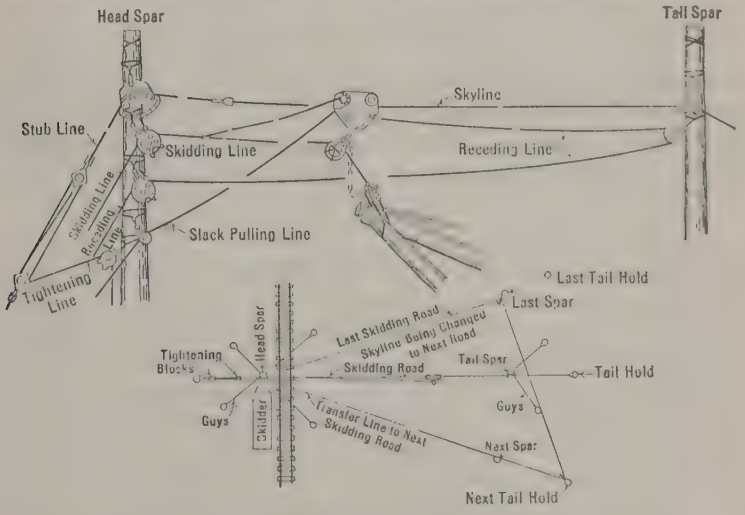

FIG. 18.—INTERLOCKING SKIDDER SYSTEM.

slack puller, is fastened to the skidding line some distance back from the block and runs through the slack-puller sheave on the carriage and in through another block on the spar-tree and on to a drum, the slack puller. The part of the skidding line from the point where the slack puller is attached to the end where the chokers are fastened, is called the tong line. The haulback or

receding line, as it is called, on the skidder is fastened in the carriage and runs out to or near the tail spar-tree and returns to the drum on the engine, known as the receding drum. This drum is geared so that the line speed, when unwinding, equals the line speed of the skidding drum when winding. These two drums, when both are engaged, make an interlock, hence the name. The strain on the skidding and receding line is thus equalized on level ground as the tendency to unwind the receding line is transmitted through the gears to a winding strain on the skidding line. With both drum diameters and gear ratios alike, there is a dead strain resulting from the weight of the turn. Opening the throttle of the engine gives the required travel. These are, of course, only the main points in the system, as it will be understood that with one drum unwinding while the other is winding with a fixed gear ratio, there will eventually be a differential in speed to be equalized. To reduce this differential to a minimum is a matter of engine proportions, which follows well-defined practice as in all other skyline methods.

Another way of obtaining an equalized interlock line speed is to use two gypsy spools of the same diameter and arranged to be interlocked for handling skidding and receding lines, which are wound in opposite directions around the spools. These spools are independent of the skidding and receding drums, which are not geared for interlock. The line pull is imparted from whichever drum happens to be winding. The other drum is left to unwind with just sufficient strain on the brake to keep the line from sliding on the spool. Interlocking skidders are used both for yarding and swinging.

Cableway System

The cableway system, consisting of a tight skyline, a lifting line, a hauling and a haulback line, is used only rarely, due to the short life of the lines when stressed as high as logging practice demands. This system has been somewhat modified and in its present form is known as the "Tyler system."

Tyler System

With respect to number and general arrangement of lines, the Tyler system (Fig. 19) is identical with the cableway system. The load, or lifting line, however, instead of being run through the carriage and fall-block with reverse bends, runs over the sheaves in the carriage and fall-block with all bends in the same direction. This is considered easier on lines at very high speeds with heavy loads being handled. The hauling and haulback lines are fastened in the fall-block instead of in the carriage as in the cableway system. This is done to facilitate hooking and unhooking. This system has been used for yarding, but is essentially a swing system and as such is without doubt one of the most efficient for this purpose.

Dunham System

This new yarding method has only been in use a few years and has proved its worth in short yarding settings. The engine for operating need not be specially built for the purpose, although with such an engine, the usefulness

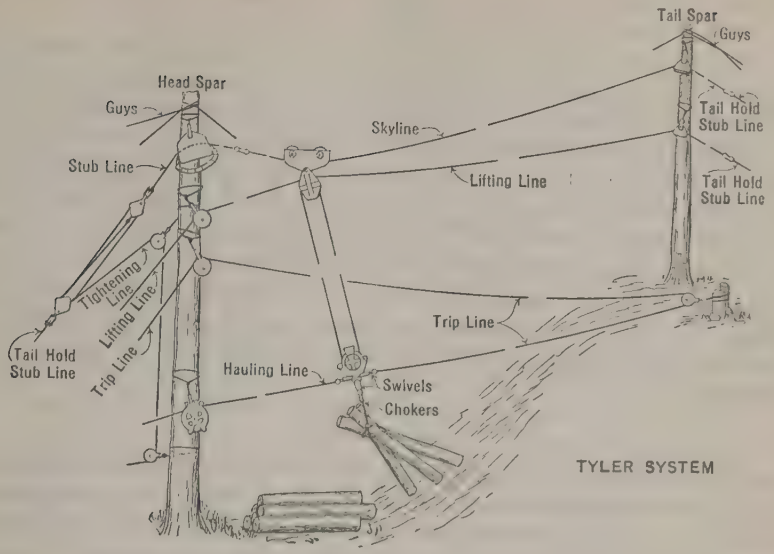

FIG. 19.

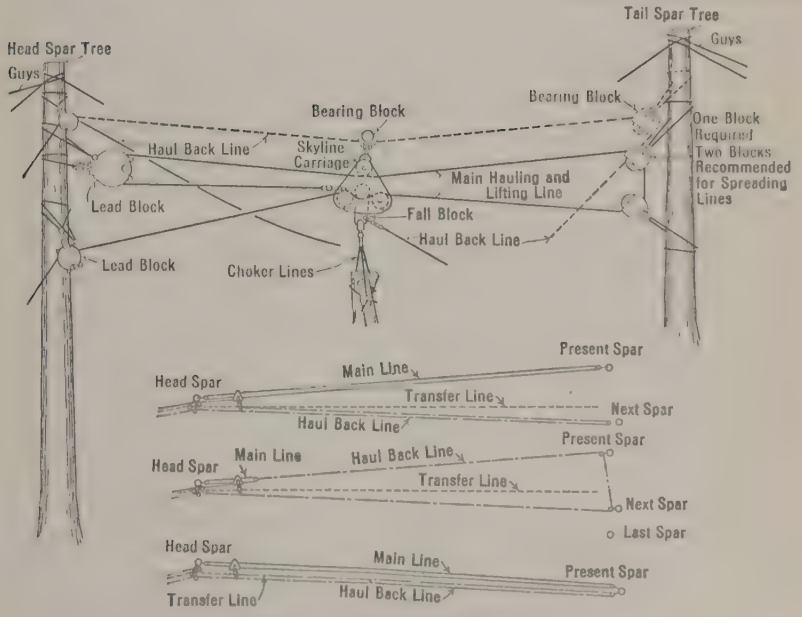

FIG. 20.—DUNHAM SYSTEM.

of the system would be extended considerably. To the present only simple three-drum machines, with good brakes on two drums, have been used, one of these drums having a large line capacity.

In this system (Fig. 20) the hauling line is fastened in the carriage on the edge nearest the engine. From this point it is led through a block on the spar-tree and back under a sheave in the top of the carriage, thence to the tail tree and back over another sheave in the lower part of the carriage; through a fall-block, then over another sheave in the lower part of the carriage and in through a lead-block on the spar-tree to the hauling drum on the engine. The hauling line, it will be seen, thus serves as a skyline. The haulback line is fastened in the fall-block and is led through a haulback block at the point at which the loads are to be hooked. Any retarding strain on the haulback line will cause the turn to be raised from the ground. In this system, as in all other systems, modifications have been used to suit individual conditions.

Conclusions

Not any one of the skyline systems mentioned could be used exclusively because of the varying working conditions obtained in the woods. The kind of equipment at hand, the amount of timber to be handled, the contour of the ground, and the organization, all have a bearing on which system is the most economical to use. Radical improvements in the equipment for handling any one system may eliminate others, but there would still be conditions justifying the use of most systems.

LOGGING FLUMES

By Ulysses B. Hough,* Esq.

For some years the writer has been interested in the transporting of white pine logs, mining timber, and cedar poles from their place of production in Idaho, Washington, and British Columbia, to the place of manufacture and shipment to Eastern markets. Two methods have been used for transporting where such distances as 20 to 100 miles are necessary: First by the use of natural streams having sufficient water to float timber at all seasons of the year; and, second, by railroads, the former being much cheaper but not always available.

Methods of Transportation.—In using either method of transportation—by water or by rail—the products must be gathered to some central point of loading. Various means are used for this, such as hauling by sleighs in winter, the use of trucks in summer, V-shaped flumes, and sliding or trailing chutes in which two logs are placed side by side and the top hewn to form a flat V, the logs sliding by gravity on the heavy grades and being hauled over the lighter grades by horses, caterpillar tractors, or donkey engines.

Water Supply.—The writer early saw the value of the V-shaped flumes, as much of the country is rough and rolling and well supplied with small streams. Some streams afford an abundant supply of water at all seasons of the year for transporting timber, whereas others have so small a flow that impounding dams are necessary to store water for flood periods. A very insignificant stream affording only 2 to 5 sec-ft., if impounded for 2 to 12 hours, will afford an abundant supply of water to transport 100 000 to 200 000 ft. of timber many miles each day. Although the initial cost of the flumes is great, the cost of upkeep and operation is so low that it becomes a very attractive means of transporting timber.

Construction Methods.—The usual method of constructing these flumes is shown in Fig. 21. The sides are placed 45° from the vertical, forming a V, with an opening of 90 degrees. Various angles have been tried for this opening, but 90° requires the least water for floating the timber and affords a ready relief in event of jams, by increasing the quantity of water, thereby affording a greater carrying surface. A three-cornered piece, formed by splitting a 6 by 6-in. timber cornerwise, is placed at the bottom of the V to economize in the use of water and afford strengthening as well. The yokes or ribs of the flume are spaced 4 ft. on centers, and these, in turn, are supported by stringers 16 ft. long. A walk is usually provided to afford easy inspection of the inside of the flumes and access to any jam that may occur. Fig. 21 shows by circles up to 36 in., how little water is required to move the timber. Advantage of this is taken in branch flumes where only 4 000 000 to 10 000 000 ft. of timber is to be removed to the main line. Although the logs may drag heavily, causing excessive wear, the flume will last through the operation which is all that is desired.

* Cons. Engr., Spokane, Wash.

Hugus Creek Flume.—To show more fully the use of these flumes and afford a basis of costs the writer will describe the flume built by him on Hugus Creek, near St. Joe, Idaho, for the Winton Lumber Company. This flume, known as the main-line flume, is 7 miles long, with three branches, 1, $1\frac{1}{2}$, and $1\frac{3}{4}$ miles long, respectively. The main Hugus Creek has a flow of only 8 sec-ft. at low stage, making impounding dams necessary. This dam is large enough to hold water for a 1-hour flood. As much as 100 000 ft. of timber is removed in 40 min. to the St. Joe River, where it floats to the mill at St. Joe, about 9 miles below.

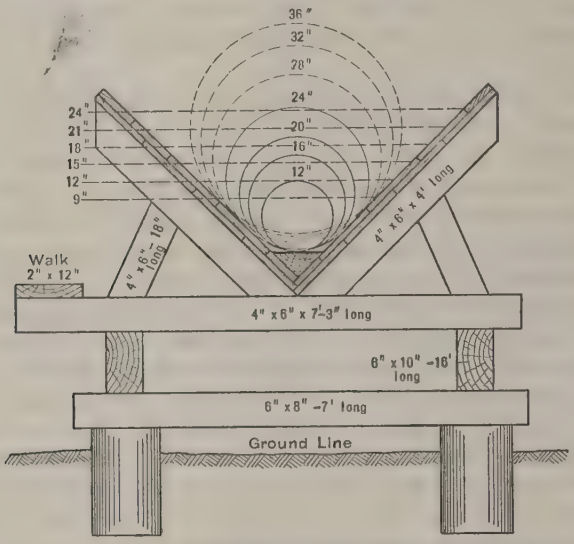

FIG. 21.—SECTION SHOWING METHOD OF CONSTRUCTING LOGGING FLUMES.

Use of Flume in Dry Gulches.—The three branch flumes were built in nearly dry gulches so that the rains in the fall and the melting snow and rain in the spring had to be relied upon for removing the crop. Dams were built at the head of each flume, by the same method as that used on the main-line flume. The 1-mile flume had about 14 000 000 ft. of timber tributary to it and 7 000 cedar poles, all of which were removed in two seasons with no trouble. The $1\frac{1}{2}$-mile flume had no water that would resemble a creek in the summer season, but 4 000 000 ft. of timber and 4 000 cedar poles were removed in one season. The logs were decked along the flume during the fall and winter and were removed the following spring in a few days. The $1\frac{3}{4}$-mile flume had 7 000 000 ft. of logs and 4 000 poles which were removed in two seasons. This gulch had a set of logging camps and the water supply was not enough to supply the camps the entire season, yet, 7 000 000 ft. of timber were removed at a cost far below any other method that could have been used.

Size of Flume.—The timber of this part of the country is generally small, 10 to 11 logs to 1 000 board-ft., although some logs in the upper part of the main line were 4 ft. in diameter. A flume with 4-ft. sides was selected for

Fig. 22.—Logging Flume from 30% to 9% Grade.

Fig. 23.—Long Radius Curve in Logging Flume.

the main line, 3½-ft. for the 1-mile line, and 3-ft. for the other two. All flumes are lined with 1-in., rough material doubled. Small saw-mills of capacities of 10 000 to 15 000 ft. per day were located along the main line, 2 and 2½ miles apart, for cutting the material. The flume was started at each mill and the water of the stream diverted into it, the construction material being floated to place from day to day as the work advanced, no material however, being allowed to get on the ground after leaving the mill. Only such timber as spruce, red and white fir, and tamarack were used in the construction. The average progress per day was 320 ft., the greatest in one month being 8 000 ft. The branch flumes being smaller, greater progress was made; as much as 640 ft. was placed in 1 day and 400 ft. was an ordinary day's work.

Power.—Steam was used for power in some of the small saw-mills and in others gasoline engines were used, with the result that gas has proved the cheaper, although the gasoline was brought in on muleback or pack train and cost on the ground $0.30 per gal. Two elements entered into the use of gasoline: First, the fire risk which is almost negligible; and, second, the inaccessibility of the territory in which such flumes are used. As these flumes are often built in countries that have no wagon roads, simply pack trails, the mill and engine can be taken apart, loaded on muleback, packed to the place, and re-assembled. The writer has built one flume in which the plant has been moved 20 miles in this way. The gasoline used was 2¼ gal. per 1 000 ft. of lumber cut.

Allowable Grades.—The grades of flumes vary, being 1% at the discharge end and as high as 16% in some parts of the main line. One of the branches has a 22% grade for 800 ft. As a rule, 3 to 6% grades are used. What the limiting grades of a flume should be is a question; the writer has used as high as 40% with satisfactory results. Care should be taken in the transition from one grade to the other to use long vertical curves. Although it is desirable to use as little change in grade as possible, this particular flume was intended to receive timber nearly its entire length and, therefore, had to be located on the lowest ground and near to the ground, in order that the object for which it was being built might not be defeated, namely, moving timber cheaply. Too much money should not be expended in getting timber into it.

Curvature.—Curves should be of as long radius as possible to prevent wear on the sides of the flume, 10° being the maximum used in this construction. Poles 60 to 70 ft. long pass these curves with no trouble. Fig. 22 shows a change in grade from 30% to 9% in a V-type flume and Fig. 23 illustrates the use of long radius curves in such flume.

Heavy Grades.—These flumes on heavy grades are often spoken of as "wet chutes", but the timber, traveling faster than the water by 10 to 12%, plows the water out of the flume to some extent, and, at the same time, piles it up and rides on top of it, preventing the heavy wear that occurs in wet chutes or slides.

Handling Timber to Flume.—It is often desirable to place timber in the pond formed by the impounding dam. Part of these logs can be sluiced through when the water has flowed out so that the flume will not overflow at

full-gate opening. A bear-trap gate placed in the sluiceway up stream from the sluice-gate is more convenient, and enables the sluicing of logs during the entire flood. The shorter leg of the bear-trap is placed up stream so as to control the flow of water at full head, the longer leg forming a guiding apron for the passage of logs and water to the floor of the sluice below. This trap is hinged at its upper end to the sluiceway floor and the cables attached to the apex hinge-pin pass to a winch on the top of the dam. It is better practice, however, to place the timber in the flume below the dam, and if a constant flow of water is available to dispose of it as fast as received. Otherwise, the timbers are decked alongside so that advantage may be taken of periodical floods or splashes.

Fig. 24 shows the number of logs that will pass through the flume per hour for various depths of water and grades.

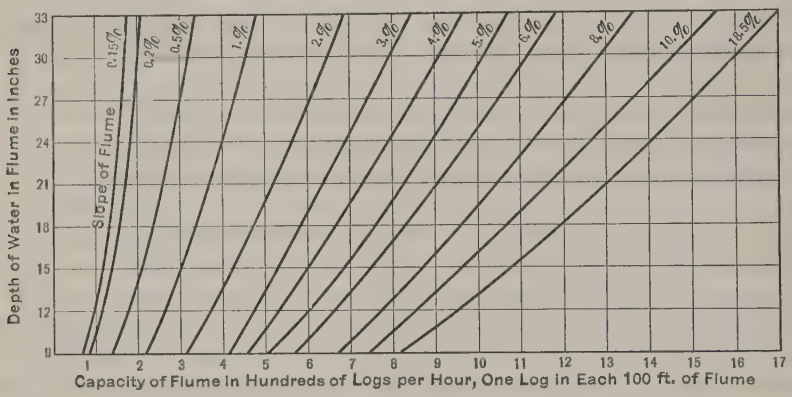

FIG. 24.

Cost of Flume.—The cost of this flume has been as follows: The 4-ft. flume mentioned cost $9 183 per mile, or $1.74 per ft. With the impounding dams, the cost was $9 733 per mile, or $1.84 per ft. of flume. The main flume has two dams, one at the head and the other 2 miles below. The wages paid were $6.00 for flume carpenters and $4.50 for common laborers for an 8-hour day.

The 1¾ miles of 3-ft. flume cost $6 466 per mile, or $1.22 per ft. of flume, the dam and flume costing $7 379 per mile, or $1.40 per ft. of flume. The wages paid were $5.00 per day for flume carpenters and $4.00 for common laborers for an 8-hour day.

The entire flume, dams and branches, cost $106 899. The timber to be removed was 60 000 000 ft. of logs, thus making a cost of $1.78 per 1 000 ft. b. m. for the flume. The cost of upkeep of the flume for 1925 was $0.03 per 1 000 ft. of logs flumed and the cost of fluming has been $0.49 per 1 000 ft. b. m. Only the flume walker was employed for the entire length of the flume, with an occasional day of extra help for repairs.

Future Possibilities.—These flumes have been used successfully for transporting cord wood, posts, poles, mining timber, lumber, and logs over long as well as short distances, and as knowledge of their reliability becomes more general, their uses will be extended.

LOGGING INCLINES

By H. G. Cowling,* Esq.

The logging incline may be defined as the connecting link between two separate and distinct units of logging.

Modern logging operations of any magnitude cover stands of timber ranging in elevation from the main watercourses to the natural timber line. This difference of elevation may be 3 000 ft., or more, depending on the topography of the country in the timber holdings.

The logging industry, like any other, has developed with the demands made upon it. The early operations were naturally along the coast line and as the timber line moved slowly away from the coast up the natural waterways to the higher levels, the method of logging necessarily changed, not only to take care of the rougher ground but to supply the increased demand. Having passed through the era of "bulls and cant-hooks", horses, road engines with horse yarding, and road engines with ground-lead yarding engines, lumbermen now use the high lead, slack skyline, and skidders. With these more modern methods of yarding and by the aid of the switchback method of railroading, the higher timber of lower unit is successfully logged.

Change of Method

As early as 1906 it became apparent that some plan had to be devised for removing timber from places that for physical or financial reasons were inaccessible to the logging railroad. Such conditions brought about the first spur-tracks too steep for geared locomotives. Thus, with an old yarding donkey or road donkey engine used as a snubber the first single-line incline was devised.

The empty car was "snubbed down", and without unhooking, was "spotted" at the landing. When loaded the car was pulled up the incline by the donkey to the top of the hill and another empty car sent down. No money was spent for additional equipment, and under the conditions at the time it probably served its purpose well in comparison with other equipment and camp output.

It is evident that such an appliance could not keep pace with the strides in logging during the past twenty years (1906-26). The single line ("load down one trip and empty up the next trip") type of incline is still used in the logging of isolated settings, and in some instances this type has been refined by the use of a special snubbing engine, special line, and the necessary side and track rollers.

The first snubber of this kind was installed near Ranier, Ore., about 1906, and replaced a log chute 3 300 ft. long, with an average grade of 25 per cent. The operation of the log chute was discontinued because of the large loss in breakage. The first snubber was equipped with hydraulic cylinders to control the load in its descent but proved impractical and was soon discontinued. It was used long enough to demonstrate that the general plan of handling cars in this manner was feasible, provided the right kind of equipment was built to serve it.

* Chf. Engr., St. Paul & Tacoma Lumber Co., Tacoma, Wash.

First Snubber Built

For this purpose the Willamette Iron and Steel Works, of Portland, Ore., constructed a direct-geared engine with 16 by 20-in. cylinders and a single drum. Steam was furnished by a horizontal tubular boiler. This engine was in successful operation for many years, and probably was the first hoisting and lowering engine used in the logging industry.

The forerunner of the modern lowering engine designed particularly for the job, was the "gypsy"* type, counterbalance machine, built for the Yosemite Lumber Company, of El Portal, Calif., in which an empty car ascended as a loaded car descended. The next important counterbalance was Incline No. 1 of the Manley-Moore Lumber Company's operation at Fairfax, Wash., in 1914. Later, the writer had the opportunity of operating this incline, and studying that operation technically.

About 1913, Mr. Hugh E. Sessoms, of the Ebey Logging Company, at Arlington, Wash., conceived the idea of putting a block purchase in the line, using a pilot car carrying three 36-in. sheaves around which the lowering line passed in going from the "snubber" to the tail hold. This, with the counterbalance type of incline, will be elaborated later.

Since 1916 the development of the "snubber" or lowering engine has reached a very high order. Extensive investigations and tests have been made to determine the power consumed, the proper dissipation of the heat generated, and the economical distribution of materials. The design of the brake has been a great study as well as the character and cross-section of the brake flange. The cross-sectional design of the "gypsy" has come in for its share of study to eliminate rope wear through the side and end slipping of the rope during one operating run, and there is still room for improvement. Brakes are operated by steam, air, and hand levers, with the most recent installations using air almost exclusively.

The steam requirements of a lowering engine of the counterbalance type are usually very small, and the size of the steam plant is determined by the loads to be hoisted. In the single-line system, steam requirements are much greater. Electricity lends itself admirably to the incline problem and where available should be used. Advantage can be taken of the generating feature of the motor to assist in braking or retarding the loads in their descent.

The importance of the development of the lowering engine can be gauged from the fact that the simple early machines of twenty years ago sold for $3 000 to $4 000, whereas recent self-contained machines sell for as much as $20 000 and, in one instance, an electric machine was installed at a cost of about $60 000.

The Yosemite Incline

The first counterbalance incline of the Yosemite Lumber Company, at El Portal, measured 8 000 ft. on the slope of the track, with a difference of elevation of 3 100 ft., starting at Elevation 1 900. The foot of the incline is 54 miles up the Merced River from the mill at Merced Falls. From the top of the

* Large drum built like a spool, which carries 3½ wraps of line.

incline all timber was reached from a main line using 4% grade with a maximum curve of 40 degrees. The incline is located from the highest point of the ridge, without horizontal curves, to the center of the railroad yards at El Portal, and has gravity switching tracks at the top and bottom. The Merced River is crossed with a 76-ft. span and there are two other trestles over ravines and a bent trestle at a point where one side is over a cliff. The grades range from 10 to 78% maximum. The 10% grade is in a saddle in the ridge, and comes at the foot of 700 ft. of 78% grade. At this point on the double track, towers were erected, anchored with rock and concrete to prevent the cable from lifting 250 ft. in the air. A system of ten sheaves for each cable, set in the arc of a circle 16 ft. above the track holds the line in place and the cars pass under as they would enter the portal of a tunnel.

The flat cars used are the steel under-frame type especially designed. A bulkhead is built at one end 5 ft. above the bunk line, and riveted to the car. The cable is attached to a cast-steel draw-bar riveted to the car above the draft gear.

The first car was lowered on this incline on July 27, 1912, seventeen cars being lowered that day. The success of the operation having been proved with an initial line speed of 500 ft. per min., this was increased to 960 ft. per min. the following year, and with a few changes in vertical curves the ultimate result was the safe delivery of a car in 7 min. with 1 min. for switching and hooking on another car. This Company is now operating its second incline, 9 000 ft. long, with a maximum grade of 68%, in conjunction with a third incline about 2 miles back, 1 500 ft. long, with a 30% maximum grade.

The first incline of the counterbalance type in the State of Washington was built by the Manley-Moore Lumber Company, at Fairfax, Wash. This incline is 4 900 ft. long horizontal measurement, with a difference of elevation of 1 600 ft., beginning at Elevation 1 500. It has a maximum grade of 59 per cent.

After a careful study of this incline the writer was asked to select the proper site and build Incline No. 2 across the Carbon River from the mill of the Company. This incline is 3 323 ft. in horizontal measurement, with a difference of elevation of 815 ft. Of rock, 5 000 cu. yd. were moved, and a log bulkhead, 400 ft. long and 14 ft. high, was built near the top. The "snubber" is designed to handle 40 loads of logs per day of 8 hours. About 280 000 000 board-ft. are to be moved. There must be gravity switching tracks at the top and bottom; single track on the lower half and double track on the upper half, the cars passing in the clear above the half-way switch. A contour map was made of the strip of ground selected for the site, and a center line projected, which would place the 50-ft. contours as nearly an equal distance apart horizontally as practical, thus insuring a minimum of excavation with the most uniform grade possible.

It is the curve of the uncounterbalanced load rather than the actual ground profile that is the measure by which the operation of an incline can be judged. The "snubber" at the top of the hill absorbs the energy not otherwise consumed in friction and in bringing up the empty car. This is evident in the

form of heat at the brake drum. Points on the load curve were calculated for each 40 ft. from "hook-on" to "hook-on" and plotted as on Fig. 25, showing a profile of the incline on which has been drawn the curves for two different conditions of loading. The lower curve is for a 32-ton loaded car and a 14-ton empty, and the upper curve is for a 45-ton loaded car and a 13-ton empty.

The ascending (heavy) portions of the curve represent brake applications; the nearly horizontal portions represent a period of holding the brakes applied and the descending portions represent periods of brake releases. For example, following the descending load, note that, while the load is passing over the 200-ft. vertical curve from 11 to 45% at Station 65, the brake application increases from 3 250 to 29 800 lb., at which point there is a slight release as the load comes on the 45% grade. This release is necessary for the reason that, while the load continues on the 45% grade, the ascending empty car is changing from a 28% grade to a 34% grade on the upper end of the 160-ft. vertical curve at Station 49 + 50 (Fig. 25). Note, also, that of the two calculated braking curves, the lower one shows five brake applications, whereas the upper shows seven applications. This difference was caused by the change in grade shown at the foot of the hill from 9 to 10 and 13%, and the shortening of the vertical curve from 200 ft. to 160 ft.

Time is also a factor in the operation. For instance, on the vertical curve from the 11% to the 45% grade at Station 65, 14.3 sec. are required with a line speed of 840 ft. per min. During this time the uncounterbalanced load increases 26 550 lb., or 1 856 lb. per sec., and the strain on the load end of the rope increases 27 090 lb., or 1 894 lb. per sec. If the vertical curve were only 100 ft. long these changes would take place in one-half the time. This illustrates the advisability of long vertical curves.

To keep the engine man advised at all times as to the exact position of the cars the profile and brake-power curve is before him on a vertical cylinder with an indicator wire.

Experience has developed the fact that the construction of the rope used is very important. Various kinds of track rollers and side rollers have been made to protect the line on vertical and horizontal curves, and it has proved economical to use well constructed roller-bearing journals.

A tower is constructed at the head of the incline between the hook-on point and the "snubber". The cars, in switching, pass under this tower while the ropes pass over the top. Beginning at the upper hook-on point and following through to the lower hook-on point, the cable passes over six 20-in. tower sheaves set on a uniform radius of 30.46 ft.; thence it passes over the top of the tower to the 5½-ft. gypsy around which there are 3½ turns, thence over six 20-in. sheaves on the tower set on a radius of 33.84 ft.; thence down over the numerous track rollers to the foot of the hill. These changes in direction of the rope in running its course are necessary to the operation, and rope manufacturers are bending every effort to evolve a product to satisfy the variable conditions under which these ropes must work. The ropes used on a counterbalance are from 1½ in. to 1¾ in. in diameter.

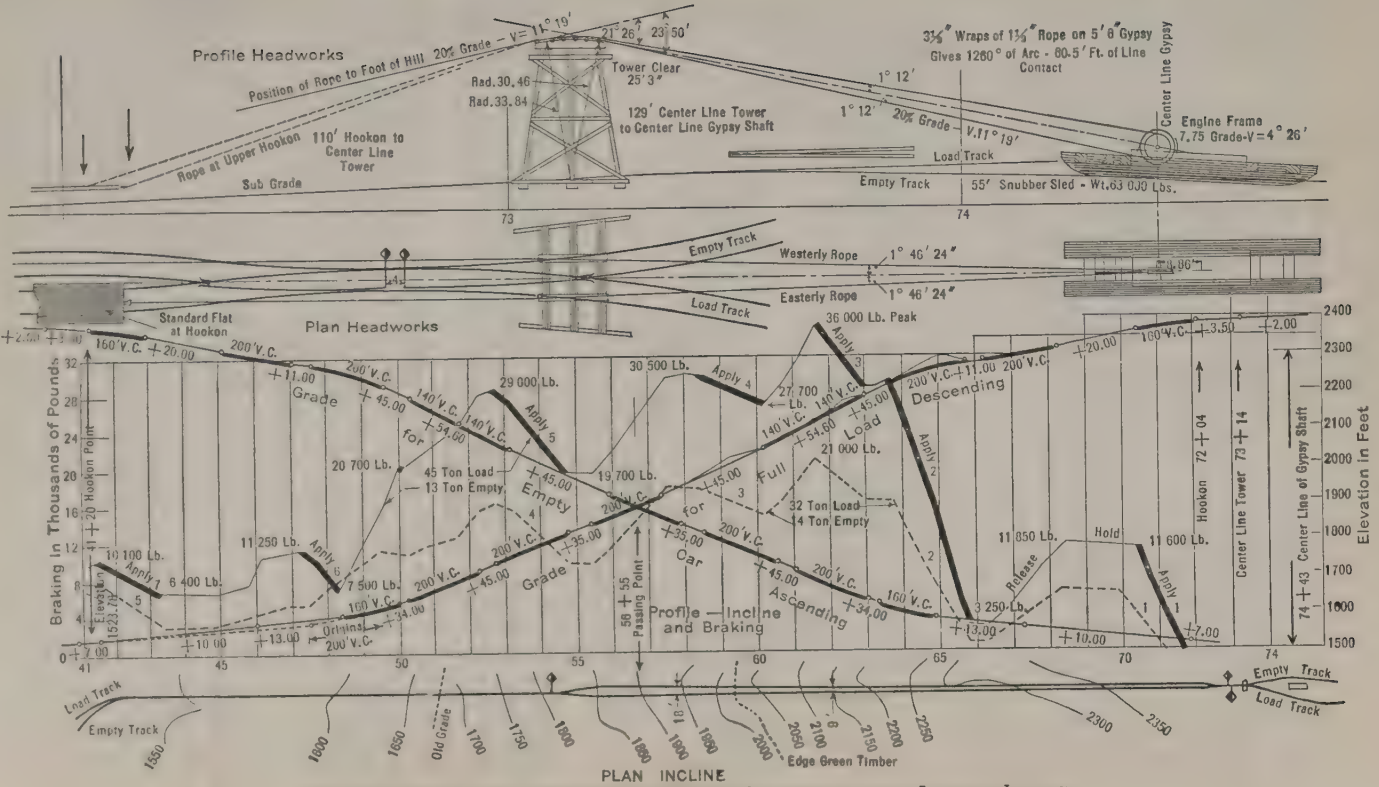

FIG. 25.—DETAILS AND OPERATION OF TYPICAL COUNTERBALANCED LOGGING INCLINE.

The Sessoms Incline

Mr. Sessoms has described* another development of the incline principle, as shown on Fig. 26. The construction of the "snubber" is the same as that for the counterbalance, with the exception of the drum. The gypsy is supplanted by a drum the capacity of which is double the length of the incline, with enough extra for "tail hold" at the dead end swivel and a few wraps on the drum.

The pilot car, as shown in Fig. 26, carries one 6-ft. sheave instead of the original three 36-in. sheaves in the block proper, and two outrigger sheaves 19 in. in diameter at the upper end of the car, so placed that the live and dead line runs of the rope lay 7 ft. 1⅛ in. from the center of the car. The two sheaves on the bunk between the large block and the outrigger have been eliminated.

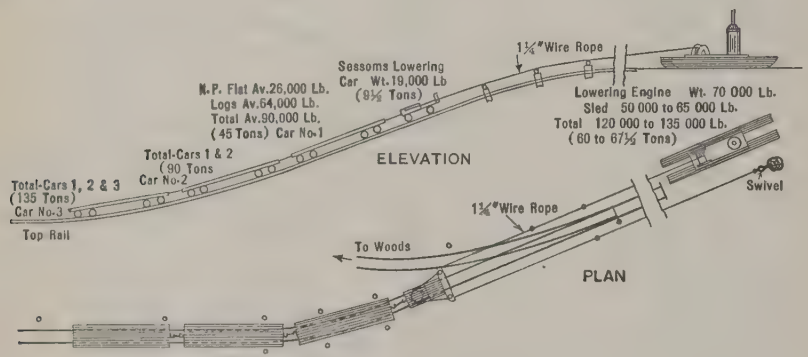

Fig. 26.—Sessoms Lowering Car Type of Incline.

The pliability of this rigging is apparent. The scheme may be described as a track system of main line and spurs tipped up on end far enough to give sufficient grade to insure that switching may be done by gravity under the control of the engineer at the "snubber".

Grading for incline railroads is no heavier and no more difficult than for any road using locomotive power. Contrary to the general idea, there is no trouble with creeping track as there is no tractive effort on the rails, and it is possible to use lighter rail without harm to the operation.

Acknowledgments

The writer wishes to acknowledge his appreciation to A. G. Labbe, President, Willamette Iron and Steel Works; Gerald Frink, President, Washington Iron Works; Messrs. Fennell and Chriswell, of the Pacific Car and Foundry Company, and to Mr. Jack Wilson, of the Seattle Office of John A. Roebling's Sons Company, whose kind co-operation made this paper possible.

OCEAN LOG RAFTS

By W. T. Evenson,* Esq.

The subject of "Lumber Rafts" is so broad that this paper has been limited to "Ocean Log Rafts". The Davis raft and the Benson raft are the only two types of ocean-going rafts now in practical use. The Davis raft is built by various loggers and operators under patents held by Captain G. T. Davis. The Benson raft is now used only by the Benson Timber Company, and the Benson Lumber Company, affiliated corporations.

The Davis Raft

The Davis raft is built without the aid of a cradle, and as constructed by the Multnomah Lumber and Box Company, of Portland, Ore., contains from 600 000 to 900 000 ft. of logs. It is much in demand for short trips across rough water, and because of the economy of building. It is practical for use in salt water because it requires no cradle for its construction as does the Benson raft.

The Davis raft is built by first laying a floor of long logs, held together by interlacing cables over and under the logs of the floor which are properly fastened to keep the floor intact until the raft is broken up at its destination. When the floor is completed, logs are rolled upon it, submerging it gradually. At intervals wires are run across the raft to strengthen and bind it together. When the floor is submerged to the proper depth, the cables are fastened across the top and the raft is ready for towing.

The loss on this type of raft has not been large, and the distance of the tow in no instance has been very far. At present (1926), a new Davis raft is in course of development which will take logs of all lengths and which, it is estimated, will carry in excess of 3 000 000 ft. of logs on long tows.

The Benson Raft

In 1906, Messrs. S. Benson and O. J. Evenson started in the ocean-rafting business at Wallace Slough, Ore., on the Columbia River, engaging Mr. J. A. Festabend to superintend the construction of a cradle and raft. Previous to this time Mr. Festabend had constructed rafts for Captain Robertson, the originator of the ocean log raft. Messrs. Festabend and Evenson constructed a simple cradle with an improved center-locking device, and improved on the towing gear and system used by Captain Robertson.

The first raft built was small as compared with present-day rafts and contained not only piling and saw-logs of all sizes and lengths, but several hundred thousand feet of sawn timbers and lumber for a complete saw-mill which was to be constructed in San Diego, Calif. The towing distance was 1 100 miles and was twice that ever before attempted with an ocean raft. The

* Asst. Mgr., Benson Timber Co., Clatskanie, Ore.

safe arrival and excellent condition of the raft caused considerable comment in San Diego. These rafts produce from 4 000 000 to 5 000 000 ft. of lumber. Of these rafts, seventy-two have been landed safely in San Diego Harbor, only two meeting with misfortune. More than 50% of these rafts have carried deck loads. Cedar poles, spars, shingles, lath, and fence posts have been successfully "decked-loaded" and delivered in good order.

The towing season is from June 15 to September 15. The average towing time is about 15 days from bar to bar. For safety, the rafts are equipped with two lights which will burn for 21 days without any attention from the tugboat.

The Benson raft, which is cigar-shaped (Fig. 27), is built in a floating cradle, or form, which is constructed in sections so that on the completion of the raft the sections can be removed from one side and the raft "kicked out" of the other half of the cradle which is moored to piling. When the completed raft is launched the sections are towed back into place, the center locks are set, and the cradle is ready for the next raft. The Benson raft is not feasible in bacteria infested waters because the cradle will not last more than two years. On the side of the cradle moored to the piling, a derrick moves back and forth on a running line, pushing and pulling the river raft with it as the logs are placed throughout the raft, course upon course, over the length of the cradle. All sizes and lengths of logs are used, but the strength of the raft is dependent on a large portion of tree-length material. The long logs give the necessary strength to resist the action of the ocean waves and groundswells.

The cradle keeps sinking in the water as the logs are loaded, and when one-half the raft is completed, a 2½-in. anchor chain is run along the center from end to end. This chain is the back-bone of the raft. Herring-bone chains shackled to the center chain are attached to the five chains that circle the raft at each end. A tow chain, 180 ft. in length, is attached under the raft to the third circle chain from each end, which furnishes an emergency tow chain to be used if the one in service becomes unshackled or breaks from any cause. The raft tows equally well from either end. When pull is exerted the 180 ft. of chain acts as an equalizer, taking care of the surges of the tug, the pull being transmitted by the tow chain through the herring-bone chains to the circle chains on the opposite end of the raft, and the slack created is taken up by the working of the raft in the sea which always tends to lengthen the raft. After the tow chain is in place the process of piling on logs continues until a draft of 26 to 28 ft. is reached. Then the circle chains are fastened around the raft and cinched with the aid of a donkey engine and a set of six sheave-blocks and grab-shackles. The circle chains are of 1⅞-in. anchor chain and are placed at 12-ft. intervals. The total weight of the chain on one of these rafts is about 175 tons. The raft dimensions are 55 ft. wide, about 35 ft. deep, and 835 ft. long, with a draft of 26 to 28 ft.

The great advantage of the Benson type of raft is that it is self-tightening, and there is no tendency to loosen the mass. When the raft is being towed and, in fact, as soon as it is out of the cradle, it tends to flatten and tighten the circle chains, and as it is towed it tends to lengthen and tighten itself.

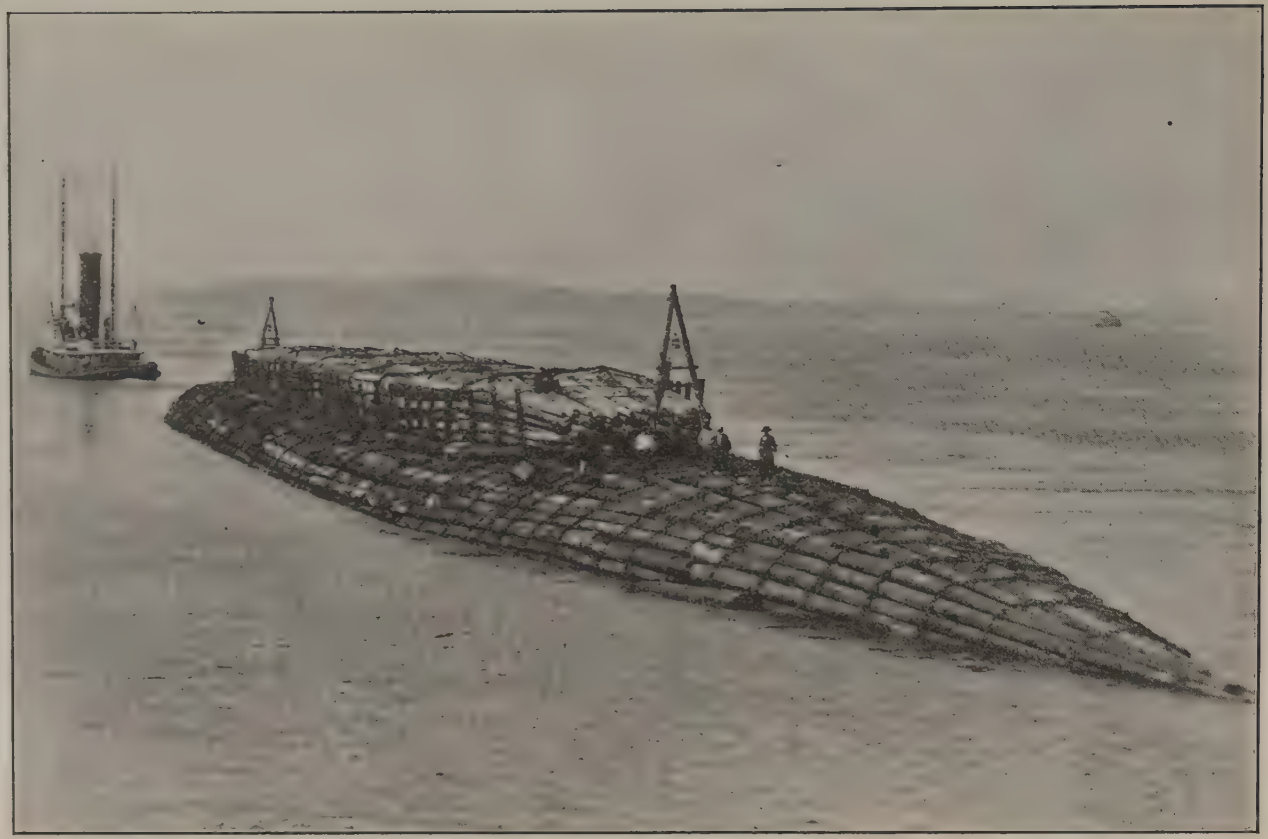

FIG. 27.—VIEW OF LOGGING RAFT.

THE ENGINEERING ASPECTS OF SAW-MILL CONSTRUCTION AND OPERATION

By Bror L. Grondal,* Esq.

This paper refers mainly to saw-mills of the Douglas fir region, and to saw-mills that may be classed as of fair size, for it is in these that engineering problems become more real.

Douglas Fir Logs Are Long and Large

The logs in the Douglas fir region are often very large and heavy. Many reach very great dimensions, both in diameter and in length. The tallest Douglas fir on record was 380 ft. high—which is also the maximum height recorded for redwood. The largest tree ever found had a diameter, at breast height, of 15 ft., and individual trees have yielded as much as 60 000 board-ft. of lumber.

Such trees are of course exceptional specimens, but this will serve to emphasize the fact that Douglas fir is often a very large tree. It is customary to cut logs in long lengths—usually about 40 ft.—to build full flat-car loads, and as these logs often scale as much as 5 000 ft., b. m., with a consequent dead weight of 16 tons, or more, the necessity for a log pond, in which the logs may be dumped from the cars and sorted, becomes apparent.

Log Ponds Offer Problems

Here is one of the engineering problems that confronts the mill designer. A site must be chosen where level land for the mill itself and the yard may be obtained. Moreover, this site must have good transportation facilities, not only to permit logs to be hauled to the mill, but in order that the finished lumber may be shipped; and more, this site must be where a log pond large enough to store a sufficient number of logs to run the mill at least three weeks or a month can be provided. A fairly large Douglas fir mill, cutting 300 000 board-ft. per day, operating on a double shift, will require, therefore, a pond at least 15 acres in extent, preferably larger. This pond must be reasonably deep, so that it will not fill up quickly with débris. A good water supply, to replenish the loss by evaporation and to keep the pond from fouling, is also necessary.

No great stretch of the imagination is required, therefore, to assume that dams must often be built, reliable dams, but cheap, for the margin of profit in the sawing of logs is very small, and the overhead cost of the mill must be held to a reasonable figure.

From the pond the logs may be lifted into the mill with the aid of a sling hoist, by which the logs are parbuckled to the deck; or they may be carried up on an endless chain, known as a log jacker, log haul, or log chain.

* Associate Prof., Forest Products, Coll. of Forestry, Univ. of Washington, Seattle, Wash.

Heavy Logs Demand Power Devices for Handling

As the log deck, which must be heavily built, is inclined toward the carriage, a log-stop must be provided to prevent the log from rolling forward when not wanted. This, as well as a log kicker, to kick the logs out of the haul-up, when such a device is used to bring the logs into the mill, must be actuated by a steam cylinder. A log turner, to load the logs on the carriage, and to turn them as occasion demands during the sawing, must also be provided. A "Simondson" turner is usually provided for larger logs, a "nigger" for smaller logs, and an overhead canting gear for emergencies and to handle extremely large logs.

Automatic Log Carriage Equipment Saves Sawing Time

The carriage must be large enough, and sufficiently strong, to accommodate the largest logs that are likely to be sawed. The carriage is usually operated by a reversible twin steam engine geared to a drum, around which is wrapped a cable. This passes through sheaves at both ends of the track, and both ends are attached to the carriage. In one of the most modern mills, an electrically driven motor carriage feed is provided. In still another modern mill a huge steam "shot-gun" feed has been installed. This feed, consisting of a 48-ft. steam cylinder, piston, and piston rod, dwarfs the familiar "shot-guns" of mills in other regions. On the carriage itself are skids of steel or "blocks" on which the log rests. On these skids are also "knees" against which the logs are held by power or hand-operated "dogs". Two types of quick-acting, automatic, power, dogging devices have been developed—one a compressed air apparatus, and the other an electrically controlled mechanism. Both types are good and save valuable time.

Set Works Are Electrically Operated

The log is moved out into the line of cut with the aid of the "set works", which is now usually electrically driven, and which moves the knees forward on the blocks an equal distance, when the log has been squared, but which must also be built in such a manner that one knee can be moved at a faster rate than the others on the carriage.

Taper of Giant Logs Complicates Sawing Methods

Here, again, is an engineering problem in operation. Although many logs are approximately round, all of them taper. The most valuable material in the log is in the outer part, which is free from knots. If the taper of the log is disregarded in sawing, expensive waste occurs. The scope of this paper does not permit extended discussion of the proper sawing of logs, and the so-called taper-sawing, but engineers who are interested in mathematics as an abstract science will find some very interesting problems in it. A "head sawyer" can almost make or break a mill, and it is obvious that he must be, intuitively, a good engineer. It may be of interest that one of the best head sawyers the writer has ever known was a graduate civil engineer who liked his "job".

Band-saws are now almost exclusively used in Douglas fir mills; for large logs, the single-cutting type, and, for smaller logs, the double-cutting type. Band-saws produce less saw-dust than circular saws and have other marked superiorities in producing a high grade of lumber. Band head-saws with 10-ft. wheels are very common, and larger saws are in use in many plants.

Head Saws Do Not Govern Mill Capacity

In other regions most of the sawing is done on the head-saw, and, in the Baltic pine region of Europe, gang head-saws are commonly used. In Douglas fir mills the head-saws are used primarily to break the logs into large cants, and to square up timbers from the interior of the log. A mill of comparatively small capacity may be provided with just as complete deck equipment and as large a head-saw as one of large capacity. The capacity of a mill depends to a great extent on the type of equipment after the head-saw has been passed. Two head-saws, one single cutting and one double cutting, represent the "head end" of one of the largest mills ever built.

A band head-saw of the type commonly used demands a motor of approximately 400 h.p., and larger motors have been used. These motors usually drive through belts, although at least one machinery manufacturer is now successfully building such a saw with a direct-connected motor suspended from the massive extended base of the machine. Roller and ball-bearings, which reduce the starting demand and the average input of power materially, are now often used in mounting the wheels of band mills.

As the cants drop from the carriage, they are carried away on "live rolls", of steel, and are picked off by means of "jump chains" to the chains on which they are conveyed to the edger-feed table. Mechanical liners are used for lining up the cants before they go through the edger, for they are often too heavy to be moved by hand.

Heavy Edgers Require Mechanical Saw Shifters

The edgers are large, to accommodate wide and thick cants—often as large as 14 by 72 in.—and are usually provided with mechanical saw shifters to move the large and heavy saws. The largest edgers require as much as 400 h.p., and are often equipped with direct-connected motors. At the rear of the edger is a series of live rolls carried on a truss extending over the chains which carry the edgings and slabs to the "slasher". The boards coming from the edger are dumped over the end of these rolls on chains leading to the automatic trimmer.

Edgers in Douglas fir mills often serve a dual purpose. Heavy boards and cants are edged, to free them from bark and wane. In this respect, the edger is operated in the manner that its name implies it should be. On the other hand, the edger is commonly used to re-saw cants into thick boards, which, in turn, are re-sawed later. In this process of re-sawing, the heavy kerf of the circular saws used in the edger causes a great waste of valuable wood, for the teeth of the saw are often swaged to a width of almost ½ in.

Timbers cut on the head-saw go out to the timber dock on live rolls, passing right through the mill. Slabs are kicked off by means of jump chains to the

slasher chains below. Edgings and slabs pass under a battery of ten saws, spaced 4 ft. apart, all on the same arbor, driven by a direct-connected motor of approximately 50 h.p.

Mechanical Automatic Trimmers an Innovation

The boards that have passed through the edger go to the trimmer which, in all modern mills, is of the automatic type, with twenty-one saws that can be dropped at the will of the trimmerman so that the boards passing under the saw on chains can be trimmed to proper length and in such a manner that a proper grade of lumber will be produced. Three types of automatic trimmers are in use. In the most common type the saws are lifted by compressed air acting on pistons in cylinders. In extremely cold weather, the air lines may become frozen, but this can be prevented by introducing alcohol into them. On another type the saws are lifted by means of electric solenoids. Several modern mills have such installations. A new and vastly improved type is purely mechanical and as it is free from complications it bids fair to become the standard type of trimmer. In every case, the trimmerman operates the saws by remote control from a cage facing the bank of saws, a keyboard being provided for his convenience. The saws in the trimmer are belted to a series of pulleys on a single shaft, driven by a direct-connected motor of about 50 h.p. After the lumber passes through the trimmer, it is discharged on a sorting table, from which it is pulled for re-sawing, re-edging, or re-trimming.

Pony and Gang Saws Simplify Cutting of Vertical Grain Material

As has been indicated previously, the capacity of a mill in this region depends on the amount and nature of machinery after the lumber has passed the head-saw. So-called "pony rigs", for re-sawing cants produced on the head-saw, may be included in the design of the mill. A pony rig must have a cant deck with chains, turners (usually of the "nigger" type), and a carriage similar to that used at the head rig. Means must be provided for conveying the cants from the head rig to the pony rig, and, therefore, the pony rig is usually the first piece of re-sawing equipment in the mill. As the pony rig usually consists of a band-saw cutting a narrow kerf, its use is advantageous.

Another machine, which is achieving deserved popularity in the mills of the Douglas fir region, is the vertical reciprocating gang saw. These saws are often built to accommodate cants 12 in. thick, and sometimes have a width of 4 ft. They require extremely heavy foundations, as the vibration caused by the reciprocating parts is very great, although, recently, so-called "balanced" gangs have been introduced. The gang saw is always belt-driven, and requires, in the larger sizes, a 100-h.p. motor.

The pony head rig and the vertical gang saw save much lumber and greatly simplify the cutting of vertical grain material. They also greatly increase the cost of mill construction and complicate the work of the mill designer, but are almost indispensable in large mills.

In the re-sawing room of the mill, the layout must be such that lumber may be pulled from the sorting chains for re-sawing, re-edging, or re-trimming,

and returned to the same chains in such a manner that it may be re-worked over and over again. At the same time, sufficient storage room must be provided at each machine, so that the mill can be kept running at the highest efficiency in every department.

A vertical gang saw will usually produce enough lumber in 1 or 2-in. thicknesses to keep a trimmer busy. Plenty of storage space for cants must be provided in front of the gang, so that it may be kept supplied with proper material.

Two types of band re-saws are commonly used. The most popular is the vertical roller band mill with 6, 7, or 8-ft. wheels. In this device the boards to be re-sawed are fed to the saw on edge between rollers, and, therefore, the stock to be re-sawed must have at least one straight edge. A horizontal band re-saw, in which the lumber is re-sawed while flat, does not demand square-edged stock, and, therefore, has advantages that are quite apparent. On the other hand, horizontal band re-saws require more skillful filing, because if the saws are not properly fitted, very poor lumber may be produced. Horizontal band re-saws are sometimes used for re-sawing slabs, and are useful for this purpose.

After the lumber leaves the re-sawing room it passes out on the sorting chains, where it is graded and sorted, being pulled from the chains by hand and placed on trucks.

Various types of automatic drop sorters have been installed in the largest Douglas fir mills, but these are expensive and are not as practical in this as in other regions, for the multiplicity of sizes, grades, and length produced greatly complicates the problem of automatic sorting.

Kiln-Drying of Entire Output of Mill a Recent Development

A recent development, and a logical one, has been the kiln-drying of the complete output of the mill, with the exception of timbers. Air-drying on the Pacific Coast is very slow and expensive, for the relative humidity is comparatively high, except during the summer months. The cost of shipping green lumber is enormous, for almost one-half its weight is due to moisture. All this water cannot, of course, be removed, but a large proportion can be eliminated by proper kiln-drying. As the freight charges paid to the railroad companies sometimes exceed the value of the lumber at the mill, the desirability of kiln-drying becomes apparent.

Edge stacking for the dry kilns is common practice at most of the larger mills, and is very desirable, as it reduces the cost of stacking and unstacking, increases the capacity of the mills, and permits better circulation within the kilns. In dry kilns of modern design the circulation of the heated air is produced mechanically by fans, and the relative humidity and temperature are held at predetermined points with the aid of automatic controlling and recording instruments.

Use of Electric Drives Removes Old Restrictions in Mill Design

A few years ago, when all saw-mills were driven by mechanically distributed power, the saw-mill designer was so burdened and harassed by mechan-

ical details that mill-operating efficiency was often sacrificed to make possible some particular drive. To-day, these restrictions have largely disappeared, due to advances that have been made in electrical engineering. All the larger mills are electrically driven, and complicated shafting and counter-shafting, huge bevel-gears, "muley drives", and other power-stealing equipment have been relegated to the scrap heap.

To-day, the proper order of design is first a detailed consideration of the floor plan of the mill; second, the building; and, finally, the drives. The first electrical installations made use of the so-called "unit drive" system, by which power from more or less centrally located motors was distributed to various parts of the mill by belting and shafting. Now, however, the mill designer can choose between a number of types of highly efficient self-contained speed reducers, which can be coupled directly to the motors, and, therefore, most of the belting and shafting in the saw-mill have disappeared.

High-grade, steel roller chain has greatly decreased the loss due to break-downs. When the crew of a saw-mill must stand idle for a few minutes, the loss to the mill owners quickly amounts to an astounding figure.

Timber-Frame Mill Buildings Offer Advantages

Saw-mill buildings are invariably of Douglas fir. One steel and concrete mill has been erected, but the superiority of Douglas fir as a building material when maximum stiffness and strength at minimum cost is required, is apparent to all saw-mill owners who have inspected this building. Buildings must be planned to conform to the proper sawing-floor requirements. Large roof trusses can easily be built from Douglas fir. Some idea of the type of timbers that can be cut from fir trees is illustrated by the huge timber at the Forestry Museum of the University of Washington. This timber is free from wane and big knots, yet it is 18 by 18 in. in section by 156½ ft. long.

In planning the sawing floor, attention must be paid to the waste conveyors, for débris must be conveyed from the mill to the burner as rapidly and efficiently as possible. The proper design of a burner that will not throw cinders is an engineering problem that has not yet been solved.

Summary

It should be emphasized that the design of saw-mills in the Douglas fir region calls for the highest kind of engineering skill. Huge power plants must be built, the mill must handle enormous logs in an efficient manner, as well as small logs, for the trees taper, and small logs from the upper part of the stem constitute a fair proportion of the daily cut. Hemlock and cedar mills differ markedly from Douglas fir mills, because in such mills shorter logs—although they may be large in diameter—must be cut.

Every log that comes into the mill is a new problem—no two are exactly alike. A new engineering problem arises every minute, and the ingenuity of the expert mill designer is often sorely taxed—yet nowhere in the world are saw-mills as relatively efficient as in the Douglas fir region.

ELECTRIFICATION OF LOGGING AND MILL EQUIPMENT

By L. D. Beach,* Esq.

The writer has endeavored to confine this paper to a brief yet comprehensive description, of the electrical installation in general and the equipment operated by The Long-Bell Lumber Company at Ryderwood, Wash. Space does not permit mention and description of a great number of details applying to both the transmission system and the various units of electric logging equipment.

The application of electricity for driving lumber mills is not new. A number of mills were wholly, or in part, electrically driven prior to the application of electric power to logging machines. Manufacturers of electrical equipment and others have quite thoroughly covered the subject on the application of electric drive in lumber mills; however, the writer believes that it would be of interest to outline briefly several important features in electric mill drives that have not heretofore been general in their application. Comparatively recent developments in the design of motors indicates that in selecting equipment for new mills, or for mills undergoing extensive changes from steam to electric drive, serious consideration should be given the motor installations.

Power Plant and Transmission Features

Power for the operations at Ryderwood comes from a power plant located on the Company's mill site at Longview, Wash. Wood refuse and hogged fuel from milling operations is used exclusively at the power plant. The present power plant has a capacity of 18 000 kw. and consists of three 6 000-kw. turbo-generators and eight sterling water-tube boilers of 1 200 h.p. each.

Current is generated at 13 200 volts and is transmitted over three-conductor underground cables to a sub-station at the mill site, approximately 1 mile from the power plant. This sub-station serves the City of Longview, Wash., and supplies energy at its southern terminus to the high-voltage transmission line to Ryderwood.

At the sub-station the current is stepped up to a transmission line pressure of 66 000 volts, through a delta-connected outdoor bank of three 2 000-kv-a., single-phase transformers, these being connected to the transmission line through an automatic, oil circuit breaker.

The total length of the transmission line from the sub-station at Longview to the sub-station in the woods (approximately 2 miles beyond Ryderwood) is 32 miles. This line is of No. 2/0, seven-strand, bare copper cable, strung on 50-ft. cedar poles, with pin insulators on the straightaway, corners and curves being made on suspension disk insulators.

* Chf. Elec. Engr., The Long-Bell Lumber Co., Longview, Wash.

The sub-station at Ryderwood is of the outdoor type and contains a bank of three delta-connected, 1 500-kv-a., single-phase transformers, which reduce the potential from 66 000 volts to 13 200 volts.

The secondary bus is arranged with five positions for the outgoing 13 200-volt feeders, each of these feeder positions being controlled by automatic oil circuit breakers of the three-tank type and the necessary disconnecting switches, choke coil, lightning arresters, etc. The feeder lines leaving the Ryderwood Sub-Station radiate through the woods to portable sub-stations, where the line potential is stepped down to the motor-operating voltage of 600. Instead of building the lines in the woods parallel to the main line and spurs of the railroad, they are on lines dividing the yarding areas. This practice of routing the overhead lines saves from 25 to 35% of that which would obtain if the overhead lines were constructed parallel to the main logging railroad and spurs.

No poles for line construction are set in the woods, at corners, and in open spaces, the lines being carried on single disk suspension insulators fastened to the trees by short lengths of steel chain or steel cable, which are fastened in turn by bolts or cable clips.

A large portion of the woods lines are temporary, and the fastening of the lines and insulators close to the tree trunk requires only the occasional use of cross-arms. When a portable sub-station is moved to a new spar-tree location, the line feeding it is extended or moved as the case requires.

There are twelve portable sub-stations, each consisting of a 600-kv-a., 3-phase, low-reactance transformer, which steps down the potential of the woods lines from 13 200 to 600 volts. These portable sub-stations are mounted on a pair of log skids, approximately 14 ft. long, with six heavy timber cross-members connecting the two skids (Fig. 28), the entire structure being held together by heavy bolts.

The upper frame of the transformer sled is composed of 6 by 6-in. timbers, this framing also carrying the necessary auxiliary apparatus, such as the circuit breaker for the incoming line, choke coils, lightning arresters, etc.

The secondary leads from each of the portable sub-station transformers run into a steel enclosing cabinet containing copper connecting bars, arranged so that one, or if required, two, of the portable three-conductor, 600-volt, wire-armored cables can be taken from each sub-station for connection with the electric logging units. The steel cabinet also contains fuses, meters, and other equipment for metering the energy consumed and switching to one, or possibly two, logging machines which it may be supplying.

In the portable sub-stations, consideration was given to the necessity of moving them each time a unit of logging equipment was moved from one spar-tree location to another. The sub-stations are moved on railroad flat-cars, the loading and unloading being accomplished by the use of a railroad steam crane. Their construction is, therefore, unusually rugged so as to withstand rough handling.

The cable which connects the logging machines electrically to the portable sub-stations consists of three rubber-covered conductors, each of 300 000 cir.

FIG. 28.—SKID-MOUNTED, 600 KV-A., PORTABLE TRANSFORMER SUB-STATION.

FIG. 29.—COMBINATION YARDER AND LOADER.

mils, laid with tarred jute fillers, and wrapped with four layers of varnished cambric tape and one layer of half-lapped rubber-filled tape. The whole is enclosed in a galvanized steel wire armor wound with a 5-in. pitch. The short pitch in the armor winding and the fact that the cable is devoid of a lead sheath, make it very flexible and easy to handle as compared with standard cable.

In service, the cables are laid on the ground frequently through pools of water, and they are called on to withstand the rough treatment characteristic of such locations and service. The cables are made up in lengths of 500 and 250 ft. each. It is intended that the maximum transmission distance between the portable transformer sub-station and the logging machine should be 1 000 ft. However, the average distance does not exceed 500 ft.

In the woods, no provision is made for handling or moving the cable on reels. When a cable is to be moved from one location to another, it is lifted on to flat cars and laid in long loops.

Electrical Logging Equipment

At present (1926), the electric logging equipment operated at Ryderwood consists of ten units, comprising six car-mounted combination yarders and loaders one of which is shown in Fig. 29, two car-mounted interlocking skidders and loaders as shown on Fig. 30, and two single yarders mounted on sleds. This equipment was manufactured and furnished equally by the Washington Iron Works, Seattle, Wash., and the Willamette Iron and Steel Works, Portland, Ore., each of these companies supplying three combination yarders and loaders, one combination skidder and loader, and one single sled-mounted yarder. The essential difference between the two makes of machines is that the Willamette units use gearing which is controlled and shifted by compressed air to obtain high and low speeds on the main yarding line, whereas the Washington Iron Works units use a single two-speed motor to obtain the desired yard-line speeds. Fig. 31 shows a combination skidder and loader, and the spar-tree rigging.

The three Willamette yarders which are in combination with loaders and car-mounted, and one yarder which is sled-mounted, are equipped with 300-h.p., 550-volt, 450 rev. per min., variable speed type motors. The average speeds of the main yarding line are 775 ft. per min. in high and 375 ft. per min. in low gear. The average speeds of the haulback are 1 900 ft. per min. in high and 900 ft. per min. in low gear.

To eliminate mechanical shock in changing gears while under load, the gear change mechanism is such that the high-speed engagement slightly anticipates the low-speed release, the high-speed friction band dragging on its drum for a fraction of a second before the low-speed band releases. The result is an over-lapping of the two speeds which affectually prevents any surge on the yarding line during the gear (and consequent speed) change.

The Willamette loaders are equipped with 200-h.p., 550-volt, 600 rev. per min., variable speed hoisting motors and 35-h.p., 600 rev. per min., variable speed boom-swinging motors. The hoisting lines travel at an average rate of 675 ft. per min., and the boom-swinging lines at a speed of 390 ft. per min.

The Willamette interlocking skidder has a 450-h.p., 600 rev. per min., variable speed motor which operates the main line at an average speed of 750 ft. per min. in high gear and 360 ft. per min. in low. The haulback line travels at an average of 2 100 ft. per min. in high speed, and 960 ft. in low.

The three combination yarders and loaders are mounted on cars 46 ft. 9 in. long equipped with two four-wheel trucks. The weight of each of these units, devoid of any cable, is approximately 175 000 lb. The interlocking skidder and loader is mounted on a 60-ft. car with truck equipment similar to the others. The weight of this unit, without any cable, is 247 000 lb. All car-mounted units are equipped with hydraulic jacks to raise the car body, thereby relieving the truck springs of weight. Compressed air at 100 lb. pressure is used for the operation of the frictions and signals.

The Washington Iron Works yarder and skidder motors are of the two-speed type, each developing 300 h.p., and 200 h.p., respectively, on low and high speeds. The speed change is accomplished electrically by re-grouping the stator winding of the motor to obtain either 24 or 12 poles; the loader motors are 250-h.p., variable speed type and the boom-swinging motors are 50-h.p. of the same type.

In addition to the essential difference in effecting speed changes on the main lines, a further difference between the two makes of machines obtains in the motor controls. The Washington Iron Works units are supplied with electro-pneumatic operated equipment for control of the motors. The contractors are, therefore, directly operated by compressed air, instead of magnetic control. The pilot valves controlling the air cylinder are, in turn, operated by a direct-current control circuit, energy for which is furnished by a single, 1-kw., 35-volt, motor-generator set. As these units require compressed air for the operation of frictions, signals, and also control equipment, each is equipped with two 52-cu. ft. per min., Westinghouse air-cooled compressors.

The electrically operated logging machines described in the foregoing do not comprise the greatest number of units for the ultimate woods operations. The transmission lines, sub-stations, and equipment are of a design and size to supply power to at least ten additional units, each of a size not less than those now in operation.

The equipment at Ryderwood is to date the largest single installation in existence—the present and ultimate requirements were known well in advance, and the entire project was planned and built accordingly. In no instance has there developed a failure of the electric distribution system or any of the machine units to perform the maximum duty expected. In fact, every phase of the logging development has more than fully met the expectations of its designers and the company operating it. The total number of motors involved is 42, and the total aggregate horse-power, 5 750.

Table 1 shows the consumption of electricity, at point of use, for all the equipment operated at Ryderwood, with the output, in log-feet, for a 9-month period. Table 2 covers the performance data applying to each machine unit. The electric energy consumed by each unit is also included. These data cover

FIG. 30.—COMBINATION SKIDDER AND LOADER.

FIG. 31.—COMBINATION SKIDDER AND LOADER, SHOWING SPAR-TREE RIGGING.

two periods of operation, one of nine months from April to December, inclusive, 1925; and one period of five months from January to May, inclusive, 1926.

TABLE 1.

Month, 1925.	Equipment Consisting of Six Combination Yarders and Loaders. Two Interlocking Skidders Equipped with Loaders, and Two Sled-Mounted Yarders Which Always Work in Conjunction with Either a Combination Yarder and Loader, or an Interlocking Skidder Equipped with Loader.		
	Kilowatt-hours.	Net commercial scale, in log-feet.	Average log-foot per kilowatt-hour.
April	122 300	14 141 514	115.6
May	150 700	17 549 712	116.4
June	163 100	20 827 225	136.0
July	138 600	19 128 742	138·0
August	179 500	22 609 813	125.9
September	181 300	22 416 499	123.6
October	178 600	23 952 439	134.1
November	167 900	21 414 356	127.5
December	128 000	16 877 645	131.8
Total	1 400 000	178 917 945	127.9

Summary:	Electric Energy.
Total kilowatt-hours	1 400 000
Total log-feet (commercial scale)	178 917 945
General average, 9-month period	7.8 kw-hr. per 1 000 log-ft.

The net electric energy consumption of 7.8 kw-hr. per 1 000 log-ft. is based on actual meter readings, these meters being installed on the secondary side of each 600-kv-a., 600-volt logging transformer.

The total gross electric energy consumption as measured by the meter in the power plant includes transmission line losses, transformer losses at each end of the transmission line, also losses which obtain in the 13 200-volt woods branch lines and the 600-kv-a. woods logging transformers. These losses, it is conservatively estimated, are such that the gross consumption (as measured by the meter in the power plant) is 9.15 kw-hr. per 1 000 log-ft.

Motors and Control Equipment for Saw-Mills

It is to be noted by those familiar with the details in design of saw-mill equipment, that without exception, both electric and steam-driven mills include in their equipment a number of one-way rotation, also reversing power transmitting, devices commonly referred to as "spur friction drives", a number of which are used in the drive to live rolls.

These transmissions are inefficient, their performance is not positive, and their operation is expensive for maintenance and renewals. It is possibly the belief of some mill engineers and operators that such drives are essential, therefore a necessary evil. However, certain types of electric motors are available which, with their proper application, together with suitable reduc-

tion gears, would successfully replace any drive heretofore transmitted by one of the spur-friction type.

These motors with push-button operated, one-way rotation, or reversing, control equipment, as the case may require, together with suitable reduction gears, are capable of performing fully as many starts, stops, and reversals per minute as have ever been required through the medium of spur-friction drives. It is, therefore, possible, and in every respect practical, to equip an electrically driven mill eliminating all such drives.

TABLE 2.

NINE-MONTH PERIOD, APRIL TO DECEMBER, INCLUSIVE, 1925.

Machine.	Total log-feet for each machine.	Average hourly operation (log-feet per hour.)	Maximum recorded daily output of 8 hours, per single unit, in log-feet.
A	13 116 810	11 278	153 106
B	21 122 468	14 796	243 418
C	21 042 311	13 739	259 486
D	22 060 574	14 667	259 365
E	25 245 879	16 713	267 611
F	24 506 732	16 497	*344 945
G	27 235 955	19 384	271 008
H	24 587 216	16 085	240 250
Total	178 917 945	.....	.....

General Average (per Single Unit):
(Based on total output and total net hours in service), 9-month period, in log-feet per hour.....15 381

FIVE-MONTH PERIOD, JANUARY TO MAY, INCLUSIVE, 1926.

Machine.	Number of logs.	Log-feet. (commercial scale).
A	8 809	9 804 835
B	13 080	12 428 282
C	13 456	10 787 578
D	12 284	10 490 658
E	9 895	15 755 568
F	9 984	15 236 927
G	12 098	18 097 727
H	6 797	9 701 341
Total	86 353	102 302 916

* Machine F, 344 945 log-ft. maximum for year 1925. This machine logged 443 552 log-ft., or 36 cars on March 31, 1926, which constitutes an average date, and is the highest output for one day attained by a single unit.

In the design of electrically driven mills, regardless of their size, the engineer in selecting induction motors for driving various units of equipment, has always been confronted with the problem of providing motors of adequate size to meet any reasonable operating condition.

Furthermore, occasional operating conditions would arise in which the maximum load on the motor would be in excess of what it could be expected

to perform for any great length of time, and this resulted in decreased production.

If the engineer provided motors of adequate size to insure meeting occasional maximum loads, the result was that the motor operated underloaded about 85% of the time, this underloading being conducive to a low power factor.

Electrical manufacturers have made great improvements in synchronous motors and control equipment and their cost has been materially reduced. Both have been simplified and there is now available push-button operated control for them. They therefore do not require skilled attendance for their operation, and might be classified as general purpose synchronous motors, inasmuch as their starting torque is fully as great as that of the squirrel-cage motor, their starting current corresponding to full load starting torque does not exceed 450% rated full load current, and their pull out, or maximum running torque, under normal voltage and frequency, is not less than 175% of the rated full load torque.

In the design of new mills, or in making extensive alterations in existing mills, consideration should be given to the application of synchronous motors for driving fans, compressors, positive pressure blowers, trimmers, slashers, and, under certain conditions, edgers. The correct application and use of such motors would permit, where required, and remedy the evil attendant on, the use of induction motors of comparatively large size to meet maximum load conditions. The results would be higher efficiency and increased production.

ECONOMIC ASPECTS OF REFORESTATION

E. T. Allen,* Esq.

The viewpoint of the lumberman, the forester, and the public on reforestation differs widely, or reforestation problems would be nearer solution.

In addition to being as interested as any citizens in the general welfare, lumbermen want to perpetuate their industry and land values. Probably they are no more nor less individually selfish. Their first concern is to stay solvent, furnishing every one lumber at a price that all can afford to pay. They have no inclination or ability to grow future forests at a loss for a public apparently unwilling to share the cost or even to provide encouraging fire and tax conditions. Experience makes them skeptical of public co-operation; tradition confined to conversion and marketing, not production, gives them no independent assurance. The broad advice they receive from foresters is so consistently optimistic that they doubt its reliability, knowing that no business enterprise is automatically secure under the conditions involved. They find it equally inconsistent in matters of important detail for, on these, foresters disagree notoriously; but as never before, lumbermen now face the last virgin supply, consequently the reforestation problem also, and they know it. They are endeavoring to solve it as a business problem. To them its economic aspects mean success or failure.

The typical viewpoint of the forester, with exceptions, is that of a professional man exalted almost into a creed by traditions of his teaching. He feels ethically constrained to seek the ideal in forest-growing, as an engineer wants to achieve it in his designing, and mostly he believes this an end in itself, bound somehow to be justifiable. Forest land not doing its best, like avoidable timber shortage, seems to him an economic crime that must be unprofitable for any one concerned. He would compel the owner to save himself such economic loss, even if he does not go so far, as many do, as to advocate the regulation of lumbering by police power in order to save the community from it. His creed is production to the capacity of the land. Seldom does this creed consider profit and loss, or who shall pay the bills, as other than secondary details that will straighten out somehow through some economic justice that he takes on faith and does not feel it his responsibility to guarantee. He sees the same obstacles the lumberman sees, and often advocates the same public remedies, but they do not assume to him the same economic aspect. He is neither the short-sighted lumberman nor the short-sighted public. He owns no lands, pays no costs, takes no risks, buys or sells no lumber. He is too often a doctor prescribing something analogous to the long rest or the trip to Europe. If the patient cannot take it, the doctor's economic aspect remains the same as ever.

* Forester in Chg., Western Forestry and Conservation Assoc., Portland, Ore.

Viewpoints Must Be Compromised

The essential differences between these viewpoints, creating misunderstandings and mutual suspicion, have done much to retard forestry in America. Perhaps each side has been equally narrow in the past. At present, when lumbermen as a class are at least interested, seeking to learn how far they can go, and how, many actually trying, the writer thinks they are showing more progressiveness of thought than the foresters as a class, who incline more to stand uncompromisingly on the ground they first occupied. When the lumberman can be induced to go as far as he sees the way clear, the forester's duty is to get out of the cloudland of an ideal future and down to the ground of to-day, so they may begin together with combined and common vision, together taking step by step forward to make forestry a self-sustaining but intelligent business that can be conducted, as well as dreamed of, for the public good.

Therefore, in this paper, to be read by professional men, and aware that it may make him an apostate in the eyes of many fellow foresters, the writer is going to express for the first time publicly a conviction that has been growing during his twenty-seven years in the work and is now positive as a result of analyzing the present situation. That is, that very great harm is done by this tradition that forestry is necessarily a profession with professional creeds and ideals never to be compromised.

Medicine quite clearly is, probably law. Engineering may be, although perhaps it sometimes involves the point the writer wishes to make. However, whether or not forestry is a profession, forestry itself as private enterprise—commercially growing and using trees anywhere but in words, or publicly subsidized forests—is a business. It is intelligent lumbering or else lumbering is practical forestry. It is not advising, but doing; with all responsibility for using the best judgment at command under existing conditions and exigencies; always a compromise, always shifting, always seeking to learn and to improve conditions, but not ignoring those confronted. Ideals and ethics, yes; but those of business may be, and usually are, as high and prideworthy as those of a profession. The real measure of each is actual resultant good.

When foresters see this, and become as proud of making the business of forestry both honorable and successful as they are of making the profession of forestry honorable if unsuccessful, and when enough lumbermen see they mean it, the three viewpoints will be reduced to two—their own and that of the public.

Public Often Inconsistent

The viewpoint of the public is simple; it merely wants the primeval forest undisturbed for sentimental reasons, considers the destroyer of a tree a social criminal, and at the same time wants lumber produced by wasteful methods if these make it cheaper. If production is so cheap that the producer goes broke, this is assumed to be a public gain. It wants reforestation, and, also, to set 60 000 fires a year to destroy it, and if this fails, to tax the

crop so it cannot be held to maturity, thus ignoring not only the immorality of demanding such contribution to government while confiscating the only chance of reimbursement—crop profit—but also its evident futility. It believes in State and National forestry, but not in appropriations to conduct it. Of nearly 470 000 acres of true forest land in the United States, one-fifth is publicly owned. This belongs to the public to do with as it pleases. One-third is owned by farmers. They have a hard time anyway, so the public will not bother them. This leaves 47% owned by lumbermen, who are assumed to be more unreasonable than the others. Something ought to be done about this! There really ought to be a law compelling them to grow all the trees needed! If they owned the mines, too, they might be made to produce enough gold to make all rich. This is not a fanciful statement of composite public viewpoint, but the writer is unable to picture any economic aspect it surveys with consistency.

The economic aspect of reforestation to those who have the job to do is largely determined by the prospect of reconciling all these views. In most cases starting the crop is simple. It is doing very well starting itself. On the Pacific Coast, where natural restocking is usually swift and certain if given any chance, this is the least of the problems, certainly not the one that deters lumbermen. A large proportion of their cut-over land bears varying aged second-growth timber and little that shows no recovery needs much artificial help except better fire prevention. The problem is mainly of carrying the land, tax, and protection investment for the long term involved, with the risk of destruction before harvest. Bear in mind that private reforestation requires not only reasonable assurance that these obstacles can be overcome, but also that there will be the continuing revenue with which to do it. Since the promise to unrelated capital seeking investment is small, this means a going, profitable lumber operation for the period. In New England, successive crops since original exploitation meet this need for many companies, especially paper companies. On the Pacific Coast the reserves of uncut timber may meet the needs for many companies, but by no means for all. The problem is regionally hardest in the Central States, with little virgin timber or re-established forest. In any region, however, the owner without supply to bridge the gap until he can cut again, can seldom see his way through.

It further becomes an individual problem through the different financing methods of companies; the demands of their stockholders for early or late liquidation or for dividends re-investable in better paying lines, their plant construction, or other ability to use or sell the different products of the new crop; their transportation problems; the size and location of their holdings; the policy of their neighbors; and other things. Again, there is the fundamental question of land quality for growing new crops, or its accidental condition through fire or past error; with other factors bearing on competition with other owners or other regions, or perhaps with Government or State forest competing without interest, taxes, or even the necessity of meeting costs.

Lumbermen Are Attacking Problems

Very conspicuously, long-life operators in the two great producing regions of the country—the South and the Pacific Coast—are passing out of the indifferent drifting stage that always belongs with early exploitation and are setting themselves to the solving of these problems. That it is a joint private and public responsibility has also been expressed as National policy by the Clarke-McNary Law for the building up of Federal, State, and private cooperation to deal with fire first, so other steps may be warranted, and then with taxation, at the same time creating incident spirit and machinery for solving other problems in the same joint way. This law also recognizes, as National forest policy, that the most urgent need is not to govern the cutting of forests still uncut, affecting a comparatively small area in the near future and certain to improve in method, but to foster and protect reforestation on the vast already cut areas, on which the public will first depend, which object is exactly the one that is becoming of keen business interest to the accumulator of cut-over land.

On the Pacific Coast there are more than 9 000 000 acres of privately owned cut-over and burned forest land, the majority in some stage of natural restocking. Its area is increasing rapidly. A large proportion is capable, with small effort except protection, of producing another crop in 40 to 60 years. Some areas are well along with this crop. The question with the owner is not whether he shall engage in reforestation. He is engaged in it. He has the land and cannot dispose of it. In all Pacific Coast States except Montana there are compulsory patrol laws requiring him to protect it. Fire prevention has reached its highest development here. The organizations the writer represents spend from $1 000 000 to $2 000 000 per year on it. Therefore, the owner has the land, a crop started, or fairly assured in most cases, a heavy fire bill, and a heavy increasing tax burden. Without much forethought he has been caught in the current and is swimming. He is now calculating how long he can last. Although this is a fair way of describing an industrial situation, no two individuals have the same problem. They vary tremendously as to their own strength, the strength of the current against them, and the distance from shore. Reforestation is no more an abstract calculation than farming, fishing, or horse-racing.

About thirty large companies on the Pacific Coast have gone into the question, perhaps ten of them being committed to continuous production on their lands, and the remainder still investigating. The Research Department of the Western Forestry and Conservation Association has eighteen such clients to date, including some of the largest owners. Great variation is found in economic possibilities, even on similar cost and return estimates, due to differing productivity and condition of lands. Roughly, it sums up that well-along second-growth, if it survives, seems able to stand quite heavy charges because the carry is short; but that much land now being cut, or recently burned, so that it must be carried fifty years or more, will not pay fire and tax charges as now seen. In either case, there is the risk of still

higher taxation and of fire destruction, and some companies have not the operating life to bridge the gap until another harvest.

On the other hand, there is a different way of looking at it; not the traditional forester's way, nor yet the traditional lumberman's way, but a straight business way. Modern business tries to reduce loss and waste to the minimum. Although it is often difficult to show probable profit in private reforestation as an enterprise, it is equally often easy to show certain loss without reforestation as a part of operation. In other words, if there is to be a loss in this land, it pays to reduce it. If as a by-product it has no value to be redeemed for the stockholders, except its forest-producing value, it cannot possibly be left around outdoors, a charge and a fire hazard; without any policy of management, use, or disposal; without gathering needless costs and bringing needless losses. If charges against it are inevitable, they should not be increased but the redeeming earnings should.

Responsibility Must Be Shared

This is exactly where the lumberman is arriving, by combining technical forestry appraisal of possibilities with his own technical operating administration, to make reforestation a business equation. No one knows the ultimate distribution of forest-land ownership. The industry will hold more than it now thinks, but history shows it rarely keeps one-half in any country, the less profitable majority being feasibly carried only by the public. Therefore, it will be here, the ownership and responsibility shifting for many years, under economic pressures, toward a distribution based on what the industry can hold profitably with the remainder going to State and Government either in good condition through purchase or in bad condition through enforced neglect and abandonment. The public burden of the poorest land will increase with the difficulties it imposes on private enterprise and *vice versa*.

However, whether retention or disposal is the ultimate course of any lumberman with all or part of his land, it is obviously his gain to sustain values realizable either by use or by disposal, in order to repay costs meanwhile, to the extent this can be done without too great further expense. This is becoming the policy of the progressive lumberman of the Pacific Coast. He does not know yet to what extent it may be frustrated by the public through fire, taxation, and other lack of reciprocity. He does not know whether the harvest will pay; or whether he, another, or the public will reap it. Meanwhile, however, if possible, it must be better to preserve than to destroy the productivity that is the only, if an uncertain, asset. Toward this end he is studying harder, working harder, spending more money, than any of the other eventual beneficiaries. He is succeeding very well as it is. A little more reciprocity and it will be a go.

REFORESTATION

J. B. Woods,* Esq.

During the past ten years (1916-26), many American lumber manufacturers have investigated the possibility of practising forestry and year after year increasing numbers of progressive operators are taking up these various activities, termed reforestation.

All are agreed that the future welfare of the country demands the working out of some general forest policy whereby private owners and the public may find profit in the perpetuation of productive forests on forest lands. This problem is one of land use—the production of timber trees on lands best suited to such growth.

In the final working out of permanent forestry it may be expected that timber will be produced near the various centers of consumption so that long freight hauls may be reduced to a few miles instead of thousands of miles. It is expected also that the present large areas of stump land will be restored to the beauty and productivity of the early days before the saw and axe.

Leaving aside the esthetic considerations—and they are worthy of serious thought—the commercial and industrial future of this country demands a rapid development of forestry practice. It is also fair to state that social solidity rests on a foundation of accessible and relatively cheap building materials. In other words, plentiful forest materials are essential to the small structure which shelters the typical American family or business. To maintain the supply of cheap but good building materials the forests must be perpetuated by wise use.

Problems and Hazards of Forestry

There are problems, however, before the lumberman who would practise forestry. Taxation is a serious and well-nigh universal problem. The revenue requirements of States and counties are increasing with correspondingly heavier levies year by year on cut-over lands as well as timber and physical properties. Heavy property taxes on standing timber have been instrumental in forcing a rapid depletion of the forests. Similarly, in some sections, excessive taxation of denuded lands has caused many owners to allow them to revert to the State. If forestry is to be undertaken by private capital, taxes must be kept at reasonable levels, and private owners must be able to budget this yearly item of capital expenditure over long periods. To-day, in most States, the tax laws do not recognize that timber is a crop; land taxes are excessive, and there is no way of forecasting the future tax outlay over a period of years to come. Whether timber is in the South or in the Pacific Northwest its worst enemy is fire, and the great American public is chiefly responsible for the increasing yearly toll of loss by forest fires. In the Southern States fire which runs over the ground does not kill the large pines,

* Forester, Long-Bell Lumber Co., Longview, Wash.

as a rule, but it does kill the millions of seedlings which Nature plants to replenish the forest, and repeated fires impoverish the soil so that scarcely anything will grow. In the Western pine country the effect of fire is similar to that in the South, whereas in the regions where Douglas fir predominates there is danger of crown fires which may destroy virgin timber. Fortunately, the hazard in the Northwest is restricted to the summer months.

Throughout this country the public is foolishly complacent regarding forest fires. Year by year the State and Federal forestry agencies, groups of timber owners, and individuals spend money in protective work and strive to awaken the public to a fire-consciousness, but progress is disappointing, the fire damage increases, and the land owner who would grow a new forest must face the necessity of providing fire protection over a long period of years, largely through his own efforts and with his own money.

Investigation discloses other enemies of growing forests. Hogs at large, insects, fungus diseases, windstorms, floods, and droughts are a few of these. Even coon hunters and timber thieves must be reckoned with and guarded against by efficient patrol for second growth stands containing a sprinkling of timber large enough to make into ties and round products.

One of the mainstays of forest management in Europe is selective logging, whereby tree cutting is carried on according to a pre-determined plan and results in the removal of only the largest trees leaving the smaller ones to grow; or it may be applied to improve the stand by taking poorer trees; and, of course, there are combinations of these selections.

For several years American foresters have endeavored to convince lumbermen that they should adopt selective logging methods, at least to the extent of cutting only the larger trees and leaving the smaller ones to grow. There are serious operating objections to selective logging in Southern timber and on the West Coast, and, unfortunately, neither foresters nor lumbermen in America have developed facts showing the relative advantages and disadvantages. Similarly, reliable and specific information is lacking about many other phases of forest management. For example, there are insufficient tree growth data in many localities of the South and West, and little is known of the economics of thinning young stands of sapling poles.

Virgin Timber Is Merchandising Standard

One very important fact often has been overlooked by those who urge the lumber industry to practice forestry. In the fiercely competitive business of manufacturing forest products, high quality timber is essential. In the past the buying public has demanded the best lumber obtainable, even if cheaper material might have been more suitable for certain purposes, and so long as high grade timber is available the lumberman must meet competition based on the manufacture of such timber. There are purposes for which second-growth timber and even thinnings from young stands are suitable. These uses will increase, but here, again, competition enters—the damaging competition of careless and often irresponsible marginal operators who are in business to-day and gone to-morrow. The established lumber manufacturer

may place some material of this quality which he may develop, in markets where its use will be most satisfactory, but as a rule he must hold and protect this second growth until it reaches commercial maturity.

Meanwhile, in order to maintain the standards of his forest products, the lumberman must secure reserves of high-grade virgin timber to last as long as the supplies of his competitors. He can begin now to prepare for a future wherein man-grown trees will replace virgin forests by applying forestry principles to certain phases of his operation, but he knows that virgin timber will dominate the lumber markets of America for many years to come. It is evident that the application of forestry science to the business of manufacturing lumber is complicated by many economic considerations.

However, progress is being made and certain activities now being carried on by the writer's company will indicate what can be done. Taxation is a serious and almost universal problem. On the Pacific Coast some progress has been made in formulating legislation to encourage timber growing by lightening taxes. A proposed amendment to the Constitution of the State of Washington, if ratified by public vote, will form a basis on which to frame constructive tax legislation for the future.* Meanwhile, a program of reforestation has been formulated at Longview and Ryderwood, based on the proposition that the voters will give constructive tax legislation which will permit the growing of trees over a long period of years.

Longview Reforestation Plan

The underlying idea of this plan is to re-seed the cut-over land at a rate equal to the progress of denudation. This probably will range from 2 000 to 3 000 acres per year. If one could be sure that Nature would re-seed the cut-over lands, it would be very simple for the forester. He would merely protect the lands from fire and wait for the trees to start, but natural restocking is a tedious process often occupying several years. As interest on land investments, taxes, and other carrying charges must be taken into account, it is evident that the forester must take steps to get his new forests started if he expects the trees to reach merchantable age and return any income to the owner. Compound interest is his enemy.

The idea at Ryderwood is to wait two years for Nature to begin her own process of re-seeding, then it will be possible to tell where natural seeding can be expected to develop favorably. Where Nature does not appear to be able to start anything, nursery grown stock will be planted. An area cut over in the winter of 1926 would be planted in the early spring of 1928 after having been slash-burned either in the spring or fall. A word should be said about slash-burning. There is a statute of the State of Washington requiring owners or operators of logging enterprises to abate the nuisances left by them in the form of logging débris. The law does not stipulate that this shall be burned, but there is no other way that it can be removed and abated to-day at reasonable cost; therefore, it is necessary to burn all cut-over lands after

* This proposed amendment was defeated at the general election in November, 1926, see p. 538.

logging and before reforestation can proceed. The question of advisability of such burning may be open to argument but slash-burning is carried on regularly and with all possible precautions to prevent undue damage, outside the slash-covered area.

It is sincerely hoped that the next few years will bring about developments in wood utilization which will make possible the abatement of slashing nuisances through pulping or wood distillation and without the use of fire on the land.

Forest Nursery Maintained.—Although it is hoped that natural seeding will account for two-thirds of the cut-over area, nursery facilities are provided for growing enough plants to re-stock two-thirds each year. The nursery maintained at Ryderwood has a capacity for the continuous production of 2 000 000 seedlings per year. A tentative growth period for this new forest has been set at 50 years. On soil such as this forest will occupy, it is expected the growth in 50 years will amount to 20 000 b. m. per acre on the poorest sites and probably 40 000 b. m. per acre on the best. Probably after 25 years it will be desirable to enter these stands and remove enough poles and small trees to thin and improve the growing conditions. One of the many places that engineers can help conserve timber and encourage reforestation is in the adoption of creosoted or treated-wood products specifications of "construction materials". In the South where the writer's company maintains several creosoting plants it is possible to thin growing stands of pine at profit because this raw material is made into fence posts, telephone and telegraph poles, piling, and ties and the Company is willing to pay a satisfactory stumpage rate for it. By treating such materials the period of useful life is extended five to tenfold. Twenty years ago such a development was rarely found in the Southern States. Therefore, it is likely that the next twenty years will witness a growth of the wood-treatment business in the West and that when stands of growing Douglas fir are thinned a market will be found for these products in the construction field.

Improvement of Species.—While working out the program of starting new forests for Longview, it is felt that every reasonable effort should be made to improve the quality and variety of materials for the future cut; therefore, experiments with redwood, white pine, and Port Orford cedar are being made to supplement Douglas fir. Douglas fir is the most valuable wood for all-around use, but there are sites on which other species will do better than the fir and on these it is expected to grow redwood and Port Orford cedar and possibly some white pine. If this plan can be carried out, a balanced future forest will be obtained with Douglas fir as the principal species and certain other well-known trees for special purpose woods.

In addition to these species, it is expected that the new forest will contain large quantities of hardwood, chiefly alder, which attains large size on the Coast. Alder seedlings are planted along abandoned rail spurs to form fire screens for the protection of the stands of young conifers. The plantations are thus subdivided into compartments and the fire hazard is correspondingly diminished.

Naturally, fire protection is the prime requisite of reforestation. In addition to timberland patrol with its 100 miles of trail and telephone line, its lookout and patrol stations scattered throughout the woods, there is the camp patrol maintained by the Logging Department, and a special patrol for the new plantations of Douglas fir, redwood, and Port Orford cedar. All this is at the Ryderwood operation. In other parts of the country the writer's company maintains eleven more fire-protective organizations watching virgin timber reserves, logging operations, and young forests.

Other Forestry Activities

Forestry activities are not confined to the State of Washington. In Southern Oregon about $200 000 has been expended by a group of private owners in co-operation with Governmental authorities to arrest and control the ravages of certain pine-tree killing beetles. Despite disappointments as a result of repeated years of adverse climatic conditions which have favored the beetles by retarding tree growth, progress is being made.

In Arkansas, Louisiana, and Texas, the Company has set aside more than 200 000 acres of forest reserves where young timber is growing under the best care and fire protection that can be given. In Western Louisiana another forest nursery has been started to provide planting stock for a large program of re-stocking cut-over lands with longleaf and slash pine. It is hoped that in time the Company shall have there a naval stores enterprise similar to the hand-grown forests of Southern France, and, meanwhile the production of posts, poles, and ties will be continued for the treating plants.

Experiments in selective logging are under way in California. This involves replacement of steam skidding equipment with caterpillar tractors and two-wheeled carts, in order to save the young timber and the seedlings, but to be worth while such experiments must be made on a large scale and over a considerable period.

In common with other large operators the Long-Bell Company is attacking these reforestation problems aggressively, but with caution. Lumbermen must have help to work out such solutions as will benefit the public as well as themselves; they must have constructive tax legislation in all timber-producing regions and the helpful fire consciousness of an awakened public; and they must have a better realization of the merits of wood as a material for construction and for fabrication into other products, and through this channel a larger measure of wood utilization and less waste. The manufacturer of forest products who cannot do business profitably and who must leave much of his raw materials to rot on the ground for lack of a market will be too deeply harassed by present difficulties to devote much time to thinking about growing trees for future generations.

DISCUSSION

ROLAND H. STOCK,* M. AM. SOC. C. E.—The great variety of physical conditions and of timber in the Northwest make logging operations considerably different from those elsewhere, so that the work of the engineer is extremely varied. In the old days most of the logging was done at tide-water and along the banks of navigable streams. The equipment was simple and the engineering was even simpler. About the only engineering structures built were log dams from 10 to 50 ft. in height, used to store water which, when released, assisted in floating logs to market. Now, the timber stands are away from streams mostly in the extremely rugged territory of the Cascades and Olympics, so that the larger operators have come to see the necessity of more thorough engineering advice.

Formerly, in starting a new district, it was customary to locate railroads on a 5% grade, to keep the curvature as low as possible, and to proceed as far as convenient. Even a few years ago, the logging superintendent would decide where the line was to go, and then hire a surveyor to help lay out the location. Soon they would be halted by a box canyon and have to start a switchback. In one instance when they got to the top of the divide, they found they were too high, so they had to put in a grade adverse to the loads. Latterly, the advice of competent engineers has demonstrated the possibility of attacking this particular problem in an entirely different way, which would have saved its cost in construction on the first mile of road. Furthermore, the correct location would have made available 200 000 000 ft. of timber that cannot be reached with the present location.

Progress, particularly in the line of new machinery, has reached a point where radical improvement is not likely. The field of the engineer lies more in the economical use of that machinery in connection with logging railroads. To the best of the speaker's knowledge little progress has been made to this end. As an illustration of the economies possible, one logging engineer was able to raise the efficiency from 1 200 to 1 800 ft. per man per day. This, however, required six months' work on the management before he could convince it of the feasibility of the plan.

The first requisite in the development of a tract is a complete and reasonably accurate estimate of the timber on the area, both as to types and amounts. Then comes a proper topographical survey, reasonably accurate, depending on the roughness of the topography.

In some of the rough Northwest country there is a field for the air map showing a mosaic of a tract. Since logging is conducted largely by non-technical men, a relief map of the entire tract also has a distinct value in evolving a plan of logging, as it gives a visual representation of the tract itself to a numerical scale.

Flumes are valuable for transportation in the so-called "short-log" country east of the Cascades, but have no value in the "big-log" country. However, as more second growth is logged this method may become of value.

* Cons. Civ. and Hydr. Engr., Aberdeen, Wash.

The speaker agrees with Mr. Donovan that reforestation is largely a matter of controlling fires. At least 75% of the logged-off lands will reforest themselves if given a chance. The first growth is generally hemlock, and, later, fir. With the heavy rainfall, the moderate climate, and a topography unfit for agriculture, the Pacific Northwest should always be the lumber center of the United States.

HUGO WINKENWERDER,* ESQ.—The papers comprising this Symposium are splendid. The various subjects discussed are, however, so specialized that it would be impossible for any one person to discuss all of them intelligently. The speaker, therefore, will confine his remarks to the papers of Mr. Allen and Mr. Woods.

These papers give much food for thought. It is true, as Mr. Allen stated, that people generally are not familiar with what is going on along the lines of reforestation. It is of course to be expected that the persons engaged in the lumber industry, the professional foresters, and the public, will view this problem from different angles. There is, however, a growing tendency for these groups to understand the other's viewpoint, and they are well on the road toward a common understanding. The more progressive lumbermen have come a long way toward the forester's viewpoint on reforestation as a business. While it was difficult for the forester to give up what he considered his idea and "come down to earth", every forester recognizes that the first principle of his profession is that forestry is a business. It is true that many foresters have been more or less in the clouds, but it must be recognized that they, too, have come a long way toward understanding the more practical business viewpoint of the lumbermen.

With reference to the general public, sentiment toward the practice of forestry was never better than at present. This is evidenced by the provisions of the Clark-McNary Act, by the interest displayed by the public in forest fire prevention, and by the reforestation legislation passed in recent years by the various States. These various groups, therefore, are fast approaching a common ground. The difficulty in the way of more thorough co-operation in the past has been a lack of understanding of each other's problems. What the public needs is a little more good sound business education on this problem—something to show how vital the problem is to the public generally, for it is certainly as vital to them as it is to the forester and the lumberman. Just a little better understanding by each group of the other one's special problems should result in the best spirit of co-operation.

Mr. Woods has shown, in his paper, the rapid strides being made by the Long-Bell Company in the extension of its policy of reforestation. This is most illuminating, particularly at a time when so few lumbermen on the Pacific Coast have taken any definite steps toward putting their logged-off lands under permanent forest production.

He referred to the problem of forest taxation. The present system of taxing growing forests amounts to practically the same thing as taxing the farmer on his wheat crop once a month, or even every week, until it is har-

* Dean, Coll. of Forestry, Univ. of Washington, Seattle, Wash.

vested. The young growing crop of timber is not taxed according to its present worth. The general property tax, as applied to growing forests, is fundamentally wrong in principle, and it is this system of forest taxation that is doing more to hinder the owners of timberland from adopting a policy of continuous forest production than anything else. The Federal Government is now making a special study of this problem. Certain States have enacted rather satisfactory laws based on the principle of the yield tax, outstanding examples being the States of Michigan and Louisiana. Many other States are studying the problem, and in the State of Washington considerable progress is being made.

In Washington the problem is one of extreme importance. Timber has, from the beginning, been the most important natural resource. The early industrial development of the State has hinged more largely on its magnificent virgin forests than on all other resources combined. People were attracted in the early days because the forests offered most excellent opportunities for labor, for the investment of capital, and for the development of industry. Even to this day, 65% of the industrial payroll of the State comes from the lumber industry. It is often argued that even if the timber in time will be exhausted other industries are taking the place of the lumber industry so rapidly that its failure will not materially affect industry. Even such an industry as transportation is largely dependent, in the State of Washington, on forest products; 65% of the freight shipped out of the State, over the four large transcontinental railroads, and 80% of the boat tonnage of Puget Sound are composed of forest products. This is only one illustration of the far-reaching influences of the timber resources in their relation to all industries. Again, probably only 50% of the land area of the State of Washington is suitable for agricultural development, 15% is absolutely waste land, and 35% will be valuable only if kept under timber production. This shows how intimately the forestry problem is involved with the entire land problem.

Although Washington has been used as an illustration, the same principles may be applied to every section of the country where timber is the chief resource. The real solution to the problem is to be sought in a further education of the public, which will lead to proper legislation. The Washington State Legislature has passed an amendment to the Constitution which will pave the way for proper reforestation legislation, but before it can become a law it must be approved by popular vote. This may be done at the general election in November.*

The people of the Pacific Coast region, however, are beginning to realize the necessity for action, and it may be expected that such legislation as is needed will soon be on the statute books. The problem is too big for the State and Federal Government to handle alone. It is generally believed that it will be solved only if each of the three large groups of timberland owners, namely, the Federal Government, the State, and the private owner, all do their share.

* The Constitutional Amendment was defeated at the general election in November, 1926. Similar legislation was also defeated in Oregon, but was successfully passed in California.

Timber growth becomes spontaneous (that is, the forest is naturally regenerated) provided the fire situation is handled properly. Much depends on this. There is a diversity of opinion as to whether or not the slashings should be burned after logging. The burning is a matter of future protection against fires. If the slashings are burned during the first year after logging, quite satisfactory reforestation can be expected, and the fire hazard to the new growth has been eliminated.

Douglas fir seed retains its vitality for seven years. There is quite an accumulation in the ground when the old forest is cut off, and if it is not destroyed completely in the burning there will be spontaneous growth. Mr. Allen has mentioned the subject of wind-blown seed. This method of regeneration is slower than, but as effective as, natural reforestation, and is very successful.

The utilization of the slashing material is another matter that has great possibilities. It is one of the great problems in forest conservation. Logging methods will also change in the future, and a great deal more of the small material will be utilized. The wood material will also be used in somewhat different form. Many pulp and paper companies use slashings and small-sized trees, and there are extensive possibilities for their further use.

Research work along these lines of utilization of timber waste is most urgent. More is known on this subject concerning Eastern than Western species. Products are manufactured that will yield from 50 to 400% more value than raw lumber. Through extended research, factories could eventually be established to utilize this large amount of waste and manufacture it into products that would be of great commercial value.

C. S. Chapman,* Esq. (by letter).—Mr. Woods very properly places strong emphasis on the need for tax reform and better fire protection. These are to-day the two great stumbling blocks to forest practice in the Northwest. It must be recognized that a crop requiring a century to mature should receive every consideration from a taxation standpoint. Especially is this so since the per unit yearly increment of a forest is a very small amount and the land used for forest growing is largely of a sort that cannot be utilized for any other purpose. Instead, however, of encouraging reforestation through enactment of tax legislation to meet a peculiar situation, forest crops are singled out for taxation and the timber is taxed over and over again, whereas most annual crops escape any taxation whatever. Most States are attempting, in one way or another, to remedy this situation, and it is hoped the day is not far off when the forest land owner can definitely compute his annual tax charges, paying on his crop (when cut) a proper proportion of its then value. The public cannot lose by such an equitable arrangement, which will go far toward making forest growing an attractive enterprise.

In the matter of fire prevention, Mr. Woods refers to fires in cut-over and burned-over areas where re-stocking is taking place. Losses of this kind, while at present not computable, or at least practically so, are far too general, and more co-operative effort is required to reduce the damage to a minimum.

* Forester, Weyerhaeuser Timber Co., Tacoma, Wash.

There is often, however, a mistaken idea as to the loss of mature timber through fires in the Pacific Northwest. In the past ten years since 1917, or since patrol and protective effort has become well organized, losses of this nature have been small compared with the value of the resource. In Western Washington, for example, since 1916 the computable monetary loss to logging equipment and logs has been more than three times that of standing timber.

In reality, merchantable timber should not be regarded as a resource seriously threatened by fire as long as efficient protection systems are in effect. The need for public co-operation and increasing expenditure by all agencies to keep abreast of the fire hazard is, however, apparent. Fires in the Douglas fir belt are not of a character that in any way interferes with tourist travel. In fact, fires are seldom seen along the main traveled highways.

The Northwest is quite proud of the record established by its protection organizations. It has gone a long way, although far from all the way, toward the solution of its fire problem, and it is going to pursue the forest taxation question until some rational solution is put into effect.

Wesley Vandercook,* Esq.—As pointed out by Mr. Donovan, each year lumbering is extending farther back from the river slopes. The pioneers went as far with their horse teams and wagons as they could. When modern logging equipment came—donkey engines and rails—the industry went farther, until now the remaining timber requires expensive railroad construction. Naturally, there must be large tracts to warrant such construction, there must be larger logging operations, and there must be more careful planning and engineering.

While the Northwest is very rough, its timber stand is wonderful; this makes it possible to manufacture profitably—although the margin is small. The Douglas fir of the Northwest is the greatest and best stand of timber in the United States to-day. As to its structural qualifications, engineers well know its value. The stand per acre in the Northwest is so much greater than elsewhere, that the cost per 1 000-log scale is not excessive, even if expensive equipment is required. Furthermore, the opportunities for marketing are excellent, with wonderful deep-water harbors, giving access by shipping to three-fourths of the people in the world who live in countries bordering on the Pacific Ocean.

Paper No. 1666

SOME PHASES OF IRRIGATION FINANCE*

By D. C. Henny,† M. Am. Soc. C. E.

With Discussion by Messrs. M. C. Hinderlider, C. E. Grunsky, Joseph Jacobs, H. F. Dunham, F. H. Newell, J. C. Stevens, R. P. Teele, J. L. Burkholder, Morrough P. O'Brien, and D. C. Henny.

The arid portion of the United States is to a very great extent dependent for its development on irrigation. It must grow the bulk of its own food requirements in order to permit industries to enlarge and its resources to be developed. In the earlier years of Far Western settlement, mining was the principal industry and afforded sufficient excess profit to stand the burden of high food prices resulting from expensive transportation. With the exhaustion of exceptionally rich mining fields and the advent of other industries, growth has progressively become more dependent on local food supplies.

The part of the United States most directly affected by irrigation is comprised of the States of Wyoming, Colorado, and New Mexico, and those lying farther West. The importance of this region to the nation is due not solely to its own development, but especially to the far-reaching influence which a populous West will have on the future of the United States and the degree of pressure it will be able to exert in the solution of international problems surrounding the Pacific Ocean.

The population of the West has been growing faster than that of the country as a whole. The area under irrigation has shown even a relatively greater growth prior to 1910 than the population, as is indicated by Table 1, derived from United States Census reports.

The number of irrigated acres per inhabitant was small during the early mining years. By 1890 it had increased to 1.14 and since that time it has

* Presented at the meeting of the Irrigation Division, Seattle, Wash., July 15, 1926.
† Cons. Engr., Portland, Ore.

continued to grow, so that in 1920 it had become 1.94. From 1910 to 1920 there was no increase in this relation, which appears for the time being to have become stabilized at about 2 acres per inhabitant.

TABLE 1.*

Year.	Population.		Irrigated Area, in Acres.	
	Total.	Percentage of United States.	Total.	Per capita.
1890	3 102 000	4.8	3 555 000	1.14
1900	4 101 000	5.4	7 253 000	1.76
1910	6 826 000	7.4	13 202 000	1.94
1920	8 903 000	8.4	17 401 000	1.94

* In this, as in the following tables, large figures are expressed to the nearest thousand.

The tier of States reaching from North Dakota to Texas was excluded intentionally from these statistics. Along the western and southern borders of this area irrigation is of great importance. The eastern border, however, penetrates the humid zone and figures for all the States include preponderating population and farming areas not dependent on irrigation.

It is well known that a considerable portion of irrigation enterprises remains uncultivated for a long time after they are opened to settlement. The late R. P. Teele presented* the figures in Table 2, which are based on U. S. Census reports, relative to this statement.

TABLE 2.—Extent to Which Estimated Full Capacity of Irrigation Enterprises Is Utilized at Various Periods After Commencement of Construction.

Years.	Percentage.	Years.	Percentage.
5	36	25	60
10	45	30	62
15	52	35	63
20	56	40	65

At first sight the condition revealed by Table 2 will be regarded as exceedingly unsatisfactory and as showing serious irrigation over-development. It should be noted, however, that the term, "Estimated Capacity of Irrigation Enterprises", has a rather uncertain meaning. Mr. Teele pointed out that it represents the hopes of owners rather than actual irrigation possibilities.

If tardy settlement and over-development are under consideration, the area irrigated may best be compared with the area which could have been served with an irrigation supply. This has been done in Table 3, the figures covering all States west of a line drawn from Galveston, Tex., to Grand Forks, N. Dak., thus including all States grouped by the U. S. Census Bureau in its irrigation statistics, except Arkansas and Louisiana.

* *Bulletin No. 1257*, U. S. Dept. of Agriculture, 1924.

Table 3 tends to show that in 1920 about 6 800 000 acres were lying idle to which existing works were capable of supplying water, an area more than one-third of that actually irrigated. Although this showing is not as bad as that implied by Table 2, it would indicate nevertheless a serious condition of over-development. It is believed that these figures, however, are also strongly colored by optimism. The reports for Oregon, for instance, give an area of 350 000 acres to which water could have been served but which was not irrigated. The writer's familiarity with the State inclines him to the belief that this figure is grossly in error.

TABLE 3.

Year.	Area enterprises were capable of irrigating, in acres.	Area irrigated, in acres.	Percentage of area irrigated.
1890	Not reported.	3 631 000	.....
1900	" "	7 519 000	.....
1910	19 685 000	14 025 000	71
1920	25 112 000	18 593 000	74

The reports of the United States Bureau of Reclamation are undoubtedly more accurate than the general average. These reports give for 1920 a corresponding 75% irrigation. The average age of settlement on Government projects is far less than that on the entire irrigated area of the West and for the same age a considerably higher percentage is likely to be found as compared with 74% for the whole, as given in Table 3. There may be, however, some difference in favor of Government projects as offering superior inducements.

Before drawing conclusions in a matter of this importance it may be well to consider that the partial settlement of irrigation enterprises, were it correctly known, is not in its entirety a measure of excess development. The first settlers generally select the best soil and the remnant available to new settlers leaves lesser possibilities of profitable farming. The water supply may have proved unsatisfactory for the full area reported as irrigable, some land may have, or threatens to, become water-logged and even in the most intensively farmed areas some land is always found unused due to change of ownership, failure, and other causes.

If from these considerations, 85 to 90% may be judged as the normal maximum it may be reasonably estimated that from 1 500 000 to 2 000 000 acres to which water could have been furnished, remained uncultivated in 1920. To what extent this area may consist of land which because of roughness of topography or character of soil remains unused is very doubtful. Some of this land cannot place a new settler on a competitive parity with other settlers on land in the same locality until a sufficient price difference has developed and as this, in turn, depends on crop prices, margin of profit, and availability of better land elsewhere, a large part of this land may have to be considered as not available at the present time.

A considerable slack has probably always existed and cannot in itself be regarded as evidence of over-development. In any expanding industry there is usually provided a margin ahead of pressing demands. The question of over-development of irrigation has only been generally raised during periods of agricultural depression, which affect the East and West alike. The severity of the present (1926) agricultural depression may be judged from the changes in the area of improved farm land in successive decades, as reported by the U. S. Census Bureau (Table 4).

It is of the utmost importance in connection with all irrigation finance to understand as fully as may be the causes which have contributed to this depression in order to have some judgment of its probable duration. This is especially true when dealing with reclamation projects on such scale as is now becoming unavoidable, requiring many years in the process of mere building and possibly decades in the course of their normal development.

Low crop prices are the direct cause of agricultural depression and are due mostly to over-production resulting either from lack of purchasing power on the part of the consuming public or to over-development. It cannot be said that there is any lack of purchasing power at present in the domestic market; on the contrary this is probably higher than it has ever been, all industries other than agriculture being in a reasonably prosperous state. On the other hand, the foreign market is in an unsatisfactory condition as regards absorbing any normal surplus which is usually exported. This is well illustrated by the fact that of the 31 000 000 acres decrease in improved farm land area from 1920 to 1925, wheat land accounts for 22 000 000 acres, this being about 30% of the total area devoted to wheat raising in 1920. During the same period, however, the area in cotton, prehaps the next most important article of export, has increased more than 5 000 000 acres, or about 15%, which in part accounts for the relative prosperity of far Southern agriculture until the recent slump in the price of cotton.

TABLE 4.

Year.	Land in improved farms, in acres.	Increase, in acres.
1890	623 000 000	.....
1900	839 000 000	116 000 000
1910	879 000 000	40 000 000
1920	956 000 000	77 000 000
1925	925 000 000	-31 000 000

On the whole, it is probable that over-production in relation to available markets is the outstanding cause of the present depression. As far as over-production is local, it may in part be mended for those products which can stand long-distance transportation cost by reaching out for more distant domestic markets, as has been successfully done in the case of citrus fruits and, later, of deciduous fruits.

Farm production is as yet entirely uncontrolled and unrestricted. Good prices at once cause increased production, the tendency being always toward

over-production in the industrial, as well as the agricultural, field. In the former, production is in fewer hands and intelligent forecasts have their beneficial effect on output control. If large steel corporations should rapidly increase the output of certain steel products, simply because the margin of profit was high during the previous year and without reference to the absorbing capacity of the market, they would soon be in no better financial condition than the farmers.

Restriction of output to correspond with probable demand is as necessary to maintain the agricultural industry in a satisfactory condition as it is for other lines of industry, but is far more difficult of realization. Uncontrolled output results in violent fluctuation of prices with the ever-recurring succession of periods of inflation and deflation. These, in turn, produce a similar effect on land values with the aggravating subsequent combination of heavy investment and low crop returns. The writer visited Europe a few years ago and found that, in Holland, shrinkage in exports had resulted in over-production, causing a serious agricultural crisis. On the other hand, farmers in France and Germany were relatively prosperous, the effects of the World War having caused under-production.

If economic laws are not interfered with by legislation, an agricultural setback has at least this beneficial feature—that it causes marginal lands to go rapidly out of cultivation. In the meantime the growth of population maintains a rising curve in the domestic demand and it is merely a question of time when it will cross the falling curve of output. When this happens crop prices will rise, the farmer's prosperity will return, and the demand for farming land will revive. Artificial revival can be brought about by legislation. Legislative interference with economic laws is believed to be justified only under exceptional conditions and for distinctly temporary purposes. Price maintenance is extremely costly to the nation as a whole, because it aggravates the original cause by encouraging production at a time when the demand for price maintenance is created by over-production.

The importance of stabilizing crop prices when once they have reached a point yielding profits in proportion to other industries cannot be exaggerated provided it can be done without violating economic laws. It is possible that some healthy progress may be made in that direction by the distribution of reliable statistical information and by the forming of farmers' organizations leading to output restriction, in all of which Governmental action may be helpful. Upon recurrence of profitable crop prices there will develop, as far as irrigated agriculture is concerned, an immediate tendency to take up the slack by occupation of the best farming sections of the 1 500 000 or 2 000 000 acres for which water is reported to be ready. This can be done without starting new irrigation projects. If about one-half this area is destined to come into early use and if the eleven Western States should continue to increase in population as they did in the last decade at the rate of 240 000 per year, requiring an increase in irrigated area of possibly 460 000 acres, it is evident that the available excess may be absorbed with surprising rapidity.

Most irrigation projects require two years and more for construction, and some of the larger ones need in excess of four years. Ordinary human foresight, therefore, would indicate that the desirability of energetically resuming irrigation construction may become apparent before long. The present time, therefore, is not inopportune for inquiring into the various means by which expansion is most likely to be brought about and into the manner in which it will probably be financed. The agencies through which irrigation has been accomplished in the past may be judged from Table 5.

Irrigation effected by individuals, partnerships, and corporations, accounts for by far the bulk of accomplishment to the present time. It is probable that through these agencies, in numerous localities where improved transportation removes previous obstacles, small areas will continue to be developed, which, in their aggregate, will continue for a time to be an important factor of irrigation expansion. Since 1910, however, irrigation fostered by legislative action or carried on directly by Governmental agencies has been gaining rapidly in relative importance. The acreage percentage thus reclaimed more than doubled during the decade, 1910-20, while the gain in area was 2 500 000 acres as against 2 250 000 by other agencies.

TABLE 5.

Agency.	1910.		1920.	
	Acres.	Percentage of total.	Acres.	Percentage of total.
Reclamation Bureau	396 000	2.7	1 255 000	6.5
Indian Service	173 000	1.2	285 000	1.5
Total, Federal	569 000	3.9	1 540 000	8.0
State	Not reported	.....	6 000	0.003
Governmental	569 000	3.9	1 546 000	8.0
Carey Act	289 000	2.0	524 000	2.7
Irrigation districts	529 000	3.7	1 823 000	9.6
Sub-total	1 387 000	9.6	3 893 000	20.3
Other agencies	13 046 000	90.4	15 299 000	79.7
Total	14 433 000	100.00	19 192 000	100.0

The largest proportionate increase was that produced by the U. S. Reclamation Bureau, its percentage in 1920 being 2.4 times that in 1910. The largest acreage increase due to any single agency was brought about by irrigation districts, amounting to 1 300 000 acres during the decade. The Carey Act, passed in 1894, which at first held out great promise, has thus far accounted for less than 3% of the total irrigated area. It grants to each of the arid States 1 000 000 acres of desert land subject to provision for reclamation by the States. This has been done by State contracts with construction com-

panies which provide the money for and build the works, these companies being authorized to sell water rights to parties buying the land from the States.

The Carey Act contains a sound financial principle in that it permits invested capital to earn, besides interest, a profit which may be commensurate with the risk involved. The unsatisfactory feature in its application was that companies willing to undertake the work were poorly financed and depended on advance water-right sales and the proceeds of bond issues not secured by the land, for a large part of their construction funds. The States of Idaho and Wyoming are the only ones that have largely availed themselves of this method. A few well-selected projects were reasonably successful. Others failed through insufficient water supply or from tardy settlement, causing the financial plan of interest and bond repayment to be upset, with the general result that this method of irrigation expansion is at present dormant. There is, however, no fundamental reason, except possibly inavailability of suitable public land projects, for discarding its use in the future especially if State legislation can be changed so as to permit the land itself to become security for bond issues. It is safe to say that investors will not avail themselves of this Act until a large margin of profit can be calculated, and this cannot be hoped for until crop returns and land values show a considerable advance over present conditions.

The irrigation district method of developing and handling irrigation deserves the most serious attention. From the standpoint of total acreage and recent increase of acreage, it exceeds in importance all direct financing by Governmental agencies. From the social standpoint, its comparative independence of Governmental aid and control is strongly in its favor. Dependence on commercial financing through the sale of bonds has, in addition, the advantage that selection of locality is not influenced by political considerations and that over-development is to some extent automatically checked. In considering this subject, distinction should be made between the various enterprises which now operate under the district plan. These divide into two general groups: (1) "A" Districts with land values greater, and (2) "B" Districts with land values smaller, than the face value of the proposed bond issue.

It is apparent that where the immediately existing land values, independent of any speculative element, leave a large margin over the amount of the bond issue, and other conditions are favorable, the security is good. This is generally the case with districts which have developed prosperously under some other plan and which are organized and issue bonds for taking over existing and proved works and for improving them; also, with many districts on Government projects. It is equally apparent that where the aggregate land values are far below the bond issue the case is essentially different, the security is uncertain and becomes dependent on the numerous factors which may lead to relative success or failure. There are many risks arising from possible under-estimated cost, insufficient water supply, faulty engineering, and over-estimated rapidity of subdivision and settlement.

The bond-buying public has no means of determining for itself the risks involved and, in purchasing bonds, depends on the standing of bond houses and on their representations. On the whole, bond houses have responded conscientiously to the call thus made on them by a thorough investigation on their part and by refusal to handle bonds involving excessive risks. Risk in greatly varying degree is, however, always present in the absence of an ample margin of security independent of future development. There have been many cases, of course, where bond dealers of the highest standing have misjudged the risk and also where less conservative dealers have handled doubtful issues.

This subject was ably and exhaustively discussed by Mr. Teele in *Bulletin No. 1257* of the U. S. Department of Agriculture, already referred to, which for unbiased and comprehensive information deserves more publicity and distribution than it appears to have received. In this *Bulletin* a division between districts is made along somewhat the same lines as that suggested. It distinguishes between Class I Districts organized for taking over projects developed by other agencies and Class II Districts organized for developing new projects. Class II Districts may thus be regarded as largely identical with the writer's Class B Districts, except that the former excludes, and the latter includes, districts which, although partly developed, show an unsatisfactory relation between existing land value and face value of bonds. On the basis of his division, Mr. Teele reported the results given in Table 6, after eliminating all districts which did not pass beyond the preliminary stage.

TABLE 6.

Districts.	Number.	Gone Out of Business.	
		Number.	Percentage.
Class I	246	48	19.5
Class II	156	110	70.5
Total	402	158	39.3

The showing made by Class II Districts is extremely bad and if doubtful security districts in Class I had been included in districts in Class II, so as to make it identical with Class B, it would be still worse. On the other hand, the results for Class I Districts if so amended and made the same as those for Class A, would be very good as the percentage of failures would have dropped probably below ten and possibly might be close to zero. This might be so even if the percentage of failures had included districts which have not gone out of business, but which have defaulted on their obligations.

There are exceptional cases in Class II Districts where the risk in bond investment may be sufficiently paid for by the rate of interest which these bonds carry and by the price at which they are sold, as, for instance, small districts with choice opportunities and with relative cheap irrigation supply. Again, there are instances where the risk in bond investment is deliberately incurred by parties likely to benefit in other ways by land development. On

the whole, however, it must be concluded that the district bonding method is not well adapted to the reclamation of unimproved or only slightly improved land. It is mainly for this reason that efforts have been made to throw Governmental safeguards around district bond investment.

These efforts have consisted of public investigation of feasibility, requirement that bonded debt does not exceed 50% of the value of land and works, provision for certification of bonds by State Commissions, and limitation of price at which bonds may be sold. In addition, some States authorize the inclusion in the bond issue of interest for the first few years, and Oregon permits a guaranty of interest for a maximum of five years. Measures of this kind are helpful only if sound judgment is used in their application, which unfortunately has not always been the case. Pronouncing a project feasible although its success is quite uncertain and the security it offers as a bonding proposition is very unsatisfactory, is an action likely to be taken by a sympathetic State board. To certify the face value of the bonds to be no more than 50% of the value of lands and works when this can be true only, as in the case of desert land, on the basis of speculative or potential land value, is far more questionable. These things have all been done. The Oregon State interest guaranty has been granted with more genuine care but, nevertheless, at times with prospects of loss to the State, and bond buyers have probably attached too great significance to this feature as well as to State certification often prominently displayed on the face of each bond and likely to imply a far-reaching but non-existent State obligation.

All these attempts are for the purpose of helping out a situation which in the case of Class B bonds is unsound, while in the case of Class A bonds they are largely unnecessary for the purpose of financing although they may be beneficial. If reasonable excess security is lacking at the time the bonds are issued, bond buyers run a risk for which the permissible rate of interest and of selling price does not ordinarily offer just compensation, a fact which cannot be changed by law in any way except by flatly placing the credit of the State or Nation behind the district.

The belief that the lien which a district holds on the land, permitting its forced sale when taxes remain unpaid, is of special value to holders of Class B district bonds has often been rudely shaken in practice. When relatively large areas are in default the reason is not a personal but an economic one which cannot be helped by change of ownership. The general obligation clause is also of little avail in such cases because it leads to undue concentration of assessments on lands remaining in cultivation, which is sure to add to the area in default and to result in further decrease of cultivation and of bond security.

In the matter of Class A Districts the district laws have operated with gratifying results. The success attained would be still greater if Class A Districts could be removed from the cloud which the failure of Class B Districts has raised as to district bond investment generally. Class A bonds are in their nature improvement and not development bonds and if this distinction can be brought fully home to the investing public, it should be pos-

sible to sell such bonds at a better price or with a lower rate of interest. To some extent this has been successfully done in California and Idaho.

There now remains to be considered irrigation through direct Governmental financing, accounting in 1920 for 8% of the total development. Irrigation has been accomplished to a small extent by the three Pacific Coast States. The experience to date (1926) has not been up to expectation. In Washington, one small project was started with funds provided by the State Reclamation Service. Heavy reservoir seepage has compelled a severe cutting down of the project area, and the State stands to suffer a heavy loss. In Oregon, a project started with money appropriated by the Legislature for the purpose has met with a similar although somewhat less disastrous fate, also by reason of reservoir leakage. It has recently been supplied by the State with additional water and there is a probability of reasonably good results being secured, the State, however, writing off a heavy loss unless the reservoir can be made tight at no excessive expense. In California, two State projects have been built both with State aid in partial financing of settlers. The Durham Project may be regarded as wholly successful. As to the Delhi Project there appears to be great difference of opinion, it being uncertain to what extent heavy arrears in payments to the State should be fairly attributed to adverse agricultural conditions.

Federal irrigation has been developed in two directions, both controlled by the Interior Department. The Indian Service is doing very important work, which, however, is apart from commercial irrigation as it is intended primarily for the benefit of the Indians and is to be only indirectly judged by financial results. The writer has been unable to ascertain the full facts from which the benefit to the Indians and to the Nation can be judged. Within the limited scope of his own observation it is found that the Indians themselves do not take readily to intensive irrigation farming and in some reservations a large part of the land under ditches lies uncultivated. Where the lands are attractive to white settlers and can be leased by them, the results are comparable with those obtained by tenants on U. S. Reclamation Bureau projects, the Indians merely benefiting as landlords.

The work of the Bureau of Reclamation has been repeatedly the subject of public investigation. Reports have been made by committees of Congress, by an Army board, and also by the so-called Fact Finding Commission. These reports enter into great detail and have received considerable publicity for which reason the writer proposes to deal only with a few general features.

In judging the working of a law like the Reclamation Act, applied under a remarkable variety of climate, crops, transportation facilities, and cost of farm help, certain broad facts should be borne in mind, some of which affect agriculture in general, whereas others pertain solely to Western agriculture and, again, others are of a political and psychological nature.

Much has been heard of the inability of farmers on Government projects to earn a living, of the hardships and misery suffered by them, and of projects being abandoned. It may be presumed that through all the published reports and through direct observation the Western public and its

Congressional representatives are fairly well informed as to the general results achieved. In the face of the severe criticism which has been leveled at the Reclamation Bureau, it is a most significant fact that from all the Western States there is a persistent clamor for more Government projects and that this clamor is ably and vigorously supported by their Congressmen. The demand, moreover, is for new projects on an increasing scale of magnitude and is so general and unanimous that it cannot logically be ascribed to motives reminiscent of "pork barrel" appropriations. If sufficiently informed the public is not readily carried away by partisan commendation or condemnation. As regards the alleged severe suffering of Government project settlers, the desire for more from each locality where the facts should be most fully known, carries rather complete refutation.

The reports made so far are unanimous in approving and commending the technical side of Federal irrigation. Criticism has been made of the cost of the work having been under-estimated. There have been of course many cases of erroneous judgment, much of the work being of a novel nature and in partly inaccessible localities. The excess cost complained of, however, has been largely due to a persistent and unforeseeable rise in prices of labor and material and to the addition of numerous construction features not originally contemplated. To that extent criticism on this score is believed to have been unjust.

It is undeniable, however, that the financial results of the Reclamation Act from the direct Government investment angle are not what had been originally expected. The Act as first passed required the repayment of the estimated construction cost without interest in ten equal annual payments. Payment of 10% of construction cost per year, in addition to operation and maintenance charges to be paid by settlers on raw desert land, is indeed a task which, as is now fully understood, only a few could perform.

British Indian irrigation is often and with justice pointed to as an example of efficiency and financial success. There are enormous differences between British India and the United States as to economic and climatic conditions, density and character of population, and need of additional land. A direct comparison is, therefore, not practicable. Nevertheless, it is instructive to note where the Public Works Department of British India draws the line between financial success and failure. The criterion is whether within ten years of the completion of construction a project produces sufficient revenue to cover its working expenses and 5% on its capital cost. Although the aggregate results have been very satisfactory there were, out of 64 productive projects, 15 which failed to meet this test.

Irrigation district, Carey Act, and corporate experience in the United States is conclusive to the effect that the repayment requirements of the original Reclamation Act were too severe and that as a test of success or failure the inability of most farmers on Government projects to make such payments has no value. The inevitable result of these requirements was a search for the easiest way out. This was found in the discretionary power of the Secretary of the Interior to defer the time when payments should com-

mence. That this means of escape was badly stressed even after other remedies were provided, is evident from the fact that on some of the most successful projects more than ten years elapsed after water was first turned on before construction repayments began. The next result was that by successive changes in the law, annual payments were reduced to 5% or, under certain conditions, to a graduated scale beginning with 2 per cent. This has since been further changed to 5% of the gross crop returns.

The comparative ease with which these and other relief measures were secured from Congress, the fact that not in a single case, even after the passage of the newer Acts, has the Government enforced collection by foreclosure under lien, and the ready encouragement of farmers' demands by Congressmen, have had an unfortunate effect on the psychological condition on some of the Government projects and on financial returns to the Reclamation Fund. It is to the great credit of the officers of some of the Water Users' Associations and Districts that payments have been made without demur and with a small percentage of arrears. Under these conditions it is also deemed rather creditable that out of $28 000 000 due under the new Act for construction charges nearly $23 000 000 has been paid. About the same proportion of maintenance and operation charges, namely, $14 500 000 out of $18 000 000, were collected, all as of June 30, 1925.

The economic features of Reclamation projects have lately been called to the attention of the public with entire propriety. This appears, however, to have created to some extent at least the erroneous impression that the essential elements leading to success or failure were neglected or entirely disregarded in previous planning of irrigation development. To that extent injustice has been done to earlier workers in this irrigation field. It was as well known twenty years ago as it is now that irrigation cannot be successful unless it brings suitable financial rewards and that such rewards are possible only where reasonable crop prices combine with good soil, a sufficient water supply, proper drainage, and individual industry, experience, business ability, and adequate financial resources. It was realized that requirements are high, but that they are in most essentials not different from those demanded in agriculture generally and in other gainful pursuits. An average percentage of failures, therefore, could be reasonably expected on Government projects. The number of failures has never been determined and it is, therefore, an open question whether their number is greater or smaller than in other occupations, in other irrigation enterprises, and in other gainful pursuits. It is by such determination only that results can be fairly appraised.

Since the beginning of irrigation, suitable soil and sufficient water supply have been recognized as essential factors. Soil examination by agricultural experts, as far as the writer is aware, has always preceded approval of Government projects. The knowledge of soils is advancing rapidly and much has been learned from past mistakes so that the chance of erroneous judgment is constantly lessening. As to the desired qualifications of settlers, it has been regarded as good policy for many years, especially by private irrigation managers, to select the proper kind of men. It has been found exceedingly diffi-

cult, however, to carry this policy into full effect. It has indeed been a rare occasion when any irrigation settlement scheme was confronted with a plethora of settlers from whom to select, even if an abundance of speculative investors has at times been in evidence. On the contrary the case has generally been quite the reverse, land waiting for settlers and irrigation companies making expensive efforts to sell and colonize. Under such conditions the turning away of prospective settlers no matter how poorly equipped has been frowned upon both by the community itself and by the interests in control.

On projects fostered by State or National Government the financial stress is not so immediate, but in many private irrigation enterprises the need of money has been often so great that immediate income from any settler who offers to buy, must be accepted. The exaction on Government projects of certain qualifications which a settler has to meet is based on sound economics, but in this case, too, a policy of careful selection may be found extremely difficult to enforce. A common argument for securing public funds for irrigation has been that it furnishes homes for the poor. It was only a few years ago that the late Secretary Ballinger was severely and widely criticized for stating at an Irrigation Congress that a poor man had small chance to succeed on a Government project.

If an applicant for land is in earnest but is turned away, the person responsible therefor will probably have to make repeated explanations to Congressman, Senator, or Land Board of his ruling against a worthy Republican or Democrat, as the case may be. The result, of course, should be a strict adherence to the approved policy but, unfortunately, it is likely to be an easing off or even a practical suspension of restrictions unless public opinion can be fully awakened in its support.

Lack of settlement control produces undesirable results. Yet the economic law of the survival of the fittest tends to provide a slow cure. The settler who cannot succeed for reasons inherent in himself will fail, and the sooner he engages in some other pursuit and releases his land the better for all. If a settler of that type is coddled by easy Government credit or continued release from obligations the economic law referred to, ceases to operate and both physical and psychological conditions of the community are adversely affected. To this cause is due in large part the lack of complete success of Federal irrigation. It does not result from the attitude of any man in control but from conditions beyond any one's control where business and politics cannot be kept strictly apart. This is the most valid argument which has been advanced against Federal irrigation and might be conclusive if a continued healthy expansion could be brought about by private enterprise, unless some remedy can be found which will keep politics out of Government irrigation.

This may not be altogether an irridescent dream. There may be ways in which progress is possible. For instance, a very valuable suggestion was made in that direction by Mr. R. E. Shepherd,* who advanced the proposition that Federal irrigation be placed in the hands of a corporation created by

* *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 716.

the Government, connected with, but not controlled by, the Departments of the Interior and Agriculture. It is unbelievable that when the absolute need is apparent careful thought and discussion should fail to find some satisfactory solution.

The Reclamation Act has been frequently alleged as constituting a subsidy. The Teele *Bulletin,* previously referred to, states: "There is no justification for a National subsidy to land reclamation. If local interests justify the subsidizing of land reclamation the subsidy should be local." The writer cannot fully concur in this conclusion because he believes it is too sweeping. The great National interest in rapid development of the West has induced railroad subsidies on an enormous scale. Cities on deep water have received subsidies in the shape of funds for harbor development. Import tariffs are in the nature of subsidy to certain industries. The extensive and valuable work of the U. S. Department of Agriculture in establishing experimental farms, giving free agriculture and even engineering advice, and distributing seeds, is essentially a subsidy to agriculture. It cannot be denied that some, if not most, of this subsidial assistance has been of great benefit to the Nation. Subsidy as such is not necessarily unjust or harmful although it readily becomes so if extended unwisely or too freely.

Material expansion of irrigation involves ever-increasing expenditure per acre, as it can depend only on residual stream flow necessitating relatively greater outlay for storage and because it usually requires longer average distance of water carriage. In a broad way the rising cost is confirmed by Table 7 based on U. S. Census reports.

TABLE 7.

Year.	Cost per Acre.	
	Construction.	Annual maintenance and operation.
1890	$ 7.96	.....
1900	9.04	.....
1910	15.85	$1.07
1920	26.81	2.43

As is well known, the average construction cost as reported by the U. S. Census Bureau gives no fair conception of the cost of projects being contemplated and executed, which vary from $75 to $175 and more per acre. The averages reported are low because they include the construction of a great number of early simple systems free from the necessity of storage, that were often built in the cheapest and most temporary manner and with the land close to the source of supply.

Table 7 might be revised to bring out somewhat more clearly the growing cost of irrigation. This is done in Table 8.

No accuracy can be claimed for the figures given in Table 8. The acreage is that which enterprises reported as capable of irrigation and, for reasons previously stated, this may have been seriously over-estimated, while for the

practical irrigation of some of it, heavy additional outlay may be required. The figures, however, are of undoubted value as showing the rising trend.

The limitations of desert land reclamation by private finance under such conditions have been discussed. The question of helping out by local subsidy was raised by Mr. Teele who presumably referred to State subsidy. So far, the work done directly by States is very small, but it is possible that this method of financing irrigation may be utilized in the future to a greater extent, especially if in this case also the baneful effect of mixing business and politics can be avoided.

TABLE 8.

Year.	Area covered by projects, in acres.	Total cost.	Increases of area, in acres.	Increase of total cost.	Cost per acre of increased area.
1890.....	3 710 000	$ 29 534 000	3 710 000	$ 29 534 000	$ 8.15
1900.....	7 744 000	70 010 000	4 034 000	40 476 000	10.40
1910.....	20 285 000	321 454 000	12 541 000	251 444 000	20.10
1920.....	26 020 000	697 657 000	5 735 000	376 203 000	65.60

It should be remembered that most Western States are highly taxed not only because the standard of life is high, but also because a large portion of the land, in some States well exceeding 50%, continues in public ownership and pays no taxes. Much of this land is in forest reserve and in Indian reservations and has great value. It should be apparent, therefore, that although some States have made courageous efforts, no great results can be hoped for in that direction, and it is evident that Western irrigation and, consequently, population will advance slowly unless Federal aid on an increasing scale can be extended. If the belief should prevail that continued rapid growth of the West is for the good of the Nation, whether for international reasons, or because it contributes heavily to Eastern industrial prosperity and to the well-being of the transcontinental railroad system, or because it adds to the value of Government land, or for any other sound reason, a certain help from the National Government even if termed subsidy may be fully justified.

If it be conceded that National aid to Western irrigation is wise and should be extended in proportion to the need as it may develop, then it is important that any commitment which the Government may undertake, be known in advance as far as practicable, so that it may be fairly compared with the expected benefit. All tendency to minimize deliberately or carelessly such commitment should be definitely discountenanced.

In the past, construction cost estimates of U. S. Reclamation Bureau work have been as fair as engineering ability and integrity could make them. In the course of experience, however, there have come to the front elements of cost which had previously been rarely considered. One of these elements is drainage. There are some projects where surface conditions were not deceptive and natural under-drainage has fulfilled all requirements. In some, it is

now apparent that artificial drainage should have been provided from the beginning, and there are others where apparently very favorable underdrainage was found blocked by dikes or other obstructions. This experience has led to the recent practice of making provision for drainage cost in all estimates.

Another and far more serious item of cost is the help which, under a new policy of the U. S. Bureau of Reclamation, is to be extended to settlers. When the Reclamation Act was first passed a general storage reservoir in aid of private irrigation, sometimes with and sometimes without a main canal covering a definite area of land, was deemed to constitute all the Federal aid wanted. Subsequently, Federal construction of main and sub-laterals together with drainage was added, and the new policy contemplates the construction of laterals on the farm itself and the preparation of the land for irrigation, with the possible further help of financing house, barn, and fence construction, farm implement purchase, and stocking of farms. Additional individual financing is to be done subject to a small rate of interest.

The writer deems the discussion of this subject beyond the scope of this paper. It is merely desired to point out that financial help thus extended from whatever source may require an expenditure of $50 to more than $100 per acre in addition to construction cost and that any financing beyond the conservative extent to which Federal Land Banks have carried such loans, no matter how beneficially it may work out in some cases, is quite certain to involve the Government if it grants such assistance, in direct financial losses which are essentially a part of the general commitment and which in some manner should be appraised and included in the estimated cost.

There is still another item of cost which has been ignored, sometimes intentionally, in making propaganda for desired projects. Reference is had to the equivalent of what in public utilities is called "early losses."

It has been found that the rate of land settlement in any one locality has a distinct limitation. It depends on the available supply of willing and well-equipped settlers attracted by the local climatic and other conditions. With the rising standard of living much has to be created in the way of roads, schools, banking facilities, domestic water supply, and numerous other things, many of which were only a short time ago regarded as luxuries by the pioneer farmer. Time and money are required to create these things and during their absence settlement is slow and discouraging. Moreover, with the high-priced projects of the future the speculative attraction of a rapid rise in land values, which has been one of the strongest motives where a rapid influx of population took place, will be largely absent. Thus, it will happen that irrigation projects comprising hundreds of thousands of acres which are not capable of being developed in small units, will be faced with an annual operation and maintenance charge far beyond the ability of the earlier settlers to pay.

This condition has existed to a serious extent on some large projects which have been faced with heavy operation and maintenance loss after ten years or more of operation. Yet these projects are small in comparison with some developments now (1926) being considered. The practice in Federal irrigation in the past has been to add these losses to construction charges on land

yet awaiting settlement and to give this land longer time to pay, always without any addition for interest. Later, some of these charges have been entirely written off as loss. These losses fall of necessity for the time being on the National Treasury, while the loss of interest in any case is a permanent loss to the Nation.

This subject is not argued as a reason for non-development, but because whatever is done should be based on the fullest possible information of the real total cost likely to be involved. One specific case in hand is the Columbia Basin Project comprising the enormous area of 1 750 000 acres, all dependent on one long main canal with a number of intervening reservoirs and tunnels. Part of the division canals as well as the main canal will have a capacity far in excess of the requirements during early years of development. How long it may be before the farmers on the project will be able to pay the operation and maintenance cost on such an extensive and only partly used system no man is wise enough to foretell definitely because the experiment is quite unprecedented; but that for a long series of years heavy losses are unavoidable is entirely certain. This cost and the means of meeting it should be studied and approximated in some manner, so that authorities who may ultimately approve the construction of this and other large enterprises, will not be deceived as to the total subsidy which may be involved.

To summarize the following conclusions are believed to be justified:

(*a*) Increase of irrigated area will and should be slow when and where crop prices do not render farming profitable.

(*b*) Private enterprise will continue to bring about healthy irrigation expansion on a small scale in many localities as soon as crop prices become generally profitable.

(*c*) Irrigation districts will continue to play a large part in the financing of improvements of existing projects and, to some extent, in the construction of small new projects under especially favored conditions.

(*d*) The irrigation district method is not well adapted to the reclamation of large areas of desert land.

(*e*) Continued growth of the West will require the construction of large irrigation projects for the reclamation of desert land.

(*f*) In general, the construction of large projects involving the reclamation of desert land carries under present conditions risk out of proportion to expectation of profits and will not be undertaken by unaided private enterprises for a long time.

(*g*) Stagnation of irrigation development and the consequent slowing down of Western growth may prove of serious detriment to the Nation.

(*h*) State and National subsidy to irrigation is justifiable and desirable, provided it is restricted to the needs of the immediate future and be conditioned on the finding of a reasonable relation of anticipated benefits to total cost, including all items of present and future expenditure.

(*i*) It is important that efforts be made to sever politics from business in the administration of Governmental subsidy.

DISCUSSION

M. C. Hinderlider,* M. Am. Soc. C. E.—This paper is an excellent presentation and analysis of this intricate and all-important subject. Doubtless the greatest problem of America to-day is that of the farmer.

While the tribulations of the agriculturist in the humid region have been such as to bring about the abandonment of hundreds of thousands of acres of what formerly had been either fairly profitable investments, or means of complete support to himself and family, the plight in which the farmer in the arid West has been placed for several years past is even worse, due to the relatively greater cost of production, more unfavorable location with respect to markets, and less favorable facilities for financing his needs. It is true that these handicaps have been compensated to some extent by greater crop returns per acre from the more productive soils, coupled with cheaper production of live stock through the use of the great ranges of the West; but such marginal differences in favor of the farmer in the arid region are of minor importance, particularly as regards settlers on partly developed lands not under stabilized production.

In most of the conclusions reached by the author, the speaker is in accord. The first of these is, that "increase of irrigated area will and should be slow when and where crop prices do not render farming profitable". This is largely true as regards great developments financed by private enterprise; but as to developments of lesser magnitude, the conclusiveness of this statement is largely dependent on what constitutes profitable farming. If this consists entirely in the accumulation of money, then the author's conclusion is logical; if, however, the reclamation of useless lands as an abode for the rearing of a family in any particular community and under climatic and social conditions which in his judgment are most conducive to their welfare, is the principal incentive, then the continued reclamation of lands in any particular community without regard to how profitable such reclamation may be from the standpoint of monetary returns, is justified.

In many localities in which extensive reclamation has taken place through corporate and Government effort, the climatic and social conditions do not appeal to many a capable farmer who would gladly purchase a farm under a newly constructed project in a community in which he has other interests or prefers to remain. Such reclamation development is an important factor in the gradual building up of isolated districts into homogeneous communities which make for stability in commercial and transportation lines and in the diversified pursuits needful for the well-being of a prosperous and contented people.

The speaker is unable to agree wholly with Mr. Henny's conclusion to the effect that "the irrigation district method is not well adapted to the reclamation of large areas of desert land". Many of the largest and most successful developments in Colorado have been effected under the original Irrigation District Act and amendments thereto. These projects embrace a great many

* State Engr. of Colorado, Denver, Colo.

thousand acres of some of the choicest lands in the State, and numerous large storage reservoirs, with capacities running into hundreds of thousands of acre-feet. As illustrative of the success of this method of financing and administering irrigation development, one single individual through such means was instrumental in having placed under irrigation almost as great an area of land as had been served to that time by the U. S. Reclamation projects.

As a means of administration during the colonization and development period, the irrigation district system is generally regarded by irrigationists as the most practicable method. Many large Colorado projects embodied in irrigation districts have either wholly or almost completely retired their outstanding obligations, are administering their affairs in an efficient and economical manner, and have established a credit which enables them to borrow money, when the occasion arises, on a parity with municipalities. It is true that, as experience indicates, it will be necessary to amend the irrigation district acts as now adopted in most of the Western States to meet more effectively the problems of financing and administration as necessity seems to require.

The speaker is heartily in accord with the author's view, that "stagnation of irrigation development and the consequent slowing down of Western growth may prove of serious detriment to the Nation", and this being true it naturally follows that Mr. Henny's succeeding conclusion is sound, namely, that "State and National subsidy to irrigation is justifiable".

Much has been heard in regard to the over-development of irrigated regions, especially with reference to Federal reclamation and the Government's attitude toward future reclamation in the West. It seems that in all these discussions the major purpose and objective of Western land reclamation has been insufficiently stressed. All those familiar with the progress of irrigation development recognize that it has not been accomplished without financial losses and a wastage of no little effort, which, however, has been relatively no greater than the mortality to railways, banking institutions, and mining and manufacturing industries. Yet no sane person would favor for a moment curtailment of development among these other activities.

Whether the reclamation of the arid lands of the Western States, in adding hundreds of thousands of acres of virgin soil, practically inexhaustible in its fertility, will result in a greater financial return on the necessary investment; or whether it were better to attempt to bring back to a proper degree of productiveness the worn out and abandoned lands of the Eastern States, as has recently been suggested; or, again, whether such attempts in either case would result in some financial loss to the funds appropriated for such purpose, is aside from the question.

The question is, whether or not it is needful to the country's welfare, both internally and externally, for this nation to develop along consistent lines which will eliminate radical demarcations between sections of the country, and, if so, whether such necessity may be determined by the same reasonings and units of measure commonly applied to business undertakings.

Next to the air he breathes, man's greatest necessities are food and drink, and his stomach has ever been his most relentless taskmaster. The greatest problem with which man has had to contend, has been that of food supplies. This shadow from time immemorial has laid as a pall on all nations, except possibly America. No other people has escaped the ravages of famine, that dread scourge of nations. With the passing of time, is America to be less fortunate? Future generations only can answer this question.

For two generations this Nation has prided itself on the theory that it is the melting pot in which the peoples of the earth would be blended into a superior race of individuals. It has recently awakened to the fact that in this melting pot an over-burden of slag and an excess of dregs are being accumulated. To-day, the population of many great cities largely consists of peoples who have little or no conception of the ideals on which the Government is founded, with the result that these spots have become the breeding ground for all the destructive elements of society and free government.

Was it not Marcus Cato who, fifty years before Christ, said,

"It is from the tillers of the soil that spring the best citizens and the staunchest soldiers; theirs are the enduring rewards which are most grateful and least envied. Such as devote themselves to that pursuit are least of all men given to evil counsels".

These words are as much a truism to-day as in the time of that old Roman philosopher.

There are those whose conception of National wealth is measured in dollars and cents. They demand that the Nation shall cease spending its own money in turning desert areas into oases until the Government shall have recovered the money expended in the work already accomplished, forgetting that the Nation's wealth and strength are not in its accumulated hordes of gold and credits, but rather in a united and contented people; that its safety is in their ability to look ahead with that freedom of hope born of greater opportunities made possible through the vision of their leaders.

Federal or State reclamation should not be in the nature of a gratuity. The speaker does believe, however, that the Government is justified in a continuing policy of reclamation development of all worthy projects, the cost of which is beyond the ability of the State or corporations to finance, and that the difference between the legitimate cost of such development and the price at which the farmer can pay for the lands so developed should be absorbed by the Nation at large. There is no valid reason why the Government should cease to provide opportunity for the building of homes in these desert wastes, when practically every other industry of the country is subsidized through high protective tariffs.

Very properly Mr. Henny has stated that any plan for adjusting economic conditions through price fixing or other artificial means is unsound and will eventually bring about its attendant string of evils. That inexorable economic law of supply and demand is no respecter of persons or pursuits, neither can it be evaded without penalty; the law of the survival of the fittest applies to the farmer the same as to any other individual or business. If the individual farmer has it in his make-up to succeed, success will be his; if not, very likely

he will fail. Much may be said in favor of the suggested plan for financing practically all the needs of the farmer under the Federal reclamation projects. On the other hand it is urged that such plan is leading directly to a condition fraught with more danger to the country than the incidental loss of a few million dollars invested in reclamation development could be. This refers to the destruction of that self-reliance and freedom of action which has been a characteristic pre-eminent in the builders of the Nation, and especially of the West, and the substitution therefor of a system of paternalism with all its attendant evils.

It is a most needful and sound policy for the Federal Government to build these necessary works, but when this has been done, let them be turned over to the management of irrigation districts, sponsored by the States, and free from Congressional influence, and at a price the land owner can pay. Charge him a graduated scale of payments and a low rate of interest on deferred payments, and require him to meet such payments just as the farmers in the East are required to meet their notes when due.

In a message to Congress, President Coolidge has stated that,

"Efficiency of Federal operations is impaired as their scope of operations is unduly enlarged. Efficiency of State Governments is impaired as they relinquish and turn over to the Federal Government responsibilities which are rightfully theirs."

Farming in the arid regions is one of the most highly specialized industries. Success requires a rare combination of attributes, the chief of which are an inherent love for agricultural pursuits, industry, and thrift. Without these, no farmer can be a success; with these, he will succeed no matter what his environment. The degree of his success, of course, will largely depend on his other qualifications and limitations. Too many people try their hand at farming after having made a failure at other pursuits; very naturally they fail at farming too. Many then run for Congress.

With a more equitable adjustment of the discrepancy between the cost of production and the gross return for his products, the farmer who is capable will work out his own salvation, with a consequent increase in his purchasing power, followed by a rapid demand for the few hundred thousand acres of irrigated lands now unclaimed. This, in return, will provide the opportunity to finance legitimate reclamation with certainty of a proper return on such investments.

C. E. Grunsky,* Past-President, Am. Soc. C. E.—The Engineering Profession is to be congratulated on the tendency of its members to pay more and more attention to the economic aspects of projects. This is well brought out in this paper. It takes a long time to bring most irrigation projects to the point at which income will fully cover all expenses of operation. Some good projects in California have taken thirty years to reach this point.

State aid to any project is nothing less than a subsidy or bonus. When the United States entered upon its reclamation policy, and permitted deferred

* Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

payments without interest, even on the assumption of payments made as contemplated, the bonus to the land owner was equivalent to about one-half the cost of the project.

The question arises, who benefits by the subsidy? The point to be made is that the subsidy given the land owner, as in the case of every such subsidy to farmers, as Mr. Henny has well stated, gives only temporary aid. The bonus cannot be passed on to the land owner's successor. Give the farmer assurance that his output will find a market at good prices, and up goes the value of the land; and the next owner gets no benefit from the improved market. He will soon be confronted by the same difficulties that disturbed the original owner before he obtained a subsidy.

It appears fundamental that, if a subsidy is granted, be it by State or by the Federal Government, it should be for the purpose of extending the area that is available for cultivation—extending the opportunity for home building. This is certainly a worthy object. However, when a subsidy is granted, as Mr. Henny shows, it should be granted with a full consciousness of what it amounts to and on assurance that it is worth while.

Joseph Jacobs,* M. Am. Soc. C. E.—The author apparently favors Governmental subsidy as a probable necessity. He has indicated the basis on which such subsidy might be granted. The matter of subsidy, however, should be hedged about with the greatest possible care, else its privileges will surely be abused. If a subsidy be granted at all, it should be within clearly defined limits and founded on absolute economic need.

There is an easily discernible and growing public sentiment against subsidies, both inside and outside legislative halls, as a result of which it will be increasingly difficult to secure them for irrigation development. Apparently, there is a definite future prospect of the Federal Government demanding, in so far as Federal reclamation is concerned, that all reclamation projects hereafter constructed repay in full to the Government both the principal and the interest on the construction cost. The speaker further believes that on a long-time payment basis, say, 40 years, and on an interest rate basis that the Government can afford to grant, say, 3½ to 4%, most of the projects that can be justified at all, can work themselves out to economic safety without the aid of any subsidy. Such a policy would incline the Government more favorably toward land reclamation and would probably result in a more rational and more rapid irrigation development than would otherwise be possible.

A legitimate exception to this is the desirability that the Government absorb the interest charges attaching to the unsettled lands. This would be justified on the grounds that if settlement be long delayed such accumulating interest charges would become an unbearable burden on the land and the settler; and the Government could afford to pay this relatively small subsidy for the direct economic and military benefits it derives from such agricultural development. In the guaranteeing of such a subsidy the Federal and State Governments might well co-operate.

* Cons. Engr. (Jacobs and Ober), Seattle, Wash.

H. F. DUNHAM,* M. AM. SOC. C. E. (by letter).—This excellent paper will long be noted for its thoroughness and sound views.

An individual or a corporation investing many millions usually conducts his first studies or investigations rather quietly and without special proclamation of future activity and success. It is true the Federal Government is under certain obligations to its citizens, yet it has a Secret Service of reasonable proportions and thus an opportunity to accomplish many things quietly.

A few years ago the country was startled by reports that disabled veterans were to be taken to the vicinity of Lake Okeechobee by the Federal Government and there cared for in a wonderful climate and given the best of opportunities to recover. Experienced engineers from Western projects were sent to make reports and numerous encouraging accounts appeared in the press. In no way was this district suited for the purpose, least of all from a patriotic viewpoint. Lake Okeechobee and its worst surroundings occupy less than one-tenth of the area of the State of Florida. Practically all the remaining nine-tenths could be made available for agriculture at less cost per acre than would be required to secure equally good financial results in the Okeechobee District.

Recently a great boom came upon Florida and many people were led into extravagance and at least temporary losses. Many wrong statements and unsupported conclusions exerted a great influence on people in other States. There has been a general disappointment, in large part temporary, and in some part due to Government methods, which encouraged ideas varying little from those of the early Spanish explorers—ideas of a Paradise without the trouble of making one.

F. H. NEWELL,† M. AM. SOC. C. E. (by letter).—This paper, issued to the public on practically the twenty-fifth anniversary of the passage of the Federal or Newlands Reclamation Act, marks an epoch in Federal relations to internal development. During the quarter of a century that has elapsed there has been a notable change, almost a reversal of attitude, toward reclamation ideals. A broader interest is being shown on the subject of Federal financing of reclamation enterprises. Inquiries are being made as to the propriety of spending the taxpayers' money for such purposes.

The paper throws a ray of light upon what has been an exceedingly sensitive, not to say a sore, spot; one which politicians and promoters have tried to conceal or from which they have endeavored to distract public attention. In one sense it has been forbidden ground. Engineers of ability have not been continued in Government service because they have been too outspoken or, in the words of the politician, have "not been practical"; meaning that the so-called practical needs of a party group has not outweighed their loyalty to the best interests of the whole country. Their mistakes were in not quietly acquiescing in unwarrantable expenditures. They were prone to paraphrase a classic, saying, "Reclamation, how many economic crimes are committed in thy name!"

---

* Civ. and Hydr. Engr., New York, N. Y.
† Pres., The Research Service, Inc., Washington, D. C.

The crucial point is summed up in the statement, with certain qualifications, that State and National subsidy to irrigation is necessary; that it is justifiable and desirable; and that large reclamation works "will not be undertaken by unaided private enterprises." To put it another way, large-scale irrigation or reclamation of waste lands does not pay under existing conditions. In a similar sense it has rarely paid. Comparing the actual cost of reclamation with the productive value of the land reclaimed, making fair allowance for interest, depreciation, and overhead, the facts stand out that these great enterprises, with few exceptions, always have been and always will be financial failures. This point has been avoided or obscured by interested parties and a review of twenty-five years of experiment and research is just bringing it out. It is an anathema to the "practical" politician seeking larger appropriations of Federal funds. It is the rock on which otherwise brilliant engineering reputations have been wrecked and where the "powers that be" have erected a warning to "keep off; discussion of real costs may be followed by dismissal. The door is always open for your departure."

Facts have an unpleasant way of asserting themselves. The author has made a plain analysis of the situation and has brought forward again the statements presented in 1924 by the late R. P. Teele, notably those in *Bulletin No. 1257*. Until the present time, this *Bulletin* has not been given the appreciation it deserves.

Twelve years ago (1915), the writer tentatively presented a discussion of this matter under the title of "Economic Advisability of Irrigation",* but the time was not ripe. Striking examples were not available without violating official courtesies. It has been necessary for the "disease to run its course" so as to establish beyond dispute, facts now available to all who care to go into the broad subject of reclamation finances.

In order that what follows may be clearly understood, emphasis is placed on the fact that there is no apparent reason for disagreeing with Mr. Henny's qualified statement that "State and National subsidy to irrigation is justifiable and desirable".

The one fact in this connection that should be made clear, on which the spotlight should be continually kept, is that there should be no secrecy nor camouflage with respect to the amount and character of this subsidy. It is of interest to the taxpayers. The public in general should not be kept in ignorance nor misled as to the extent to which the taxes are increased, directly or indirectly. The subsidy is not wrong in itself; it may be a good thing; but it should not be concealed.

No culpability can be attached to the payment of necessary subsidies to irrigation or to other forms of reclamation, provided the public in general knows how the money is being used. No excuse should be tolerated for the activities of those interested in obscuring the facts; more particularly as in so doing, attacks are made on the ability of the engineers who have planned and executed the works of reclamation.

* *Transactions*, Inter. Eng. Cong., San Francisco, Calif., 1915. Waterways and Irrigation, Paper No. 35, pp. 371–397.

A condition has existed that has gradually aroused the indignation of engineers and lovers of fair play. This has come about from the fact that, in order to justify or secure the necessary subsidy of reclamation works and to bring about a partial repudiation of the monies advanced for them, the easiest course of procedure has been to attack the engineers under whose immediate direction the money was expended. The story (a reflection on local political ethics) is simple, the details are familiar to those who have followed the history of Federal reclamation development.

The first chapter is that of eager importunity on the part of local land owners and their representatives for the expenditure of Federal funds. This is accompanied by a statement that no matter what reclamation costs the lands will be worth it and the owners will cheerfully repay it.

The second chapter is of popular enthusiasm, praise of the engineers and their operation, accompanied by urgent appeals to Washington that the works under construction be built in the most permanent manner regardless of cost; that the reservoir dams be raised; the capacity increased; the canals made larger; and ditches built to every farm.

The third chapter opens with the practical completion of the works, the turning of the water to the fields and the beginning of the time of repayment. Then comes the condition predicted by the late Speaker Cannon and other experienced politicians who fought the Reclamation Act. Their opposition was based frankly on the belief that when the time came to make payment to the Government the land owners would repudiate the claims. This opinion was based on a practical knowledge of human nature. These men were sure that the Federal Government could not collect from its citizens payments deferred over any considerable length of time. They had learned by experience that the only way for the Government to enforce payments is to have the cash in advance. The Post Office wisely demands payment before the mail is delivered; the Land Office, in contrast, shows a long list of unpaid claims, many of which have been subsequently cancelled by Congress.

While these statesmen (that is, politicians who have departed this life) clearly foresaw the ultimate conclusion, they did not point out, and, in fact, nobody appreciated, just how this amelioration of debts (not to use the harsh term "repudiation") might take place. Least of all did the engineers look forward to the treatment that was to be handed to them in the efforts to make them the scapegoats. No sooner were the terms of payment announced, however, than the same men, (the local land owners, bankers, and politicians, who had been urging that the engineers be instructed to do more work and make larger expenditures) reversed their position. Then began the long and heartbreaking campaign of attack which resulted in driving from the public service many able and conscientious engineers, technical assistants, men and women.

This is not the time nor the place to discuss matters of human and ethical relations, but they have peculiar interest to engineers in public employ, illustrating the fact that the moods of the public must be taken into account and studied with the same degree of care and impersonal attention

as problems of fair and stormy weather, or drought and floods, which may destroy engineering works. Equal or greater destruction can come to the engineer and his organization through changes of public sentiment.

The doubts, censure, and personal abuse heaped on the engineers following the attempt to secure repayment from the land owners was naturally accompanied by investigations. No one has attempted to keep an accurate record of them, but the Fact Finding Commission has referred to several hundred, big and little. Some were notably expensive, not merely in the time and money involved in digging into every detail, but in distracting the attention of men in executive charge during times of the greatest stress, when every effort should have been concentrated on efficient work. It is literally true that men in direct charge of Federal reclamation projects, as well as their principal assistants, have worked night after night through long periods, assembling and re-assembling data called for. Under the strain of continued attack many a good engineer has broken, or has lost his temper at what to him has appeared the most ridiculous of accusations and demands. For example, one prominent Western Senator (now deceased) called on the Department for a list of all foremen employed on the works. No explanation was given; nor was the term "foremen" defined. At that time there were several thousand names on the payrolls, some designated as foremen mechanics, foremen carpenters, and every kind of similar designation currently used by contractors. The assembling of pay rolls and the careful scrutiny to distinguish between men who might be considered as foremen, required notable labor at a time when every effort should have been concentrated on keeping ahead of the floods and the demands for water. It is doubtful whether the Senator who asked for it even looked at the list.

This incident merely illustrates the conditions under which the Governmental forces have been compelled to work since the time the land owners were required to begin to make payment. It also illustrates the author's point that it is important to sever politics from business in the administration of this Governmental subsidy.

The question at issue is not as to whether a subsidy, as such, is a good or bad thing, but as to the misunderstanding which surrounds it and the importance of clearly bringing out, at all times, the amount and character of it. There is need here for unqualified clearness of statement; it is where the politician is most solicitous and most clever in concealing the facts. He is able to confuse the issue by a somewhat clever juggling of words. He uses the word "farmer" on all possible occasions, stressing the hardships and sufferings of the pioneer, and then the public is generally willing to expend its money freely.

Bear in mind the fact that the Government, in carrying out its reclamation policies, is dealing not with farmers as such, but with land owners. These land owners may or may not be farmers in the true sense of the word. The fact that they claim to own a piece of land which may be farmed, does not make them farmers. Possibly 40% of these land owners are non-resident. The hearings before the House Committee on Irrigation have shown that on

the Government projects—to a greater extent than on private projects—the claimants to land ownership range down the alphabet from actors, bankers, and carpenters to undertakers, veterinarians, watchmen, and zoologists. Every occupation is represented; unfortunately, there is not a preponderating percentage of men who would qualify under a strict test as real "honest-to-goodness" dirt farmers. Such men are usually too wise to undertake this kind of pioneering. They prefer to wait until the hardship and the uncertainties of the life of a pioneer have past, knowing full well that, when true land values are established, they can buy a good farm, carefully selected with reference to climate, crops, and market, practically at less than real cost.

The men who seek to enter on public lands that may be reclaimed, are necessarily adventurous and certainly optimistic and imaginative. They are not held back by the dictates of experience and, as a rule, have little anticipation of remaining long in the new country. They are usually attracted by the hope of getting something for nothing and of realizing the pioneer profits. This is no reflection on them. In fact, they are what are called "typical Americans", willing to take a chance, risking comfort and even the health of their families and themselves, looking forward to something better; each doing his part according to his ability.

The turnover in ownership is large. It is popularly stated that there are at least three successive owners before a relatively permanent home is established. This means in the aggregate large individual losses with occasional gains. Each successive owner has usually contributed something in the way of buildings and labor, more or less intelligently applied, adding to the real or productive values thereby. Sometimes, however, by careless handling of the water, the land itself has deteriorated, or become impregnated with salt or alkali; about 20% of the land has thus been injured.

The popular remedy proposed is that which occurs at first to every one, namely, that the ordinary run of citizens should not be permitted to exercise their individual discretion, but should be required to pass careful scrutiny before being permitted to enter on public land reclaimed or reclaimable by Federal funds. This is fine. As a practical thing, however, there are not enough applicants or purchasers to permit this kind of selection. It has been tried at various times and under various conditions without notable success. In fact, it comes down to this: That any man who has the faith and courage to enter on such an undertaking is more than welcome, and his shortcomings are excused. Moreover, experience with thousands of families shows that sometimes success has been made by the most unpromising specimens and, on the other hand, deplorable failures have been made by men who have come on the project with plenty of money and all the qualifications specified in an approved rule of procedure. It is the intangible, the mental attitude, a thing which cannot be measured by ordinary standards, that has resulted in success or failure.

While these changes in land ownership are taking place, on a Government project as contrasted with a private enterprise, there is a steadily increasing pressure for relief. Every one is heavily in debt, the bankers, to a certain

extent, are desperate over the outlook; the local politicians advertise in speeches and in broadsides that if elected they will work for relief to the land owner. They are elected on this platform. As a result Congress, year after year, has granted substantial relief. It is true that this is not the kind of repudiation predicted by former Speaker Cannon and others, but the effect is similar in that the whole amount of money advanced by the Government is not repaid. It becomes in effect what Mr. Henny describes as a subsidy and one that is partly necessary. It is not a matter to be grieved about, nor ignored; but fairness to the taxpayers of the country demands that the extent of it should not be concealed; nor should it be forgotten that private enterprise, which has reclaimed ten times the area of Federal enterprises, has had no such relief.

At present, it is peculiarly important that the public be taken into full confidence on this matter. The time is arriving when large claims on the public purse will be made for further engineering works in connection with reclamation. The Colorado River interests are demanding not millions but tens of millions of dollars. The land owners in the Columbia Basin are well organized in their demand for hundreds of millions. In fact, it is now the fashion to speak in terms of hundreds of millions when dealing with the subject of water control and development.

The cost per acre has caused several great reclamation projects to be rejected again and again; but they are still coming forward with ingenious schemes for repayment of costs (otherwise prohibitive) on the basis of a small percentage continued through several generations. Incidentally, of course, few seriously believe that Congress will ultimately insist on these large repayments, but will follow the well-established precedent of passing annual relief bills.

On top of these demands from the West, for the construction of large irrigation works with which to reclaim desert land, there comes the still greater and more urgent demand for the entire Mississippi Valley for immediate expenditure of hundreds of millions, not to extend the agricultural area, but to save that which has already become highly developed. Then, too, added to the demands of the people upon Congress, is the unsolved problem of the St. Lawrence River; the coastal or Atlantic inland waterways; the future of the Rio Grande; and the great host of flood protection, hydro-electric developments, such as Muscle Shoals, Great Falls on the Potomac, and other schemes stimulated in every part of the country. The advocates of all these are earnest, enthusiastic, and effective. The lobbies in Washington have never been so well organized and well financed. Lobbying, as such, is recognized as a necessity; even "an essential industry", in that it is impossible for the great body of Congress to understand the problems involved.

Engineers now have an opportunity to turn their attention, for a time at least, to these financial matters (pointed out by Mr. Henny) so that they will not be uninformed or swept off their feet and that the economists may be able to perform a larger notable public service by weighing the costs and benefits of the many great enterprises presented for public approval.

J. C. STEVENS,* M. AM. SOC. C. E. (by letter).—This paper presents, in condensed form and in a very sane and rational manner, the present status of irrigation institutions in the United States. It is a sort of "looking backward" on the past 50 or more years of irrigation successes and failures.

One outstanding fact about the work of the U. S. Bureau of Reclamation deserves emphasis. To June 30, 1925, twenty-three years after the passage of the Reclamation Act, more than 82% of all monies due for construction charges and nearly 81% of all maintenance and operation charges had been paid into the United States Treasury by the settlers on the various Government projects.

When one considers that much of this work was pioneering in nature, often handicapped by lack of physical data, and hindered by political maneuvers, he must concede to Government reclamation a measure of success, equal if not superior to most corporate and private enterprises.

Another feature the author could well have included in his summary is that sound financing demands that all elements of cost be studied in advance. If drainage is essential, and it frequently is, it must be included. If settlers are to be furnished with land that has been leveled, ditched, and fenced; upon which houses have been built and implements and stock supplied; if expenditures are contemplated for colonizing; if the project must be "carried" until it is sufficiently settled to pay operation costs; these items must be included in the budget of the developing organization.

If the settlers are known in advance to be unable to meet all the items of cost, then their probable payments must be fairly estimated and the balance considered in the nature of a subsidy or carried over into an account to be amortized at some future time when the project shall have become a well ordered going concern. Many of the failures may be traced to an unwillingness on the part of the developing agency to reckon with or even inquire into these extraneous elements of cost.

The term, subsidy, is too often taken to mean cash payments, whereas it really means any aid to an enterprise for public convenience. All Federal Reclamation projects are subsidized to the extent that no interest is charged on deferred payments for construction costs. In general, such subsidies are more than repaid by the general increase in taxable values resulting from conversion of raw to productive lands.

The author's Conclusion (*d*) that "the irrigation district method is not well adapted to the reclamation of large areas of desert land", must be considered in the light of the text of the paper regarding Class B lands the initial value of which is less than the funds that must be provided for reclamation.

While it is true that in the aggregate large areas of raw land distributed over a multitude of projects, have been successfully reclaimed by the irrigation district method, it is doubtful whether this method would have been successful had all these projects been thrown into one.

Settlers have diverse individual tastes and desires, and no one project or one locality will suit all. It is practically certain, therefore, that the coloni-

* Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

zation of a multitude of smaller projects, scattered throughout the West, has generally proceeded much more rapidly than if these areas were concentrated.

The success of any enterprise for the reclamation of raw lands hinges finally on the ability to colonize it to a point where interest and operating charges may be met. Failing this the "carrying costs" will wreck almost any private or district organization. They could only be met by Federal funds the use of which would thus constitute a form of subsidy.

The writer thinks the author could well modify his Conclusion (*d*), previously mentioned, to read: "The irrigation district method is not well adapted to the reclamation of large projects of desert land".

R. P. Teele,* Esq. (by letter).—This paper agrees so completely with the writer's views† that there is little occasion to add anything to the author's discussion. It is needless to take the space to re-state points of agreement, but it would be well to discuss a few other points.

In his opening paragraph, Mr. Henny states that the West is dependent on irrigation for its development and, that "it must grow the bulk of its own food requirements to permit industries to enlarge and its resources to be developed." The implication is that the West needs more irrigation to provide its own food requirements. Yet, in the arid region, there is not one section that contains a large irrigated area that does not have to go outside to market its principal crops. In traveling over several of the larger projects, it will be found that a conspicuous feature of the local news everywhere is the number of cars of products that have "rolled" to outside markets. The point is that the bulk of the land now irrigated, is not used to produce a local food supply, nor will the bulk of the land reclaimed in the future be used for that purpose.

Mr. Henny argues, as do many others, that additional reclamation should not wait on higher prices and an actual demand for products, because it takes several years to develop a large irrigation project. In referring to the Census figures for 1920 and 1925, he gives an effective rebuttal of his own argument. He gives Census figures showing a decrease of 31 000 000 acres in "improved land" during the period 1920 to 1925. That land went out of use because of low prices. Most of it, and much other land, can and will come into use with higher prices. That 31 000 000 acres will act as a shock absorber and give ample time to build a few new projects before the shortage of tillable land becomes acute, even if the projects are not started until the pressure is felt.

It is difficult, if not impossible to follow Mr. Henny's reasoning in his discussion of the insistent demand for further reclamation in the West, when he states that:

. "The demand, moreover, is for new projects on an increasing scale of magnitude and is so general and unanimous that it cannot logically be ascribed to motives reminiscent of 'pork barrel' appropriations."

* Agricultural Economist, Bureau of Agricultural Economics, U. S. Dept. of Agriculture, Washington, D. C. Mr. Teele died on August 31, 1927.

† *Bulletin No. 1257*, U. S. Dept. of Agriculture, 1924.

It will be recalled that Congress recently provided for writing off about $27 000 000 of construction costs on Government projects and extended the period of repayment of construction charges from 20 to 40 years without interest, and that a committee was appointed to hear arguments for revising existing contracts on the ground that farmers cannot meet their payments.

Mr. Henny supplies the explanation of the "general and unanimous" demand for new projects and the refutation of his own statement:

"The comparative ease with which these and other relief measures were secured from Congress, the fact that not in a single case, even after the passage of the newer Acts, has the Government enforced collection by foreclosure under lien, and the ready encouragement of farmers' demands by Congressmen, have had an unfortunate effect on the psychological condition * * *."

He takes issue with the writer's arguments against a National subsidy to land reclamation, quoting: "There is no justification for a National subsidy to land reclamation. If local interests justify the subsidizing of land reclamation the subsidy should be local;" and states that he believes it is "too sweeping." This belief is justified and the statement should be modified by limiting it to the present time. This matter has been discussed more fully in a book by the writer.* There, it is suggested that the cost be spread in proportion to the benefits. After discussing the lack of correlation between demand for additional reclamation and the need for the products to be grown, the writer states:

"The real problem for the future of reclamation is the devising of a policy that will so strengthen that relation that it will control the rate of expansion. The most effective means of accomplishing this will be to attach financial liability to demand. That is, let those who demand the undertaking of a reclamation project assume an effective liability for the cost. This can be accomplished through the district system already utilized to a considerable extent in irrigation and almost exclusively in drainage reclamation by providing for including in districts not only the land to be actually irrigated or drained, but also the territory to be benefitted indirectly, including cities and towns in the vicinity. The extent of each district should be determined by conditions in its particular case, and, in theory, cost should be apportioned in proportion to benefits, although this is an extremely difficult task in practice.

"The apportionment of cost in proportion to benefits should be a fundamental part of our reclamation policy of the future, if there is to be any public participation in reclamation. This policy can be put into effect * * * by having districts formed under public supervision and including within them all the property that will be benefitted, not overlooking the towns and cities whose chambers of commerce are so active in demanding the undertaking of new enterprises; and requiring the approval of the districts by the counties and States if there are to be county and State contributions; and by Congress if there is to be a Federal contribution.

"Certainly, if reclamation is to be undertaken because of public benefits, the reclaimed land should not be expected to repay the whole cost.

"Such a scheme is susceptible of universal application. If it appears that there will not be such a general benefit as to justify the inclusion of

* "The Economics of Land Reclamation," by R. P. Teele, The A. W. Shaw Co., Chicago, Ill., 1927.

any land outside of that to be reclaimed, the boundaries can be fixed on that basis, and the reclaimed land alone will be liable for the cost; if only lands in the immediate vicinity will be benefitted, the boundaries can be fixed on that basis; if the benefit is county-wide, counties may undertake reclamation; if it is State-wide, the States may undertake it; and if the benefit is interstate, interstate districts may be created."

This shows what the writer meant by local subsidy. Mr. Henny compares land reclamation subsidies to railroad subsidies, rivers and harbors subsidies, and the protective tariff. There is one very important difference that he and others usually overlook. The railroads are public service corporations and furnish service to all who may have occasion to use them; the rivers and harbors and highways are open to all who may pass that way; and the tariff affords protection (if it does) to any one who may produce the protected article; while an irrigation system supplies water to designated lands and to no other lands. The immediate benefit is to those lands, and the owners of those lands have exclusive use of the water supplied. The public has no right whatever to its use.

J. L. Burkholder,* M. Am. Soc. C. E. (by letter).—This paper is of timely interest to every one having the welfare and development of the Western United States at heart. Under present conditions, and under irrigation district methods, it is almost impossible to finance large irrigation developments. There is an apparent lack of demand for new farms, and it is doubtful if projects, requiring settlement of people on the land, should be recommended for construction at this time. This fact, and the recent criticism of the Federal Reclamation Bureau and the apparent inability of some of its projects to meet construction payments, certainly indicates that irrigation problems should be given thorough study.

The paper has listed the various agencies heretofore utilized for accomplishing irrigation work as follows: (1) Federal; (2) State; (3) Carey Act; and (4) irrigation districts. The last of these agencies is divided into two general groups; (A) districts with land values greater, and (B) districts with land values smaller, than the face value of the proposed bond issues. The first-mentioned districts have been generally successful.

It may be of interest to note that New Mexico has recently organized a large district, under the Conservancy Act of the State of New Mexico, which closely follows the Conservancy Acts of the States of Ohio and Colorado. Ohio and Colorado used the conservancy form of law to accomplish flood-control work. The Conservancy Act of New Mexico has been adapted to the purpose of accomplishing flood control, irrigation, and drainage. This experiment with a fifth agency has heretofore not been tried.

The project extends along the Rio Grande from the Elephant Butte Reservoir on the south, to White Rock Canyon on the north, a distance of about 150 miles. The district is known as the Middle Rio Grande Conservancy District. This District would fall into the general group of "A" Districts, considered by Mr. Henny, because the land values are greater than the face value of the proposed bond issues. The organizers of the District had

* Chf. Engr., Middle Rio Grande Conservancy District, Albuquerque, N. Mex.

in mind that the conservancy form of law was better adapted to the local problems than the irrigation district methods, for the following principal reasons:

(1) It provides for the "benefit method" of assessments, which insures that the municipalities and corporations, affected by the proposed work, will be required to pay a fair share of the cost thereof. The flexibility of this method of assessing costs is also well suited to take care of the great variation in local soil and irrigation conditions;

(2) The law grants wide powers to the district, including the police powers of the State;

(3) The preparation of an official plan is required prior to the authorization of the work by the District Court. This Court, sitting as a Conservancy Court, either approves or disapproves the plan, after holding hearings thereon. If the Court approves the plan, it then holds hearings on the appraisals, and when these are confirmed, the District may proceed to issue and sell bonds.

The work of the Middle Rio Grande Conservancy District has not proceeded far enough to offer proof of the superiority of this form of law for accomplishing reclamation problems, but the writer believes that many advantages are gained under such a law, especially where the contemplated work includes a variety of features.

Perhaps, one of the difficulties that have surrounded irrigation development, under all the agencies utilized to date, has been the limitation of the powers of that agency. Some degree of flood control and river protection is a common need in many of the irrigated valleys. Drainage is now known to be necessary for protecting practically all irrigation developments.

Drainage and flood-control works may directly benefit municipalities and corporations as well as lands, and the problems involved are properly a part of the general reclamation scheme, including irrigation. As a rule, these features are so connected and inter-related that they can only be solved in the most effective and economical way by considering them as a single problem. The Conservancy District agency seems to offer many outstanding advantages for accomplishing reclamation work, involving irrigation, flood control, and drainage features. One of these is that all property that is benefited is taxed, not only the agricultural lands.

The success or failure of some irrigation developments to repay construction costs is judged entirely by an artificial financial status, which in no way represents the actual wealth created by the project. The time element of the repayment period has been an entirely arbitrary one, yet projects are classed as failures unless repayment is made within the period set. For these reasons, it may be pertinent to examine the question further before pronouncing sentence as to success or failure. Perhaps, if proper standards are set up, there will be more successful projects and fewer failures. Undoubtedly, some projects that are now pronounced as failures, will be adjudged successful after the early losses are absorbed.

Many of the private companies effecting irrigation work in the South Platte Valley, near Denver, Colo., became bankrupt in the early stages of the development. This District is quite successful at the present time, and the

City of Denver, and many prosperous smaller towns depend quite largely on the wealth created by the irrigation of about 1 500 000 acres in this vicinity.

Furthermore, it seems evident to the writer that the recent depression in irrigated farm values is largely the result of the general slump in value of farm products. This slump has affected land values in all parts of the country; in humid areas as well as in irrigated sections.

The Federal Reclamation Acts provide that the total cost of the projects shall be repaid by the benefited agricultural lands. Many cities and towns have developed and prospered along with the irrigated farms as the direct result of Government irrigation. Among the largest of these are El Paso, Tex.; Phœnix, Ariz.; Yakima, Wash.; and Boise, Idaho. The taxable wealth in these cities, and the many smaller communities on reclamation projects, is in no way a resource of the project and, yet, irrigation is responsible for the major part of the wealth represented by them.

Another case of wealth, created by irrigation, is the profit taken by individual land holders who sell before repaying their construction charges. Large and even excessive profits have been taken in this way from practically all large irrigation developments. The purchasers may now be having difficulty in meeting repayment costs and interest on the high price paid for the land, but the seller is enjoying the full profit. It is the rule, on all Federal projects, that the lands are commonly bought and sold without any account being taken of the unpaid construction charges.

On the Rio Grande Project, New Mexico and Texas, certain flood-control work is now being done by the City and County of El Paso. It is doubtful whether the Government could have accomplished this work under existing laws, but it is a normal phase of the Government's work. The Elephant Butte Dam is affording protection against floods in the City of El Paso; yet, no charge could be made against the municipality.

The original Reclamation Act contemplates only the development of large desert land areas owned, in part at least, by the Government. If irrigation development under Federal direction is confined to such areas, subsidies from the State or National Government are justifiable as offsets against the taxable wealth created by the development, which cannot be directly assessed for work accomplished. Federal development of desert land areas should be continued as fast as additional farms are in demand.

Federal reclamation has not been restricted to such developments, however, and, in some instances, the result of this has been an unequal distribution of the assessed cost of construction. If the Federal Government is to continue a program of reclamation that is suited to all the reclamation problems of the Western United States, the existing laws should be changed to permit greater flexibility and a wider scope of accomplishment. This should include drainage and flood-control work. The necessity of increasing the scope of Federal Reclamation may be open to question because many drainage and flood-control projects have land values greater than the cost of the proposed improvement. When this is the case, it is usually possible to finance work at favorable terms, and progress may thus be made through district organizations without help from the National Government.

MORROUGH P. O'BRIEN,* JUN. AM. SOC. C. E. (by letter).—While Mr. Henny presents the immediate problems of irrigation finance in an admirable manner, it seems that some of the more fundamental aspects of the situation are well worth consideration.

Although the development of the western part of the United States will undoubtedly strengthen its position in the Pacific Ocean, it will hasten the time when the population will be pressing against the limits of the available food supply. Mr. Raymond Pearl has predicted† that within a hundred years, the United States will have reached a point in the expenditure of its natural resources and food supply comparable to the present conditions in Europe. The time will come when it will be necessary to develop the sections of the arid States that are suitable for irrigation, but any premature development means economic waste, because the present available wealth would be used in an unprofitable venture. By a "premature development" is meant any improvement completed before the price of the products yielded by that improvement is sufficient to pay all the cost plus the compounded interest.

Contrary to the usual belief, an increase in the food supply per capita with a consequent reduction in prices is not a permanent benefit because, as Malthus has shown quite conclusively, the population immediately responds to this stimulus and in a few years the average condition is about the same as before the change. Previous to the introduction of mechanical industries into Germany, the population was very close to the maximum that the country could support as long as the inhabitants remained predominantly agrarian; but with the advent of machinery and the development of foreign markets for their goods, the population entered upon another cycle and is now approaching a second peak. Such fundamental changes will undoubtedly occur in the future, but it seems to be rather bad policy to depend on them to maintain a high standard of living. If the great areas of the West are developed only when they are necessary (and the evidence of such necessity should be their ability to pay for themselves) the period of general prosperity will be prolonged. Predictions as to the maximum population that a country can sustain are somewhat futile, but it can be stated, with a considerable degree of certainty, that at some future date the population will have reached a point where a considerable portion of it is barely able to sustain life. Such a condition has always led to wars of colonial conquest—for a "place in the sun"—and although the American national conscience has been against the acquisition and permanent retention of foreign colonies, a change is indicated by the attitude of the United States in dealing with the Philippines and Nicaragua. This country will probably, at some not very distant date, enter the competition for the sparsely inhabited regions of Asia, Africa, and South America.

That the irrigation of a few hundred thousand acres of arid lands is immediately going to involve the country in wars and misery is, of course,

* Toledo, Ohio.

† "The Biology of Population Growth."

ridiculous and it is not the purpose of this discussion to advance any such proposition. However, before deciding to construct projects of such magnitude as those proposed for the Columbia and Colorado Rivers, the question should first be decided as to whether they are really desirable at present or might better be held as a latent supply of wealth for the future.

When irrigation projects, of such magnitude that a single State or group of States cannot finance them, are found to be economically sound, Federal aid should be given, but only under conditions that safeguard the interests of the remaining States. It seems that the only equitable basis for such aid is that the States benefited, guarantee the full cost of the project plus the interest until the debt is paid. Although the principle of interest has been attacked from the ethical viewpoint by some writers, the fact remains that the Government pays interest on nearly all money expended, and this interest represents an important item of the total cost. A sum of money compounded at 4% will be doubled in about 17 years. If an irrigation project does not begin to pay off the original cost in that length of time, the cost to the Government is just double the original outlay. There seems to be no more reason for neglecting the interest charge than the original cost, although most writers on the subject regard the two very differently.

When it is remembered that most of the Federal irrigation projects have not paid their original cost and, in many cases, not even a substantial part of it, the demand for more projects hardly indicates their success, but shows a desire for more gifts from a benevolent and paternal Government. Naturally, the owner of arid land is anxious to have irrigation if all the increase in value will accrue to himself and the entire expense will be borne by the Federal Government. From a rather close observation of one large project, it would seem that for the most part the settlers were guilty of bad faith. When the project was completed, land values had increased to a point where an additional charge per acre for the cost of the project would have made a profit impossible and yet the land changed hands at this price. If this condition is not explained by sheer ignorance on the part of the buyers, it must have been due to a generally accepted belief that enough political pressure could be brought to bear to prevent the collection of the assessments.

In general, governmental expenditures for internal improvements should be put on a more equitable basis. It is sometimes argued that the prosperity of one section of the country reflects upon the prosperity of the whole. To say the least, this contention is difficult to prove, and it is certainly not true of competing regions such as California and Florida. It is extremely unfortunate that the "Sugar Bowl" region of Louisiana has been inundated, but it will be a little unjust if through sympathy a part of the cost of rehabilitation is placed on the sugar-beet growers of Ohio and Michigan, and this will be the result if the Government erects flood-protection works on the Mississippi without a guaranty that the States benefited will ultimately assume the indebtedness. Governmental aid to one of several competing districts without the definite obligation of repayment is doubly unjust, because it gives the one region an immediate advantage and, in addition, the cost of the improvement must be assumed in part by the competing regions.

D. C. Henny,* M. Am. Soc. C. E. (by letter).—The writer is under great obligation to the many distinguished authorities on the subject of irrigation for their discussions. He is gratified to find that the presentation of a paper, rather economic than technical in its nature, is commended; that it is not, for that reason, criticized; and that, on the whole, there appears to be fair agreement on the conclusions reached.

The reasons stated in the discussion for approval and resulting from greatly diversified experience and from viewing the subject from various angles, add great weight to the conclusions.

Mr. Hinderlider raises the question as to what is profitable farming. The writer believes that ability of the average industrious and intelligent farmer to raise a family according to reasonable modern standards and to keep out of debt, private or public, may be regarded as complete success even without accumulation of money. It is in this sense that the term, profitable farming, was used in the writer's Conclusion, (*a*) that "increase of irrigated area will and should be slow when and where crop prices do not render farming profitable". The Government, whether State or Federal, should not encourage, by subsidy, or otherwise, any increase of opportunities which would force a lowering of the standard of living for the average man.

Mr. Hinderlider questions the writer's conclusion that "the irrigation district method is not well adapted to the reclamation of large areas of desert land". In support of his criticism, he quotes developments in Colorado. He is far more familiar with Colorado conditions than the writer who cannot directly question the statement advanced that "many of the largest and most successful developments in Colorado have been effected under the original Irrigation District Act and amendments thereto".

The writer has some familiarity with conditions as they existed in Colorado thirty and forty years ago. At that time irrigation, after making great strides in the vicinity of Denver and Pueblo and on the Upper Rio Grande, all under private financing, received a severe setback through financial losses, partly resulting from the panic of 1893. Mr. Burkholder happens to refer to this subject where he states that, "many of the private companies effecting irrigation work in the South Platte Valley, near Denver, Colo., became bankrupt in the early stages of the development". The foundation thus laid was subsequently built upon by District organizations, which is quite another matter than starting reclamation from the virgin desert stage by District financing. Mr. Hinderlider does not state definitely to what extent the latter method by itself has proved successful in Colorado. The point which the writer tried to make is not refuted by the success which may at times have been achieved. The risk of failure is present in most cases to a high degree, as was well shown by the statistics compiled by the late R. P. Teele, and published and referred to in his discussion. It was also fully confirmed by other discussors of the writer's paper and also by the contemporaneous paper† of R. K. Tiffany, M. Am. Soc. C. E., and the discussions thereof.

* Cons. Engr., Portland, Ore.

† "State Reclamation in Washington," see p. 582, *et seq.*

The point is that the security at the time of bonding is practically all potential and that District bonds cannot be sold at reasonable figures unless the prospective buyer is kept in ignorance of the risk. The apparent necessity for concealment as well as the large percentage of failures which have resulted in such cases appear to the writer to furnish ample justification for his conclusion.

Mr. Hinderlider's argument in favor of turning over, at the earliest practicable moment, the operation and management of subsidized irrigation enterprises to District organizations, is fully concurred in and has for years been the process of the U. S. Reclamation Bureau in spite of frequent local opposition.

Mr. Grunsky argues that a Government subsidy consisting of any reduction from the full cost of irrigation, together with interest, is promptly absorbed by the land owner in the price he obtains for his land when he sells. This has been true for many years, but does not hold true for the last five years because of inability to sell at acceptable prices. It may also be stated that earnest endeavors are being made to counteract such absorption. One plan is to require of original land owners, before project work is commenced, an agreement that in case of sale the true selling price must be stated in the deed, in order to make a transfer legal and that at the time of sale, part payment must be made of water charges otherwise not yet due, in case the selling price exceeds a given base.

Other plans intended to hinder land speculation have been introduced by District organizations. The desirability of giving the ultimate farmer the benefit of the subsidy is fully appreciated and will probably in some manner and degree be realized in the future.

The writer is especially gratified in finding full support from Mr. Grunsky, Mr. Newell, and others of his contention that in case of subsidy the total extent of the commitment should, so far as practicable, be determined and made known. The difficulty of accomplishing this was forcibly pointed out by Mr. Newell in his statement referring to past policies as to Government officers, that "discussion of real costs may be followed by dismissal". The writer also is under popular disapproval in certain sections in the West for his insistence on this important requirement without which all subsidy becomes illegitimate and baneful.

Mr. Jacobs would prefer subsidy to be confined to the loan of funds for a long period and at a low rate of interest, 3½ or 4 per cent. He believes that "most of the projects that can be justified at all, can work themselves out to economic safety without the aid of any subsidy". Where this is true any subsidy, whether consisting of a low rate of interest, or no interest at all, is undesirable provided the time element is not seriously affected. The truth of Mr. Jacob's contention is, however, difficult to ascertain. It is certain that future expansion of irrigation will be greatly retarded if interest payments are insisted on and economic feasibility is determined by disinterested and well qualified men. It is an open question, however, to what particular extent subsidy should be granted at any particular time and place, and it is admitted that any type of subsidy is liable to serious abuse.

Mr. Dunham comments on publicity which unavoidably advertises contemplated Government activities. The effect of resultant land speculation is, of course, harmful and has been combatted so far as possible by withdrawal of public lands and by exacting contracts from present owners. Quiet accomplishment under methods flavoring of Secret Service is, however, believed to be impracticable as well as undesirable.

Mr. Newell reviews the history of the Reclamation Bureau from an angle which, even where it goes far beyond the original scope of the paper, makes his discussion a most valuable addition. His extensive experience leads him to approve the writer's conclusion that it is important to sever politics from business in the administration of a Government subsidy.

Mr. Stevens points out that if Government subsidies consist of the loan of money free of interest "such subsidies are more than repaid by the general increase in taxable values resulting from conversion of raw to productive lands". This is an incidental benefit of unquestioned value, but cannot in itself be an argument in favor of subsidy if it is unwise in other respects.

Mr. Stevens holds that the writer's summary should have included the necessity for studying all elements of cost in advance. Conclusion (*h*) ends with the words "total cost, including all items of present and future expenditure". This expression is believed to be sufficiently comprehensive.

He also suggests a change in Conclusion (*d*) to the effect that the ill adaptation of the irrigation district method to the reclamation of large areas of desert land should refer to large areas in single projects. This was intended to be the meaning and was so understood by others discussing this point.

Mr. Teele stated that irrigation in the West is not solely for the purpose of providing for local food production, and that a far smaller area than is at present irrigated could satisfy this requirement. This is quite true, but whether exported fruit or local food be considered the by-product, it is unquestionable that either is of benefit to the other and will permit profit at lower selling prices than if production is confined, in spite of suitability of land, to one or the other alone. The writer knows of no extended irrigated area devoted solely to production for export.

Mr. Teele in his interesting discussion further argued that 31 000 000 acres, which went out of cultivation during the period from 1920 to 1925, will act as a "shock absorber" when need for more agricultural products should become evident. This is believed to be the case to a far less extent than the acreage figure would indicate, as the greater part of this area is probably land, marginal because of being situated in the semi-arid belt and, therefore, without irrigation being capable of producing a limited character of crops, mostly cereals. When shortage of food shall first become seriously felt in the United States it will probably not be because of shortage of such products. It seems rather probable that, coincident with the gradual re-use of this area and in part preceding it, additional irrigation will be necessary to preserve a desirable balance.

Mr. Teele found the general Western demand for new projects was explained by the easing off in the enforcement of financial obligations accepted

by the farmers. This may be one reason, but it is by no means the predominant one. The demand generally results from the desire to realize on local assets supposed to be valuable, but now lying idle. It is probably made partly with the knowledge that past policies in this respect are changing for the better and mostly in ignorance of the exact showing made in regard to collections.

Mr. Teele further explained what he meant by local subsidy in his *Bulletin No. 1257*, U. S. Department of Agriculture, 1924, to the effect that this term did not refer to local government subsidy, but to a different method of taxation, including not only the land directly affected, but also interests indirectly benefited. In his book, "The Economics of Land Reclamation", it is recommended that cost be spread in proportion to benefits.

It is questionable whether the term "subsidy" is correct in such a case. A taxpayer does not ordinarily consider himself as a contributor to subsidy when he pays his improvement tax. However, the method of taxation on the basis of benefit has decided advantages whether in the case of irrigation alone or in connection with flood control and drainage, as was ably argued by Mr. Burkholder.

This method would make possible reclamation under the District bonding method where otherwise it would be of questionable legitimacy. It contains the elements of inherent justice. To the extent that its use is practicable and a fair division of benefits can be worked out agreeable to all interests it will reduce the need of Governmental aid. Mr. Burkholder correctly points out that this aid is inadvisable where it is not necessary. This method is likely to be on trial, as explained by Mr. Burkholder, on the Middle Rio Grande, and there is good reason for believing that it will work out successfully and that in many cases in this manner Class "B" Districts may be raised to the "A" class.

Mr. O'Brien enters into the wider field of the Malthusian theory. He argues that development in any section ahead of actual need of the whole country is premature and should not be countenanced, even if admitting that development of the West will strengthen America's position in the Pacific Ocean. If this theory had been applied during the earlier Colonial days, the United States would probably not extend beyond the Alleghanies. There would have been no free land grants on the part of the United States and no general encouragement of Western expansion. Subsequently, there would also have been no need of railroad land grants, food products having been relatively abundant ever since the first successful settlements west of the Atlantic. He believes that the United States should hold a large portion of the West as a reserve for future use. The writer holds that, ethically, the Nation cannot maintain a claim to any large portion of this continent against claims of other nations who may need it now, if held merely for future use. Many, especially in the West, may be misled by the urge of further early development, but they believe it to be founded on sound principles which dictate that the only right they have to the land they claim comes from occupation and beneficial use.

Mr. O'Brien considers that high living standards may become a peril in the future and, by implication, that they should be held lower to train Americans for effective competition in the future when population will press against the limits of food supply. Others, however, live in hope that science and experience may yet teach people how to ward off the fatal pressure against food limits otherwise logically predicted and to maintain and even raise living standards for all.

Mr. O'Brien advocates guaranty by States benefiting from irrigation development. If this benefit radiates from its center like waves in a pond, who shall say that it extends merely to an artificial delimitation of the pond and not to the shore line. Independent of this view it should be repeated that, comparatively speaking, Western States, in the money sense, are poor and that in the aggregate they contain an enormous area of Government land which receives benefits from all improvements, but pays no taxes. State aid, where extended, will probably have to be confined to help of worthy Districts in financial difficulties, origination of small new projects and assistance in colonizing large Federal projects.

In this matter of subsidy there is moreover apt to be an adjustment. The argument used by Mr. O'Brien would be even more effective if applied to the case of Government expenditures for the Harbor of New York, which surely benefits that wealthy city and State to a far greater extent than it does the West; also, to the case of tariffs which protect and benefit one industry more than another and all industries more than farming. The West is rather an inopportune section of the United States upon which to visit a strict limitation of Government aid, not applied elsewhere.

In various discussions, attention is called to the different nature of subsidy for the reclamation of private lands and subsidies, such as railroad grants, tariffs, and harbor improvement. This same point may be raised in connection with Mississippi River flood control. No one subsidy can be exactly like another, and the only question involved before it is granted is whether it is, on the whole, for the good of the Nation.

Paper No. 1667

STATE RECLAMATION IN WASHINGTON*

By R. K. Tiffany,† M. Am. Soc. C. E.

With Discussion by Messrs. James Rhea Luper, W. G. Swendsen, J. C. Stevens, O. L. Waller, Joseph Jacobs, F. H. Newell, and R. K. Tiffany.

That for many years the State of Washington has recognized the interest of the public in reclamation development is evidenced by many laws designed to aid and promote such development, and more particularly during recent years by the Reclamation and Land Settlement Acts of 1919, the Reclamation Bond Certification Act of 1923, and by the activity of the State in investigating and promoting the development of the great Columbia Basin irrigation project.

Reclamation, as the term is generally used, includes development for agricultural use of swamp, overflow, cut-over, and arid lands. Because irrigation is, and perhaps will continue to be, the predominant phase, this discussion will have chiefly to do with irrigation.

In irrigation development, Washington has passed through the various stages of evolution common to the Western States. First, the little private ditch, the partnership and community ditch, in both of which the development cost was low and the maintenance cost generally negligible. Later, came the stock companies taking up more ambitious enterprises, but the cost under these was generally not more than $10 to $20 per acre and the maintenance cost correspondingly low.

Thus far, all development was by the land owners themselves and without expectation of profit from the irrigation plan, as such. In the Nineties came

* Presented at the meeting of the Irrigation Division, Seattle, Wash., July 15, 1926.
† Superv. of Hydraulics, Olympia, Wash.

the promoters, financed by Eastern capital, attracted by a paper-showing of tremendous profits on the investment in irrigation works.

Following these projects came the first serious disappointments. The panic of 1893 checked the stream of westward immigration, thousands of acres of land under ditch lay idle, and operating costs on the small areas under cultivation, together with interest on the large investments in land and canal systems, soon brought financial ruin to practically all these enterprises. In later years, most of them were re-financed and have become rich and prosperous districts, but the initial investments were largely lost.

The topography of the irrigable lands and the river valleys of Washington differs from that of most of the Western States. The streams flow in deep, narrow valleys so that the building of the larger irrigation systems involves expensive construction in the way of tunnels, bench flumes, and pressure pipes. The large bodies of land irrigated and irrigable, with the single exception of the Yakima Indian Reservation, lie on benches at considerable elevations above the river valleys and are generally rolling and steep as compared with the plains of Idaho or the gentle slopes of the Salt River and Sacramento Valleys, and most of the other larger irrigated areas of the West. To overcome this combination of physical difficulties means necessarily high cost for the irrigation works. Of the remaining projects in the State of Washington on which careful estimates have been made the construction cost, exclusive of storage, will range from $100 to $150 per acre.

It was the experience of private corporations in the early development and the high cost of all remaining projects which brought the realization that there is little chance of additional irrigation development in Washington by private capital; and at the close of the World War, with good prices generally prevailing for farm products, with the good lands under existing ditches practically all producing, and with apparently a steady increase in demand for irrigated land, Washington, in 1919, enacted a State Reclamation Law. The object of the Act is declared to be,

> "To provide for the reclamation and development of such of the arid, swamp, overflow, and logged-off lands in the State of Washington as shall be determined to be suitable and economically available for reclamation and development as agricultural lands, and the State of Washington in the exercise of its sovereign and police powers declares the reclamation of such lands to be a State purpose and necessary to the public health, safety, and welfare of its people."

A State Reclamation Board was created consisting of the State Commissioner of Public Lands, the State Treasurer, the State Hydraulic Engineer, the State Commissioner of Agriculture, and the President of the State College. This Board was afterward replaced under the new administrative code by the State Department of Conservation and Development. A State Reclamation Service was authorized and a Reclamation Revolving Fund was created by the levy of a tax of 0.5 mill on all taxable property in the State.

The plan of operation provided that the engineer of the State Reclamation Service should investigate projects brought to its attention and that, if found

feasible, the Reclamation Fund should be used to purchase the bonds of properly organized irrigation districts, the construction of the works to be under the supervision of the Department, the bonds to be resold whenever they should become salable in the general market.

In the six years following the passage of the law the State Reclamation Service was extremely active, first, investigating new projects, and, later, when it appeared that there were very few projects that could safely assume the burden of repayment of the estimated cost, the activities were largely transferred to investigation and aid of old projects which were in need of additional funds for rehabilitation or extension work.

All told, about forty irrigation, drainage, and diking projects have been investigated. The State has purchased the bonds of sixteen projects to the amount of approximately $1 462 000. Of this amount the bonds of ten districts, aggregating $516 000, have been resold, practically at cost, no addition being made to cover administrative expense. Bonds of eleven districts to the amount of $946 000 are still owned by the State. Of these, $425 500 in value are considered as probably good, $316 500 as doubtful, and about $204 000 as almost certainly a total loss.

In addition to the actual purchase of bonds, advances have been made by the State to various districts for investigation and construction expense which, up to September 30, 1925, amounted to $840 000. These advances, for the most part, were made under contracts with the districts for repayment in bonds. The two principal items of these advances are $73 160 for investigation of the Methow-Okanogan Reclamation District, the repayment of which is doubtful on account of the high estimated cost; and $741 000 for the investigation and construction of the Whitestone Reclamation District, of which at least $500 000 must be charged off on account of insufficient water supply. The total loss during the first six years' operation of the State Reclamation Service on account of investigations and construction is likely to be between $777 000 and $1 093 500—this from a total investment of $2 200 000, or at the rate of 35 to 49 per cent.

Of the twenty-two projects which were fully investigated and partly or wholly financed by the State Reclamation Fund, five were aided in investigation only. Of the remaining seventeen projects, five only were new projects, the other twelve involving rehabilitation or extension of old privately owned systems. It is obvious that some of these projects were approved rather from a sympathetic motive to settlers on the ground than from any consideration of merit. Some of the heaviest losses may be traced to this cause.

The heaviest single loss is on a project which had been developed privately to serve about 800 acres and which was projected to irrigate more than 8 000 acres at a total estimated cost, including two years' interest, of $900 000. On this project, reports of competent engineers calling attention to the inadequacy of the water supply, were completely ignored, and the project was laid out and about 90% completed on the basis of serving about 8 300 acres. In September, 1925, after a comprehensive study of water supply and of storage possibilities, a board of engineers recommended the reduction of the project

to 2 500 acres located in certain definite divisions, and after classification of the lands in these divisions, the District Board of Directors, with the unanimous consent of resident land owners, took action to reduce the area to 2 207 acres of irrigable land.

Two other projects of about 1 000 and 3 000 acres, respectively, are placed in the doubtful class because, although intrinsically good, they are remote from markets and were apparently built in advance of demand for the land. Efforts are now being made by land owners, bond-holders, and various local interests to secure settlers for these projects. If these efforts are reasonably successful within the next year or two, these projects may be placed on a paying basis.

Results of operation under the State Reclamation Law to date (1926), have brought a sharp difference of opinion as to the wisdom of the State continuing in the business of reclamation. Those in favor of continuing point to the beneficial results of the State's assistance to many projects at times when it was practically impossible for them to secure funds for essential reconstruction or additional water supply through the usual banking channels. In passing, it should be said that this aid to "lame ducks", although no doubt beneficial, was not within the intent of the original Act and should not be the controlling factor in determining future State reclamation policy.

Opponents of the idea of State reclamation point out that it is unfair to tax present farmers to provide additional market competition for their products, prices for which in recent years have not been even fairly remunerative. They also point to the heavy losses to the State by reason of its venture in reclamation.

A Special Committee of the State Legislature was appointed at the Special Session in 1926 with instructions to study results of State reclamation to date and to report on or before October 1, 1926, with recommendation as to a future State reclamation policy and program.

The recommendations made by the Committee are as follows:

"1. That the laws with respect to reclamation and land settlement be retained in the statutes of the State of Washington. That the organization of the department be continued for the purposes of study of resources of the State, possibilities of successful reclamation, and for co-operation with the Federal Reclamation Department in the proper development of projects which have been undertaken by the Federal Government within the State. That depository interest and bond interest on moneys in the reclamation fund be conserved within the said fund to replace losses which have accrued and to defray the administration expenses of the department.

"2. That the State department do not undertake the financing of construction on large new projects or projects which have failed in attempted development by private capital.

"3. That the department consider the possibilities of assisting in the internal improvement of proven and successful reclamation projects by investment in the bonds of such districts, and assistance in marketing same at as low a rate of interest as is possible.

"4. That the reclamation fund levy be suspended for a period of two years, as was done at the last session.

"5. That the State co-operate with the Federal Government in affording such assistance as is required by the Federal Government and is within the

power of the State to render in and about the construction and development of those reclamation projects definitely approved by the Federal Reclamation Department."

It is of the greatest importance that this problem be considered carefully and without prejudice, having in mind not only the results of past operations under the law, but the probable future needs of the community for reclamation development, and possible alternative means of meeting such need through State, Federal, or private agencies.

It will be conceded by friend and foe alike of State reclamation that the State of Washington eventually will need all possible development of her agricultural area. Her rapid industrial and commercial development during the past few years, with promise of still more rapid growth in the future, based on her native resources in raw materials, her abundant and cheap water power, and her accessibility through maritime commerce to the raw materials and markets of all the countries bordering the Pacific, is sure to demand reasonably steady development of her agricultural possibilities.

Past experience and the magnitude and high cost of the undeveloped reclamation projects in the State will make it difficult, if not impossible, to interest private capital in these enterprises. Under any plan thus far put forth, the interest charges plus the operation and maintenance deficit during the development period will constitute a burden greater than can possibly be borne by the producing area during the earlier years. Investment bankers have learned from bitter experience that this means default in interest payments, hence the impossibility of interesting private capital in this type of development.

It appears that some public agency must assume the responsibility for carrying the larger irrigation projects through their development period. The United States Reclamation Service has been thus carrying projects ever since its inception. The State of Oregon has carried some projects through loans or direct appropriations for payment of bond interest. Is there any means other than State or Federal subsidy of building the remaining large projects?

One plan that has been suggested is that the county or counties that would benefit most directly from the development of a reclamation project should be organized into a district somewhat along the lines of the Miami Conservancy District, which would carry the burden of interest and of operation and maintenance deficit until the project becomes self-supporting.

An underwriting agency of this character might undertake complete development, or it might become responsible for a definite part only, as, for example, the necessary storage works. In some cases benefits other than for irrigation, such as flood control or power, might largely or entirely cover the cost of storage development. Such a plan, although theoretically workable and, in some cases, justifiable by reason of indirect benefits to the underwriting territory, would contain elements of difficulty and danger. If otherwise practicable it should be supported by provisions that would give to the underwriting district complete control of land development in the project so that this

development should come in progressive blocks rather than in scattered units throughout the project, based on individual ownership.

This calls for a consideration of some of the fundamental weaknesses of the present irrigation district law as a means of developing large irrigation projects. Like the district laws of most Western States, the Washington law is based on the old "Wright" Act of California, which was undoubtedly framed to meet the needs for financing groups of actual farmers and settlers who were, as a rule, occupying and farming the lands for which irrigation was sought. Under such conditions most of the land would become productive within a short time and might reasonably be expected to bring returns sufficient to meet both interest and other irrigation charges.

In the attempt to apply this law to larger projects, however, difficulties and reverses have developed. Lacking actual settlers ready to make use of the land and water, there has often been a scattering and haphazard development requiring years to bring the project to a position in which operating charges and interest could be met from returns from the land. Scattering, partial development means not only excessive operation and maintenance costs and heavy interest burden on the producing area, but also excessive costs for roads, schools, telephones, and the necessary commercial and marketing agencies. For all these items, whether public or private, are a part of the service requirements of any new community, and the cost of establishing and maintaining them must be borne ultimately by the producing land. If the productive land is scattered, a higher cost must be paid, not only in higher tax levies for public institutions, but also in higher interest rates at the bank and longer profits to "the butcher, the baker, the candlestick maker".

The Yakima Project in the State of Washington has been widely advertised as one of the most successful instances of irrigation development in the West. There are three outstanding reasons for the success of this project: First, its productive soil and favorable climate; second, its ample water supply; and, third, the fact that it has been developed in small and rather compact units so that its growth has been approximately commensurate with the demand for its land and products.

It must be recognized that the large projects remaining in Washington and other States are composed for the most part of strictly arid lands, with few or no *bona fide* settlers. The problem of building the works is simple compared with that of settling the project and bringing it into production. To do this the land must be pooled, by some means, so as to be handled with the water and irrigation works under a single competent, aggressive, and economical management. The present individual ownership must be merged for the common good, with compensation to present owners based on dry land value only. Whether the financing is done through private or public channels, the agency furnishing the funds must have the controlling hand in the operation and management of the district until it is safely established on a paying basis.

Modifications of irrigation district laws along the lines just suggested are desirable, not only to insure the success of new projects, but for the protec-

tion of existing development. The unplanned and haphazard settlement and development of an irrigation project of 100 000 to perhaps more than 1 000 000 acres is not only difficult and dangerous to the new project in itself, but may prove seriously detrimental to established agricultural interests by unsettling their markets. For example, the effect of the great irrigation development in Southern Idaho during the decade from 1905 to 1915, may be recalled, when for a time alfalfa, the easiest crop for new settlers, was produced in quantity far above the capacity of available markets. The market was wrecked, and it required years of patient and energetic effort to build up the dairy and livestock industries and to develop new markets to re-establish the economic balance.

Consider some of the obvious defects of the Washington State Reclamation Law. If State aid for reclamation becomes desirable and necessary at some future time, it should be on a basis that will offer to the project real help and not impossible burdens. Any one familiar with the undeveloped projects in the State of Washington will recognize that few, if any, of them can honestly undertake to meet the requirements of the law as it now stands. It contains at least two basic defects. First, it does not require specifically, and in its administration little attention has been paid to, any showing of economic need for a project. Direct State aid to reclamation can be justified only on the ground that there is a real need for the particular development proposed, and that there will be a market, present or prospective, for its products. Second, the interest rate is too high. To make the law workable and of benefit to the settlers, interest should be made very low or waived entirely during the development period. After development of the project is well along, the rate should be high enough so that the district bonds could be sold in the open market at or near par value.

Should conditions in the future warrant direct State aid in reclamation development, it might be advisable to re-establish a Reclamation Board somewhat along the lines provided in the original Act, its functions, however, to be largely advisory on matters of policy and on approval of projects, and not administrative. On such an advisory board, representation should be given to the State College, the State Land Commission, the State Departments of Agriculture and of Conservation and Development, the State Treasurer, and, possibly, the State organization of investment bankers. Most of the bonds handled by the State would probably be sold through the membership of this latter organization and its advice, being expert and non-political, should be of great value.

State Land Settlement Law.—The Washington State Land Settlement Law was enacted in 1919 to meet the anticipated passage of a National land settlement law which was at that time under consideration by Congress on recommendation of the then Secretary of the Interior, the late Franklin K. Lane, the measure having been prepared by Elwood Mead, M. Am. Soc. C. E.

The National legislation failed of passage, but in 1921 the State organigation of the American Legion urged and secured a State appropriation for soldier settlement, independent of National aid. The project selected was in

the south central part of the State in the vicinity of White Bluffs and Hanford, on the Columbia River. It was doomed to failure from the beginning for several reasons, among which may be mentioned:

1.—The land was mostly very sandy and difficult to place in production. Only irrigation farmers of long experience under similar conditions could expect to achieve success.

2.—Settlement was at first limited to *ex*-service men which meant, generally, young men inexperienced in handling soils of this type.

3.—The water supply from wells was unreliable and in many cases insufficient, and the cost of electric pumping was very high, especially for the development period.

4.—The tracts were scattered, making community life and organization difficult. Community organization and co-operation is one of the essential features of Mr. Mead's plan on which the State law was founded.

5.—The land selected was remote from markets and from towns or cities offering the cultural and recreational facilities to which most of the settlers were accustomed.

The State purchased approximately 2 000 acres of land which was divided into 105 tracts of about 20 acres each. Sixty-six of these tracts were improved with small houses, barns, wells for irrigation, and pumping equipment, and were sold. Thirty-nine other tracts were partly improved and offered for settlement with no takers.

For two to five years the settlers struggled valiantly to establish themselves on the land. Some, with the better tracts of land, with some experience and ample water supply, were able to make a very good showing. Others, due to lack of experience, poor land, or insufficient water, accomplished very little. Nearly all were discouraged and unable to see any possibility of paying out. They appealed to the Legislature for relief, which was authorized. Of the 66 tracts sold, settlements were made with 64 owners at a total net loss to the State of $360 000. The remaining 39 tracts, appraised at $34 000, were sold at public auction on June 1, 1926, with all improvements, except motors and pumps which had been removed, for $50 650.

It cannot be said that this was a fair test of State-aided land settlement. The land was poorly selected, remote from markets, very difficult to reclaim, and the limitation to *ex*-service men developed a certain class feeling and political situation that would be a serious handicap for any project. The results of the experiment however, have brought out several fundamental difficulties in the way of State-aided land settlement, and it is not likely that the State of Washington will be willing to undertake another project of this kind for several years to come.

Reclamation Bond Certification Law.—Following the example of Oregon and California in an effort to improve the marketability of the bonds of sound irrigation districts, the Washington State Legislature in 1923 enacted the so-called "Certification Law". The law requires an investigation by the Director of the Department of Conservation and Development and the filing of a report with the Secretary of State, embracing conclusions on the following points:

(*a*) The supply of water available for the project and the right of the district to so much water as may be needed.

(*b*) The nature of the soil as to its fertility and susceptibility to irrigation, the probable quantity of water needed for its irrigation, and the probable need of drainage.

(*c*) The feasibility of the district's irrigation system and of the specific unit for which the bonds under consideration are desired, whether such system and unit be constructed, projected, or partly completed; and the sufficiency of the amount of the proposed bond issue to complete the improvement contemplated.

(*d*) The reasonable market value of the water, water rights, canals, reservoirs, reservoir sites, and irrigation works owned by such district or to be acquired or constructed by it with the proceeds of any such bonds.

(*e*) The reasonable market value of the lands included within the district.

(*f*) The plan of operation and maintenance used or contemplated by the district.

(*g*) The method of accounting used or proposed to be used by the district.

(*h*) Any other matter material to the investigation.

Attached to the report of the Director shall be the following:

(*a*) A certificate signed by the Supervisor of Hydraulics certifying to the amount and sufficiency of water rights available for the project.

(*b*) A certificate signed by a soil expert of the Washington State College, certifying as to the character of the soil and the classification of the lands in the district.

(*c*) A certificate signed by the Supervisor of Reclamation approving the general feasibility of the system of irrigation.

(*d*) A certificate signed by the Attorney General of the State of Washington approving the legality of the organization and establishment of the district and the legality of the bond issue offered for certification.

On satisfactory showing as provided, the Secretary of State signs a certificate in the following form which is attached to all bonds issued by the district:

"Olympia, Washington, ... (insert date) .....

"I, ..., Secretary of the State of Washington, do hereby certify that the above named district has been investigated and its project approved by the Department of Conservation and Development of the State of Washington; that the legality of the bond issue of which this bond is one has been approved by the Attorney General of the State of Washington, and that the carrying out of the purposes for which this bond was issued is under the supervision of said department, as provided by law.

"(Seal) .....

"Secretary of State."

Owing presumably to the slump in irrigation securities there have been but few requests for certification under this Act, and the bonds of five districts only have been certified. Of these, three were to cover the cost of reconstruction for old districts and two were for construction of new district works. Since the enactment of the Certification Law, investment bankers have rather insisted on certification, and the few bonds sold without it have suffered heavy discounts.

Columbia Basin Project.—The State of Washington, not content with extending aid of a general character to reclamation enterprise through the medium of the legislation referred to, has seen fit to adopt, as a State project, and by appropriation of State funds to investigate and promote plans for the development of an irrigation project equal in extent, in estimated cost, and potential production to all the irrigation projects completed during the first quarter century under the Federal Reclamation Law, namely, the Columbia Basin Project.

This project embraces approximately 1 883 000 acres of irrigable land lying in Eastern Washington in the "Big Bend" of the Columbia River from which it takes its name. The land lies between 350 ft. and 1 700 ft. above sea level. In soil and climate it closely resembles the Yakima and Wenatchee Valleys which join it on the west.

Two principal sources of water supply have been considered: First, from Clark's Fork of the Columbia River by a gravity diversion at Albany Falls near the Washington-Idaho boundary, with storage supplied by Pend Oreille Lake, or by this lake supplemented by Priest Lake, also in Idaho; and, second, by pumping from the Columbia River, using power developed by a dam in that stream to lift the main water supply into Grand Coulee, from the lower end of which it would be delivered into the main canals.

These two alternative projects lend themselves to numerous variations through the use of other sources of water supply for various parts of the main project, as follows:

Wenatchee River and Lake for Quincy unit	332 000	acres
Snake River for Five-Mile Rapids pumping unit	100 000	"
Touchet River and Wynette Reservoir for part of Eureka Flat	50 000	"
Columbia River, Priest Rapids pumping unit	113 000	"
Spokane River and Lake Coeur d'Alene, southeastern part of gravity project, about	400 000	"

This project, first investigated by the U. S. Reclamation Service in 1903, was then abandoned as being too large for present consideration. In 1919, the Legislature of the State of Washington appropriated $100 000 for its investigation and created a Columbia Basin Commission which, later, became a Division of the Department of Conservation and Development. This was followed by other State and Federal appropriations under which extensive preliminary surveys and studies have been made. The latest and presumably the most authoritative report was made in 1925 by the following Board of Engineers appointed by the Secretary of the Interior: Messrs. Louis C. Hill, Joseph Jacobs, Charles H. Locher, Richard R. Lyman, Arthur J. Turner, and O. L. Waller, all of whom are members of the Society.

This Board finds that the project is structurally and economically feasible and includes these rather striking recommendations as to State and National policy in connection with the proposed development:

"That the State should assume its proper share of the responsibility for collecting payments from the settlers, and should also bear its proper share of the losses, if any, incident to the development of the project."

* * * * * * * *

"That the Government should clear and level the land and provide a reasonable financial credit for necessary farm improvements. Also, as a guaranty against land speculation, and to insure that the settler secures the land at its fair value, that the Government acquire title to all the irrigable land within the project."

The estimated construction cost of the project as a whole, or of its constituent units, is approximately $160 per acre. If the suggestions of the Board of Engineers relative to land ownership can be successfully carried out, the combined cost of land and water to the settler might be approximately $175 per acre, which is considerably less than that on the later developed units of the Yakima Project and some of the other more successful private and Government projects of recent years.

It is recognized that because of its magnitude this development can be undertaken only by the Federal Government. The State at present is only laying the foundation for future construction by negotiating a water compact with other States interested and with the Federal Government by making an economic survey as to the need and possible market outlet for its products, and a further study of potential power in connection with, or which might be affected by, the irrigation project. The economic survey will include a study of the rate of industrial and commercial growth of the western part of the United States; domestic and foreign markets for agricultural products; past and present production of irrigated and other crops in the Pacific Northwest; and possible new products and new markets which might become available through the opening of new arteries of commerce or reduced tariffs over existing lines.

The conclusions, therefore, as to the proper functions of the State with reference to reclamation, which are briefly summarized, are as follows:

1.—Present agricultural production in this and neighboring States is equal to, if not greater than, the demand in markets that can be economically reached through available channels. The State, therefore, is not justified in expending funds raised by a tax on all property, including agricultural land and products, to increase the agricultural area by reclamation. Having in mind that the rapid industrial and commercial development of the Pacific Coast may, in a relatively short period, radically change the economic situation, the State should anticipate future needs for reclamation development by adopting a sound, basic reclamation policy. The program, as far as it can be outlined, should include:

(*a*) A comprehensive study of the possibilities and needs of the State for increased agricultural production by means of reclamation.

The water supply required for approved projects should be protected by administrative or legislative withdrawal against appropriation for less essential uses.

(*b*) A continued effort to improve State laws relating to reclamation to the end that they may encourage and foster sound and necessary projects and prevent the launching of those which are not.

2.—The State should support a National reclamation policy and program based on sound, economic principles. Selection of projects on merit only; emphasis on local responsibility, especially in operation of the projects; and a strictly business corporation for collection of charges, are some of the factors that would seem to be clearly indicated by past experience as essential to future success. During periods, such as the past few years, when agriculture is in distress and there is little or no demand for land, storage construction should be stressed rather than the building of additional canals, in order to provide for and expedite the development of new areas when needed.

3.—A study of existing projects that are now in trouble and the working out of salvage plans where practicable might be justified, particularly on those projects in which the State already has some investment or has been responsible in some measure for existing conditions.

DISCUSSION

JAMES RHEA LUPER,* ASSOC. M. AM. SOC. C. E.—The author has shown the definite policy adopted by the State of Washington in extending State aid to reclamation development.

In other words, Washington has been "attending the school of experience", and the experience seems to have covered the full range of State aid policies with the exception of Oregon's guaranty of interest on irrigation and drainage district bonds. Washington evidently has passed through the experimental stage and the experiment has been expensive. Now the danger is, that instead of profiting by the experience, the people may reverse the policy and drop all development work of this nature for this generation.

It is true that all the low-cost, easily constructed, projects have been built. The development of the remaining projects will present difficulties that require the most thorough planning by experienced men if they are to be successful.

The author asks, "Is there any means other than State or Federal subsidy of building the remaining large projects?"

It seems obvious that there is not a prospective profit in further irrigation development that will attract private capital. The real profit is to the public in the permanent wealth created and in the increased business in all channels that will inevitably follow after the project has been successfully completed. State and Federal aid can only be justified on this sound theory. Further large developments of this nature must depend on such aid.

The problems in irrigation development are many. Ample water supply, adequate drainage, good markets, good engineering design, sound financing, capable administration, the elimination of land speculation, a sound settlement program, and confidence, all are essential to success. When any one of these is lacking to any large extent complete success is impossible.

Mr. Tiffany suggests the advisability of re-establishing the Reclamation Board, a non-political organization. This seems to be essential for under the present form of government it is better for the head of the Reclamation Bureau to have some protection against political pressure, and against a misguided public sentiment that may otherwise force the adoption of an undesirable project, or his resignation.

This Board should be clothed with sufficient power to control the administrative officers of the project in which the State has invested its funds until such time as the State has been reimbursed, or until the operation of the project has been turned over to the settlers.

It must not be comprised of politicians, as the word is generally used, for it must maintain continuity of policy through different political administrations. The Board should have authority to issue State bonds to a limited extent in lieu of the direct tax heretofore imposed. The beneficial effect of the development work cannot be felt for many years. This direct tax will fall on many who will receive no benefit, while the bonds may be paid as, or after, benefits are felt.

* State Engr., Salem, Ore.

In his reference to economic need for a project, the author points out an important matter that seems to have been overlooked by many others in the recent irrigation development in the West. The development of irrigated farms ahead of the economic need not only cannot be justified, but the colonization of such projects will be an uphill struggle, if not impossible.

Conditions will change, however; in fact, they are changing now. Food consumption is overtaking food production and improvement may be felt within a year. In five years a very marked change should be experienced. In the development of large projects many years may elapse before the farms will be fully developed. It is difficult to say that substantial production on such projects will come before there is need of the crops produced.

Irrigation Districts.—Under all forms of development, whether through private financing, Federal reclamation projects, or projects financed by State funds, the organization of the water users under the Irrigation District law seems essential. The irrigation district's code as adopted in Washington, Oregon, California, Idaho, and other Western States in effect provides a means whereby an independent branch of government—a municipality—can be formed. The district has power to levy taxes and assume obligations, which are guaranteed by all the property within its boundaries. The indebtedness represents a general obligation of the district, and is paid by taxes levied either on a basis of irrigated area, or as an *ad valorem* tax.

The law presents an excellent method of collecting funds and provides administrative machinery for the operation and maintenance of constructed projects. It is good for financing to a limited extent, but when the indebtedness reaches a substantial percentage of the total value of the property in the district, a dangerous situation is created, and loss of confidence may be caused with the resulting loss of credit to all settlers regardless of the value of the individual's property.

Oregon has a system of assessing the costs of furnishing water rights in proportion to the benefits received. Many of the projects include lands that had almost full water rights before the project was created. Such land may be assessed only a nominal part of the construction cost for the additional water right to be supplied. Yet when such a district gets into financial difficulties, the failure on the part of some to pay pyramids the assessments on those able to pay until all land values in the district are entirely destroyed. By providing a means for fixing the exact amount that the water user will be required to pay for a water right, his credit will be re-established and much progress will have been made toward making the district function as it should.

Oregon has an example of financing local improvements which can be well applied in reclamation development. This is, the Bancroft Bonding Act. Under its terms, a city sells its general obligation bonds in an amount necessary to finance the improvement, and is, in turn, secured by a lien on each parcel of land benefited. The lien is for a definite fixed sum, and the land owner benefited knows exactly the amount of his obligation. It can be paid in yearly installments, or more rapidly, if desired.

Why is it not practical for a State to follow the same plan in reclamation developments by the issuance of a State bond secured by the land

benefited? If thorough preliminary surveys are made—and in this must be included adequate soil surveys—the possibility of including lands that cannot bear the charge levied against them is eliminated, and the district will be free from the "kick-back" of the general obligation that occurs when the indebtedness becomes too high.

By foreclosure of its liens, the State could take the land and re-sell it just as cities have done with many vacant lots. The property will continue to have a value as long as the lien does not exceed the value of irrigated land with a water right in that vicinity.

American farmers have not yet learned co-operative development. Co-operative marketing has been successful only in certain commodities, but, on the whole, the farmers are trained in independent thought and action, and do not enter readily into situations in which their success is dependent on the success of others in the same community.

Mr. Tiffany has quoted from the Washington State Law providing for the certification of irrigation district bonds, but has refrained from criticizing that method of financing irrigation work.

It is to be noted that the law provides for an examination of the project by the State Director of the Department of Conservation and Development, whose report is filed with the Secretary of State; also, that attached to the report are certificates of various State officers to the effect that the project is feasible, that the bonds have been legally issued, that the water right is good, and that all the soils are of certain character. The certificate on the bond is signed by the Secretary of State and the seal of the State is attached.

This law has two purposes: First, to protect the investing public against the purchase of unsound securities; and, second, to promote development by making good irrigation securities salable. The State disclaims any legal responsibility for payment of the bond, but when the project defaults in either principal or interest it is difficult to convince a holder of certified bonds that the State is not morally responsible for his loss.

The State should not mar its good financial name by allowing its seal to be placed on any bond that is not essentially sound. It is not morally right, and may result in direct financial loss because of the increased interest rate that may be demanded on other financing within the State.

It is to be hoped that Washington will not go out of the reclamation business entirely, but will profit by her experiences and amend her laws so that these projects may be re-organized and that further reclamation developments may proceed on a sound basis.

W. G. Swendsen,* Assoc. M. Am. Soc. C. E. (by letter).—The history of reclamation by irrigation in the State of Washington, so well outlined by Mr. Tiffany, is repeated in Idaho and practically in all the arid States.

Much has been said about the failure of irrigation enterprises. Viewed purely from the standpoint of a return on invested capital, a large percentage of the business might well be classed as failure; if viewed, however, in its

* State Engr., Boise, Idaho.

broader aspects of developing a new country, producing the necessities of life, and increasing the taxable wealth, quite a different story is revealed.

The financial structure on which an irrigation enterprise must rest is based almost wholly on the efforts of the farmers in the area. Unfortunately, a solution of their problems is not found in any concrete formula, but is abstract in the extreme. In weighing the economic feasibility of most irrigation projects, conclusions have, therefore, necessarily been based largely on expectancy. The equation reflecting farm success is filled with many unknowns, not the least important of which is the psychology of the farmer himself, and his fitness and willingness to engage in the activity at hand. It is not surprising, under these conditions and especially in view of the fact that the art is a new one, that forecasts as to the financial outcome of irrigation projects should be found in error.

It has been a common practice on the part of the promoters in the beginning of these enterprises to absolve the engineer from responsibility in the matter of financial return; but, ultimately, and almost universally, where a financial loss has existed, the responsibility for it has been placed with the engineer. In addition to the engineer's direct personal interest, the problem of how and when the natural resources of land and water in the arid States shall be developed, is of sufficient public, State, and National importance to warrant consideration by the highest engineering and business talent.

It is true, as Mr. Tiffany states, that most of the remaining undeveloped reclamation projects are not, under existing conditions, attractive to private capital and that if they are to be constructed soon, governmental aid of some sort is necessary. Unless it is established with very reasonable certainty that additional agricultural products are necessary to the State or Nation, or to the happiness and well-being of the people, there seems to be no justification in equipping this industry with a public subsidy. The use of State or Government funds at interest rates below those prevailing in other business, or with no interest at all, can be nothing but subsidy.

Where a group of citizens are suffering hardships on farms because of insufficient irrigation water or of unoperating irrigation works, there may be some justification in using public funds for their relief, even if this term, "relief", has come within the last few years to be invoked with almost constant regularity.

Whether wisely or not, the writer has urged a policy in Idaho of directing public assistance and attention only to projects already occupied, where distressed conditions exist, considering new and undeveloped areas only to the end that their resources may be available later and unimpaired for orderly development and use when economic conditions warrant.

The engineering and structural problems in reclamation by irrigation may be definitely understood, analyzed, and solved; settling the land and bringing it to a state of profitable production is the difficult and uncertain problem. If the so-called existing "lame ducks" can be so improved that substantially all irrigated areas present successful farming conditions, much will be accomplished in stimulating the settlement of new areas. The matter of investing

public funds in such enterprises must be approached with great care so as to provide financial success to the State or Government and to guard against relieving settlers of individual responsibilities they must assume if good citizenship is to endure.

The writer entertains grave doubts as to the advisability of attempting, especially at public expense or under any form of subsidy, to reclaim by irrigation any unoccupied areas until existing projects are settled and the "lame ducks" improved, especially in advance of a greater demand than now exists for increased agricultural production.

These are to be regarded as an expression of personal views and not in any sense as reflecting public sentiment in Idaho, where, as in Washington, a difference of opinion exists.

J. C. Stevens,* M. Am. Soc. C. E.—The author believes that no more projects should be built until existing ones are entirely occupied. This policy is entirely wrong. People have particular inclinations and diversity of desires, and they will not all go on any one project. One might as well say that no more houses should be built in Seattle, Wash., until all those in Portland, Ore., are occupied.

That same principle will apply to irrigation projects. There is undoubtedly a demand for irrigation lands locally, that can only be supplied by building the smaller projects.

O. L. Waller,† M. Am. Soc. C. E.—In administering the irrigation loan, the State of Washington has made some mistakes, but they are not serious. After the World War, some banking and business houses in the State found themselves over-extended and had to charge off some bad accounts, but they did not go out of business. Neither should the State go out of the irrigation business as long as it has lands that may be developed by irrigation. It would seem that a State should be interested in the development of its resources, particularly where the necessary expenditure is beyond the reach of private individuals and of private capital.

The time is not far distant when the United States will need more food to supply a growing population, and not only each State, but the United States, should make a study of all possible land developments that may be made, looking forward to the time when this need will be imperative. It is not important whether agriculture is developed through irrigation or by other methods; but it is to the advantage of any State to look forward to the development of all its natural resources just as much as it is to the advantage of an individual to develop his resources.

As compared to other States, Washington has small acreage now under irrigation. However, it has a large area yet susceptible of such development, and its water supply is abundant. That being the case, it should be the policy of the State to render every assistance possible in developing the lands pending the time when the growing National population will demand additional food.

JOSEPH JACOBS,* M. AM. SOC. C. E. (by letter).—Are the financial losses and other difficulties which the State of Washington experienced in its reclamation work, as recited by Mr. Tiffany, attributable to defects in the law; to the method of administration; or to other causes? Are they necessary, ineradicable concomitants of State activity in this type of enterprise; or are the evils correctable by a modification of the laws and by a wiser administration of them such as would result from a policy of ignoring politics as a primary consideration in the selection of the administrators? The writer entertains the latter view and believes that the chief difficulties have been political rather than technical, economic, or fatal deficiencies in the law itself.

No accidental or obscure, mysterious causes were responsible for the financial losses mentioned in the paper. The dangers were easily discernible. Practically all the physical and economic difficulties were known in advance and, for the most part, properly weighed and reported by responsible engineers. It is creditable to engineers that they, more than any others, pointed the safe line of attack and sounded warnings. If, however, it is to be the policy of the appointing power of the State to put in control, over the engineer, men selected from the field of politics, with practically no previous experience, and whose acts and decisions may too often be colored by political considerations—then but little improvement can be expected, no matter how good the laws. Graft and willful dishonesty are not here an issue, because no such delinquencies are involved, but only the questionable policy of appointing to responsible administrative control of essentially technical or scientific departments of government men who have had no real training for such specialized work.

In this situation the Engineering Profession should make its influence felt more effectively. It should seek to have more clearly defined, by statute or otherwise, the required technical qualifications for heads of departments. It should also seek to overcome the mistaken notion, rather widely entertained, that the engineer is necessarily a narrow technician with little qualification for supreme, administrative control of a department of government, even if that department's interests are chiefly scientific and technical. It is true that the engineer is often only a technician, but it is also true that as high an average of capable, business administrators are found in the Engineering Profession as in other business callings—probably more, and certainly more than in the purely political profession. If it were necessary to admit, which fortunately it is not, that there is no hope of improving the quality of American politics, then the State Government ought to be taken entirely out of reclamation activities.

The State's remaining major projects cannot, on account of their magnitude, be built except as public enterprises. If their development is deemed necessary, the primary determination of policy should relate to whether the State or the Federal Government shall undertake them, or whether these agencies, in co-operation, shall do so. Another alternative is the creation of a large improvement district to issue its own bonds and prosecute the work. Such a

* Cons. Engr. (Jacobs & Ober), Seattle, Wash.

district would require special legislation for its creation and successful operation and, to be financially practicable, it would need to include already developed towns and other rich, taxable property to give increased security and marketability to the bonds. Such inclusion would be seriously opposed and this alternative, therefore, can be regarded as only a remote possibility.

That the State's interests in these developments—and this applies to all the irrigation States—is more intimate and immediate than those of the Federal Government cannot be gainsaid; but the Federal Government, too, has a vital interest in Western agricultural development, not only as a means of promoting National prosperity, but also in respect to military factors. Almost every consideration of the problem seems to suggest State and Federal co-operation. Because of State constitutional limitations, as well as for other substantial reasons, it would seem desirable that the actual construction of these major reclamation projects should be in charge of the Federal Government, but it is to be hoped that some satisfactory form of co-operation can be evolved that will provide for the States meeting their just obligation in the premises, particularly as relates to the colonization of the projects.

Under these auspices, and provided the Government grants long terms and low interest rates for repayment of the construction costs, it may be anticipated that these developments will be entirely successful. Under the present Federal Reclamation Act no interest is charged, but for large developments of the future it has been suggested from many sources that such interest should be charged except possibly during the period of construction and of that normally chargeable to the unsettled lands. Even these partial waivers of interest have been objected to by some as being a subsidy; but if, as a result, new values are created that redound to the advantage of the grantor as well as the grantee of the subsidy, it cannot be regarded as a charity. Purely on the basis of paternalistic charity a subsidy is not warranted, but these are not of that class. Should the Government demand interest on deferred construction cost payments, excepting only the waivers already suggested, the Western States, in the writer's judgment, should neither be surprised, nor should they complain, provided only that the time allowance is long and the interest rate low. On the contrary, they should accept such a dispensation as a sound economic basis for future irrigation development and should modify and shape their State laws to that consummation.

F. H. Newell,* M. Am. Soc. C. E. (by letter).—This paper has peculiar value at the present time, particularly when read in connection with the paper by D. C. Henny, M. Am. Soc. C. E., on "Some Phases of Irrigation Finance".† The whole subject of the duties and opportunities of the National and State Governments in connection with water control, development, and protection of agricultural lands is forced upon public attention as never before by the great flood in the Mississippi Valley, which, although not necessarily the greatest that may occur, surpassed in destruction all previous floods.

Members of the next Congress (1927-28) are being urged, not only to control the Mississippi floods, but also to provide funds for building a storage

* Pres., The Research Service, Inc., Washington, D. C.

† See p. 541.

reservoir to hold Colorado River floods. This is for furnishing electrical energy with which to pump water over a 1 300-ft. divide for Los Angeles, Calif., and neighboring cities. Claims are also being pushed for: Deep-water navigation in Northern New York; gigantic hydro-electric development on the St. Lawrence River; continued activity on the Atlantic deeper waterways; development of the international control of waters of the Rio Grande; the Columbia Basin Project; and innumerable local flood-protection, irrigation, and drainage operations. The ten years' discussion of Muscle Shoals and of power development on the Potomac River near Washington, D. C., will continue to be the subject of active controversies on the floors of Congress.

There never was a time when water resources, water power, and regulation assumed such great public importance or involved expenditure of such huge sums from the unexpended balance in the Federal Treasury.

In this connection let it be recalled that the Federal Government itself, or at least the Constitution under it, which has operated for nearly a century and a half, originated through a similar set of demands arising from the necessity of protecting commerce between the States. At that time commerce was largely dependent on waterways. The Constitutional Convention was called partly because of the controversies between the States over the control of the rivers and the obvious necessity of creating one central government strong enough to adjust the conflicting interests.

There is a demand for the development of a sound policy on the relation of the States to each other and to the Nation. The relative duties of each concerning water and the distribution of power across State boundaries are involved in this question.

The engineer is at the center of the picture. While the politician necessarily strives to attract attention to the wishes of his constituents, he realizes that he must have dependable facts. He may denounce engineers but he displays an almost childlike faith in the facts and figures issued by them. It is, therefore, peculiarly important at the present time for the engineers of the United States to present, as clearly as possible, the fundamental facts on which proposed appropriations and accompanying legislation must be based. These appropriations are no longer discussed in terms of millions of dollars; but, with the boldness, not to say recklessness, of expenditure growing out of the World War, the talk is in terms of hundreds of millions of dollars; amounts so large that even the wealthy States must call upon the Federal Treasury for aid.

Back of all these questions of reclamation and other developments comes the inquiry, more and more insistently made, "Will it pay?" A quarter of a century ago, when the Reclamation Act of June 17, 1902, was passed, this question was not asked. The enterprises then proposed were relatively cheap. There were a score of applicants for every farm that might be irrigated or drained.

In the quarter of a century that has passed there has been a reversal. All the relatively cheap projects have been undertaken or have passed under private control. There are no longer hordes of eager land seekers. On the contrary, thousands of people are leaving the farms each year; millions of acres

of land, previously cultivated, are now left untilled. While it is popularly deplored, this condition is perfectly logical.

For years, the Federal and State Departments of Agriculture have employed the best experts obtainable. They have spent millions of dollars trying to find how to produce larger and better crops on less area and with less outlay of human energy. They have succeeded in their aims. Thousands of laborers have been released for work at more profitable wages in industry. The scientists have brought about the introduction of better methods of farming, better judgment of soils, and have encouraged, indirectly at least, the concentration of efforts by good farmers, on good soil, near good markets. The resulting suffering of poorer farmers on poorer lands and without markets is deplorable, but is the inevitable outcome of conditions that have been deliberately planned.

In the face of the rapid and, in some cases desirable, decrease of area cultivated, is it wise for the tax-payers of the Nation or of a particular State to be called upon to reclaim additional areas, even if the soil may be brought to a high degree of productiveness by large expenditures? After that comes the question as to who is to pay the cost of strenuous efforts to secure good farmers and good markets?

The various efforts of the State of Washington, made in good faith, to develop lands and to secure settlers are described by Mr. Tiffany. He shows that the early individual or co-operative efforts at irrigation were successful. The pioneers, counting the cost of their labor as nothing, succeeded in making homes and, in some cases, developed lands of high productivity. Then having "skimmed the cream", they began to fail in further efforts. Later, the State endeavored to aid or stimulate new projects. Many were investigated; considerable sums of money were spent and lost. Now the State has apparently settled down to an effort, which may be characterized as the salvage of enterprises that offer hope of rehabilitation or extension.

Through or behind these efforts runs the fundamental thought, unquestioned up to the present, namely, that eventually the State of Washington (and, indeed, each and every State) "will need all possible development of her agricultural area". Accepting this as a fact, broadly applicable to all industries and human undertakings, the real question then resolves itself into what shall be included as possible.

By offering suitable inducements, it is possible to put people on the reclaimed land who will agree to cultivate it; but is it worth while? The experience of the State of Washington, as described by the author, appears to be in the negative. It has not paid, and it is only by the exercise of supreme faith and optimism that the expenditure of hundreds of millions of dollars additional may be justified.

This does not mean that extension, enlargement, and improvement of existing systems is unprofitable or unwise. Much can and will be done, especially by local interests receiving an indirect benefit. Many land owners, who now have a "toe-hold" on the soil, and disregard the value of their own labor (which otherwise might be dissipated), can, and will, join with their neighbors and bring about gradual expansion of irrigated area. This expan-

sion is taking place throughout the arid region, often by the formation of self-taxing reclamation districts. These districts are not held strictly as to questions of profit and loss. They are justified in levying taxes on the basis of the general benefit that came, directly or indirectly, to all industries or to commercial enterprises in the neighborhood.

These relatively small neighborhood undertakings will take care of themselves without other supervision than that generally given to school districts. However, there are the great enterprises like the Columbia Basin Project, involving enormous expenditures, with potential losses in interest and capital, before any lands are reclaimed; investments too great for even a wealthy State to make.

In these great undertakings the engineering features, the methods, and costs are, of course, fundamental. In addition, there is the less easily definable question as to how the improved land may be utilized so as to return a considerable part of the total cost. Theoretically, it is possible for the State and Federal Governments to join hands in securing settlers; but in view of the fact that all such undertakings in the past have been at least doubtful, it is now urged that the Federal Government buy up or acquire all the land that may be reclaimed.

As the owner of the reclaimed lands, the Government may be able to dictate to its tenants or purchasers the conditions under which the lands may be acquired. It can enforce needful conditions of cultivation to a degree comparable to that of the owner of a manufacturing establishment. Recital of these conditions cause strong doubts as to their feasibility. The successful farmer is a man who is called on to use his judgment hour by hour, his activities are constantly being modified by changes in weather, or by other conditions known only to himself. Judgment is essential, and if he surrenders his judgment to some one else, he loses those qualities that make him a real farmer.

It seems little short of a huge joke to imagine any bureau officer, selected in accord with Civil Service rules and made an expert farmer by virtue of a commission, undertaking to direct the activities of a body of real farmers. The earnings of any farmer should be larger than the salary usually paid to subordinate Federal employees. Imagine the responsibility assumed in directing a group of farmers; what crops to plant and when to harvest. Perhaps the potatoes might be successful, but if not sold at a profit who is responsible? In the opinion of the farmer the Government should at least make good for any such loss.

If, as is intimated, the Federal Government should come to the assistance of the State of Washington, in building the Columbia Basin Project, what about the other States? Each and all of them from Maine to Florida in the East, to California and Washington in the West, has a comparable problem, of water control, water power, drainage, or irrigation. Each and all argue that the agricultural possibilities should be maintained and water controlled or developed for power or other uses. Each State pleads that although the wealth per capita is great it cannot afford to go into these great enterprises; each

is equally insistent that if the Federal Government assists one State it should also consider the needs of the other.

It has already been proposed with some seriousness, that if money is spent on the arid soils of the West, similar funds should be used in clearing the rocks and stumps from the otherwise productive farms in the East. It is pointed out that with such Federal aid and with the existence of the best markets in the world, the Italians, Portuguese, and other prolific immigrants in New England can, and will, develop an agriculture comparable to that on the irrigated lands of the West. As engineering enterprises, and as economic investments, both proposals are claimed to be equally justifiable and altogether as valuable to local industries.

All engineers and economists can agree on the program outlined by the author, namely, that a comprehensive study be made of the possibilities and need of the State for increased agricultural production; that continued effort be made to improve State laws relating to reclamation; and that the State support a National reclamation policy and program based on sound economic principles.

It is in the development of such sound economic principles that there has been and still remains the greatest need. In a certain sense, this country has been limping along under assumptions that were true a quarter of a century ago and do not apply to present conditions. The needs and opportunities of the West then were unquestioned. It was assumed that it was the duty of the Federal Government to give priority to everything demanded by the West as the child or ward of the Nation. The West, however, has advanced, and a broad review of conditions shows that in many respects it has outstripped the remainder of the country, particularly the South.

Southern statesmen, under the leadership of the late Francis G. Newlands, Senator from Nevada (but a native of Mississippi), have consistently supported the claims of the West. Since the death of Senator Newlands they have begun to adopt a more questioning attitude. In fact, several of them have definitely stated to their constituents, and particularly to the engineers and economists of the South, that if Federal aid is to be given anywhere, the South, with its pressing needs for flood protection, must have preference. Southern interests are studying the methods so successfully developed by the West. They have been in contact with the competent men sent from the State of Washington to urge appropriations for Yakima Valley and Columbia Basin. They are awaking to the fact that their own States have enterprises of equal or greater importance. It is quite possible that in succeeding sessions of Congress the engineers representing these enterprises in the South will be fully as effective and energetic as those from the West.

The discussion of methods and of Federal and State responsibilities in water control is thus coming down to hard engineering facts. The relative costs and values and the real responsibilities are being seriously studied. The taxpayers are slowly realizing the fact that these subsidies, which they are called on to pay for the benefit of land owners in distant States, do not always produce the desired results. The emotional attitude, which has been so suc-

cessful in securing contributions or appropriations for relief, is giving way to questions that can be answered only by engineers who will discuss the costs and benefits impartially and clearly.

R. K. Tiffany,* M. Am. Soc. C. E. (by letter).—The discussion of State reclamation following the writer's paper has been interesting, although it has all tended more or less toward the conclusion that State reclamation, as such, is decidedly a questionable undertaking for the present time. Mr. Luper's suggestion that the State might aid reclamation by the issuance of State bonds with a limited liability, is worthy of consideration, if and when the situation becomes such that the State, in order to secure agricultural development, is justified in loaning its credit. The writer did not criticize the Washington State Law providing for certification of irrigation district bonds, simply for the reason that it has not been sufficiently used to give basis for judgment as to its value.

Mr. Swendsen questions the advisability of reclaiming any unoccupied areas until existing projects are settled, and Mr. Stevens credits the writer with a like opinion. The writer agrees with Mr. Stevens rather than with Mr. Swendsen on this point to this extent, that he believes there are certain localities and certain conditions under which new, or extensions of existing, projects, should be made, even at the present time. Washington, in the opinion of Professor Waller, presents, or will in the future present, such opportunities for profitable development, owing to the relatively small area of irrigated land in the State and to the rapid growth (past and prospective) of her industry and commerce.

The points brought out by Messrs. Jacobs and Newell have to do largely with the broader National aspects of reclamation, rather than the question of State reclamation. With Mr. Jacobs the writer will agree to the extent that State reclamation should not be condemned and abandoned by reason of the errors and losses that have occurred in Washington. The experience in these first efforts at State reclamation may be useful to Washington and to other States when the time comes that there is need for the States to take up actively the problem of increasing their agricultural production.

As to the National reclamation policy, Mr. Newell from his broad experience points out many errors in the past and need for a more sound and conservative policy in future development. In the writer's opinion there is still much to be said in support of the doctrine that the Federal Government should continue to aid in development of the arid West.

TIDES AND THEIR ENGINEERING ASPECTS*

By G. T. Rude,† M. Am. Soc. C. E.

With Discussion by Messrs. Lewis M. Haupt, H. de B. Parsons, R. L. Faris, Earl I. Brown, Edward Godfrey, William Barclay Parsons, T. Kennard Thomson, H. F. Dunham, Ralph Bennett, Victor Gelineau, W. M. Black, Francisco J. Gaston, F. W. Scheidenhelm, Charles H. Lee and Harold F. Gray, C. R. F. Coutlee, and G. T. Rude.

Synopsis

In the formulation and support of many of his theories and conclusions the scientist generally is compelled to use evidence of a qualitative nature, which later may be open to dispute when further qualitative evidence of contrary indications becomes available. The engineer, however, requires quantitative data of indisputable character and seeks continually for the accumulation of data and material of a quantitative nature, on which to base his conclusions and specifications for future operations. These data may be the result of innumerable tests of material, of structural weaknesses, etc., from which finally mean values of almost unerring certainty are obtained; or they may result from the accumulation of records of natural phenomena of periodic or seasonal character. In consequence of this continual quest, for example, long series of observations of tides and currents have been made throughout the world.

While the primary object of these observations has been to furnish data for advance predictions of the tides and currents at any future date for the use of the mariner, within recent years the needs of the engineer have been given consideration. As a result comprehensive current and tide surveys are now being made by the United States Government of all its important harbors.

* Presented at the meeting of September 7, 1927.

† Commander, U. S. Coast and Geodetic Survey, Washington, D. C.

The data from these surveys should prove of considerable value to the engineer engaged on harbor and river development and in marine construction of all kinds. These systematic surveys were begun in New York Harbor in 1922, followed by others in San Francisco in 1923, in Delaware Bay in 1924, and in Boston and Portsmouth in 1926.

To the engineer an accurate record of the rise and fall of the tide over a considerable period is not only of advantage but generally necessary to a proper understanding of the conditions under which operations will be carried on, or of the physical conditions which will result from an engineering project. As an example of the latter the reconstruction of the Chesapeake and Delaware Canal may be cited. This canal is being lowered to sea level by the Corps of Engineers, U. S. Army. The series of continuous tidal observations made at Delaware City, Del., the present eastern terminus of the canal, and at Chesapeake City, Md., the present western end, will permit the engineer to determine very closely the expected velocity of the current through the canal and will also furnish the data necessary for the tidal mathematician to predict in advance the times of slack-water.

This paper gives a brief, non-mathematical explanation of the tides and currents from the viewpoint of the engineer, and an outline of the more important phases for those who require data only incidental to operations in connection with development projects. The paper will be confined to the procedure and methods used by the United States Coast and Geodetic Survey in its comprehensive current and tide surveys of harbors, its tidal work for the control of hydrographic surveys, and in connection with its work in the preparation of advance predictions of tides and currents. A brief description of the instruments used on this work will also be given.

The tidal work of the U. S. Coast and Geodetic Survey had its origin in the need for correcting the soundings taken in hydrographic surveys for tidal fluctuation; that is, for reducing to a common level or datum plane soundings made at varying stages of the tide. The further needs of the mariner and the engineer since the early days of the Survey have resulted in the development and extension of the work until it covers the following fields: Determination of datum planes for surveying and other engineering purposes; prediction of tides and currents and the preparation of annual tide and current tables; study of the mean sea level and its relation to probable crustal movements; study of methods of observing tides and currents and reducing tidal and current observations; development of instruments for observing and predicting tides; and the study of tidal phenomena in general.

While the tidal and current data obtained by the Survey in the past were primarily for the use of the mariner, the "by-products" have proven of considerable value to the engineer and to the scientist—to the engineer particularly (1) in the establishment of datum planes based on tidal definition; (2) in the defining of mean and extreme ranges of the tide at various places, a knowledge of which is necessary in marine construction; (3) in furnishing a knowledge of the current flow throughout harbors in connection with sewer-

age and under-harbor tunnels; (4) in rivers in connection with the economical maintenance of channels to follow natural flow; and (5) in coast erosion studies in which tides and currents, in addition to wave forms and wave impact, play a large part.*

At the beginning of tidal work investigators were most familiar with the tides of the North Atlantic, and on them the earlier tidal theories were based. When observations were extended to other parts of the world, in the development of ports and the extension of maritime commerce, it was found that tides in general were not so orderly as was indicated by these comparatively simple tides of the Atlantic, the tides of the Pacific being quite different from those of the Atlantic, and the tides of the Gulf still different from those of the two oceans. This led to a study of the various types and forms of tides.

This study has also a directly practical application in the predictions of tides and the preparation of annual tide tables. Since it is physically impracticable to predict and publish the state of the tide for all ports of the world, a knowledge of the different types makes it possible to predict the times and heights of each successive high and low water for relatively few harbors as standard ports, and to refer subsidiary ports to those standard ports having tides of a similar type. In many cases it is not necessary that the secondary port be near the standard port of reference; for example, a port in the North Sea may be used as a port of reference for Nelson, B. C., Canada, a railway terminal on Hudson Bay; likewise, a constant difference exists between the time of low water at Miramichi Bay, New Brunswick, and high water in the Strait of Georgia, British Columbia, on the other side of the Continent, the two places having a similar type of tide, except that the tide curves are inverted.†

Nomenclature

As an aid in understanding the paper the nomenclature of tides and currents will be reviewed briefly:

Progressive Tidal Wave.—A wave the crest of which advances, so that the times of high and low water progress from one end of a body of water to the other.

Stationary Tidal Wave.—A wave that oscillates about an axis, high water occurring on one side of the axis at the same time that low water occurs on the other side.

Tidal Day.—Like the lunar day, the tidal day has an average length of 24 hours and 50 min.

"Moon's Meridian Passage."—Refers to the instant when the moon is directly above the meridian, and also the instant when the moon is directly below the meridian, or 180° distant in longitude. They are known as the upper and lower transits.

* "Problems Involved in Coast Erosion," R. S. Patton, M. Am. Soc. C. E., *The Military Engineer*, Vol. XVI, No. 90, November–December, 1924.

† "The Tides and Tidal Streams with Illustrative Examples from Canadian Waters," by W. Bell Dawson, Ottawa, 1920, p. 26.

High Water Lunitidal Interval.—The interval between the moon's meridian passage (upper or lower) and the following high water (abbreviated H. W. I.).

Low Water Lunitidal Interval.—The interval between the moon's meridian passage and the following low water (abbreviated L. W. I.).

Tidal Current.—The horizontal backward and forward movement of the water—the current floods and ebbs.

Tide.—The vertical movement of the water—the tide rises and falls.

High Water.—The maximum height reached by each rising tide (abbreviated H. W.).

Low Water.—The minimum height reached by each falling tide (abbreviated L. W.).

Range of Tide.—The difference in height between a high water and a preceding or following low water.

Mean Range.—The average difference in the heights of high and low water at any given place.

Semi-Diurnal Force.—The tide-producing force having a period of approximately one-half day. The semi-diurnal forces are the principal tide-producing forces.

Diurnal Force.—The tide-producing force having a period of approximately one day.

Long Period Forces.—The tide-producing forces having a period of one-half month, or more.

Spring Tides.—The tides occurring at the times of new moon and full moon.

Spring Range.—The range of tides at the time of spring tides.

Neap Tides.—The tides occurring at the times of the first and third quarters of the moon.

Neap Range.—The range of the tides at the time of neap tides.

Age of Phase Inequality, or Phase Age.—The phase age, generally ascribed to the effects of friction, is the lag in the response of the tide to the corresponding phases of the moon. It usually amounts to a day or two.

Perigee.—The position of the moon closest to the earth in its elliptical orbit around the earth.

Perigean Tides.—The tides with increased range occurring when the moon is in perigee.

Perigean Range.—The range of tide at the time of perigean tides.

Apogee.—The position of the moon farthest from the earth in its elliptical orbit around the earth.

Apogean Tides.—The decreased range tide occurring at the time the moon is in apogee.

Apogean Range.—The range of tide at the time of apogean tides.

Perihelion.—The position of the earth closest to the sun in its elliptical orbit around the sun.

Aphelion.—The position of the earth farthest from the sun in its elliptical orbit around the sun.

Age of Parallax Inequality or Parallax Age.—The lag in the response of the tide to the changing distance of the moon from the earth.

Declination of the Moon.—Its changing angular distance north or south of the plane of the earth's equator, as it passes through an angle of approximately 23½°, either side of the equator.

Age of Diurnal Inequality, or Diurnal Age.—The lag of the tides in response to the changing declination of the moon.

Equatorial Tides.—The tides occurring when the moon is on, or close to, the plane of the earth's equator (zero declination).

Tropic Tides.—The tides occurring when the moon in its changing declination is at its maximum semi-monthly declination and is near one of the tropics.

Synodical Month.—The month of the moon's phases, approximately 29½ days in length.

Anomalistic Month.—The month of the moon's distance, approximately 27½ days in length.

Tropic Month.—The month of the moon's declination, approximately 27⅓ days in length.

Diurnal Inequality.—The difference between morning and afternoon tides, due principally to the declination of the moon.

Higher High Water.—The higher of the two high waters of a day.

Lower High Water.—The lower of the two high waters of a day.

Lower Low Water.—The lower of the two low waters of a day.

Higher Low Water.—The higher of the two low waters of a day.

Semi-Diurnal, or Semi-Daily Type of Tide.—A tide in which two high and two low waters occur each day, but with little diurnal inequality.

Diurnal, or Daily Type Tide.—A tide in which only one high and one low water occur in a day.

Mixed Type Tide.—A tide in which two high and two low waters occur in a day, exhibiting marked diurnal inequality in the two highs or in the two lows.

Component Tide, or Component.—Each of the simple tides into which the tide of Nature is resolved.

Amplitude of the Tide, or of a Component.—The semi-range of that tide or component.

The Epoch.—The phase or time of occurrence of high water reckoned from a fixed time origin.

Harmonic Analysis.—The mathematical process by which epochs and amplitudes of component tides are disentangled from actual tidal observations.

*Principal Lunar Component.**—The lunar component (M_2) which gives two high and two low waters in a tidal day of 24 hours and 50 min.

*Principal Solar Component.**—The solar component (S_2) which gives two high and two low waters in a solar day of 24 hours.

*Component N_2.**—The tidal component which takes account of the moon's perigean movement.

*Components K and O.**—The tidal components which take account of the moon's changing declination. The periods of the two components are such

* These five components are the principal ones. Between twenty and thirty components are used in accurate predictions of tides.

that at maximum declination the components are at a maximum and when the moon is on the equator they neutralize each other.

Mean Sea Level.—The plane about which the tide oscillates.

Mean Tide Level.—The plane half way between mean low water and mean high water.

Plane of Mean Low Water.—The average of all low waters of a series of tide observations.

Plane of Mean Lower Low Water.—The average of all lower low waters where the tide is of the mixed type.

Plane of Mean High Water.—The average of all high waters of a series of tide observations.

Plane of Mean Higher High Water.—The average of all higher high waters.

Tidal Current.—A current brought about by tidal forces.

Non-Tidal Current.—A current brought about by causes independent of the tides, such as winds, fresh-water run-off, and differences in density and temperature.

Rectilinear Tidal Current.—The current characteristic of inland bodies of water, with slack-water and reversing direction, running flood for a period of about 6 hours, and ebb in the opposite direction for a period of about 6 hours.

Rotary Tidal Current.—The type of current in the ocean's offshore. These currents do not slack and reverse, but change direction continually, passing through all points of the compass in a tidal cyle of 12 hours and 25 min.

Flood Current.—The current that sets inland or up stream.

Ebb Current.—The current that sets seaward or down stream.

Types and Forms of Tides

The tides in the various parts of the world assume a number of different types and forms, yet they may be conveniently classed as three distinct types, with their different forms. The general classification may be made as (1) semi-daily; (2) daily; and (3) mixed types of tides. Fig. 1 shows automatic tide-gauge records, illustrating these simplest types—the semi-daily at Portland, Me., the daily at Manila, Philippine Islands, and the mixed at San Francisco, Calif. In the simple form of the semi-daily type two high and two low waters occur each day, the morning and afternoon tides being very similar. The simple form of the daily type has only one high water and one low water during a day; while the third, the mixed type, is caused by a combination of the daily and semi-daily types. It is characteristic of this type that two high and two low waters occur each day, but the two differ both as to form and height.

Even these simplest types vary with the moon's changing declination, as illustrated in Fig. 2, reproducing tidal records at Portland and Manila. The upper graph for Portland is known as an equatorial form, which occurs when the moon is near the equator in its changing declination. The lower graph for Portland is known as the declinational form, occurring when the moon's declination is large. This variation in the height of the two high waters, or of the two low waters, during a day, is known as the diurnal inequality

in the tides, and is directly related to the declination of the moon, being least when the moon is on the equator, and greatest when it is farthest north or south from the equator, causing "tropic tides". At certain times the semi-daily tide as represented by Portland approaches somewhat the mixed type, although to a minor degree in comparison with a truly mixed type.

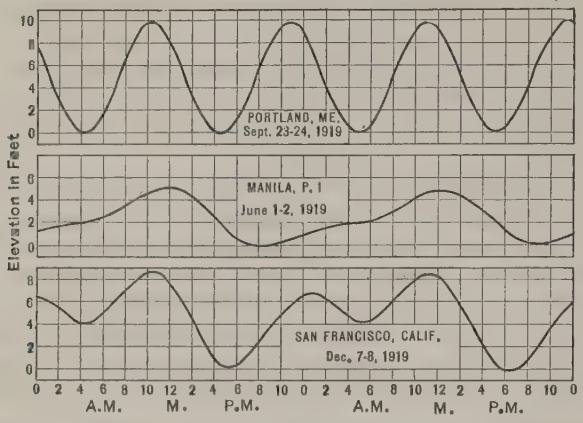

FIG. 1.—THREE TYPES OF TIDE—SEMI-DAILY, DAILY, AND MIXED.

The diagram for Manila (June 1 and 2, 1919), illustrates a tide which ordinarily is of the daily type, but which for a few days during a lunar month at the time when the moon is nearing the equator, and, therefore, when the

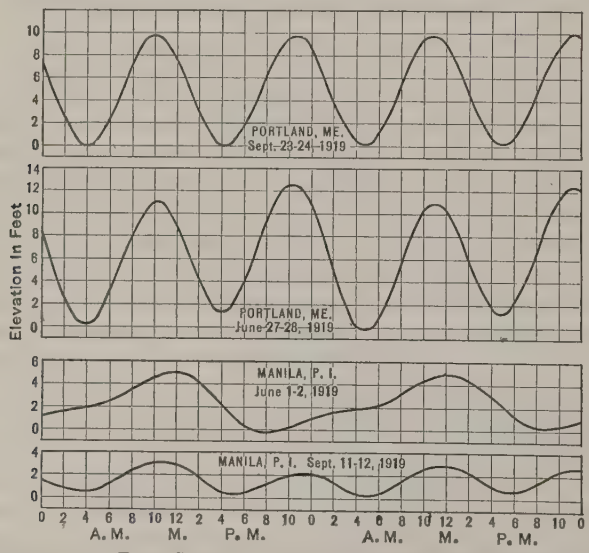

FIG. 2.—VARIATION OF TIDE CURVES DUE TO CHANGING DECLINATION OF THE MOON, EXEMPLIFIED IN TIDES AT PORTLAND, ME., AND MANILA, PHILIPPINE ISLANDS.

semi-daily forces are exerting the dominant influence, has a semi-daily variation. The remaining graph of Fig. 2 for Manila (September 11 and 12, 1919),

represents the ordinary daily tide. Likewise, the tide of a port which ordinarily has a mixed type changes for a few days during the month to a semi-daily form when the moon is near the equator.

In addition to these variations two distinct forms of the mixed type occur in some localities, as illustrated by the tides at Seattle, Wash., and Honolulu, Hawaii (Fig. 3). At Seattle there is little variation in the high waters but considerable variation in the low waters, while at Honolulu the tide shows very little difference in the height of the low waters, but a marked difference in the height of the high waters. This difference in form is due, briefly, to different combinations of the diurnal and semi-diurnal waves—they may have the same phases and different amplitudes, different phases and the same amplitudes, or both different phases and different amplitudes. It is evident, therefore, that they may combine in various ways, giving rise to many other different forms.

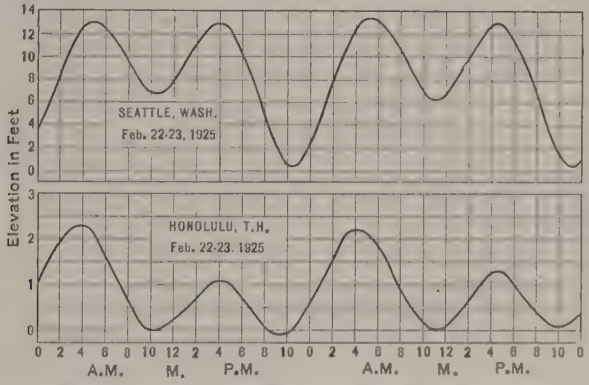

FIG. 3.—DIFFERENT FORMS OF MIXED TYPE OF TIDE EXEMPLIFIED BY TIDES AT SEATTLE, WASH., AND HONOLULU, HAWAII.

Some of the various combinations of the diurnal and semi-diurnal waves which give rise to these many different forms of mixed types of tide are shown in Fig. 4. In the upper curve the phases and amplitudes of the diurnal and semi-diurnal waves are such that their combination results in a mixed type of tide (heavy line) in which both the high and low waters of a day differ. In the middle graph the combination of the diurnal and semi-diurnal waves results in a mixed type of tide with a marked difference in the high waters of the day and with no difference in the low waters. In the lower graph the diurnal and semi-diurnal waves have phases and amplitudes the resultant of which is the "vanishing tide"; in this type the water of the falling tide remains for several hours at a fixed height at about mean sea level, then falls to the ordinary low water.

The tide in a river draining a considerable area illustrates another type of tide. The fresh-water run-off affects the tidal wave of the river to a considerable extent, causing the graph to be steep and of a comparatively short period for the flood tide and more inclined and of a longer period for the ebb tide. This is known as the "river type tide" and is illustrated by the tide at Philadelphia, Pa., and Albany, N. Y. (Fig. 5). In the upper graph the tide was

rising at Philadelphia from 3:20 A. M. to 9:00 A. M. (5 hours and 40 min.), and falling from 9:00 A. M. to 4:20 P. M. (7 hours and 20 min.); in the lower graph the tide was rising at Albany from 4:10 A. M. to 8:40 A. M. (4 hours and 30 min.), and falling from 8:40 A. M. to 4:40 P. M. (8 hours).

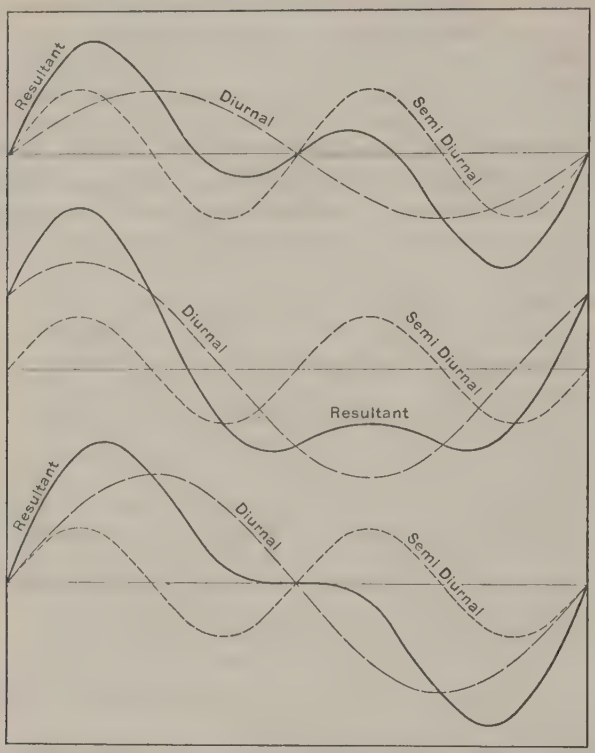

FIG. 4.—IDEALIZED TIDE CURVES ILLUSTRATING VARIOUS COMBINATIONS OF DIURNAL AND SEMI-DIURNAL WAVES WHICH GIVE RISE TO MANY DIFFERENT FORMS OF MIXED TYPES OF TIDES.

This type is very pronounced in a number of shallow rivers and estuaries which have considerable range of tide, and broad flats, bare or almost bare at low water. The extreme case is represented by the "bore"—the tide rises so rapidly that the meeting of the incoming tide wave with the natural fresh-water run-off of the river, coupled with the friction of the lower layers of water with the bottom, causes the incoming wave to assume the form of a wall of water at times several feet high, which rushes up the river or estuary. Probably the most famous bore occurs in the Tsien-tang Kiang,* in China, although smaller ones are found in Turnagain Arm, Alaska, on the Severn and Wye, in England, on the Seine, in France, on the Hoogly, in India, and on the Petitcodiac, in Canada.†

* For description see, G. H. Darwin, "Tides and Kindred Phenomena in the Solar System," p. 63.

† Observations of the bore on the Petitcodiac River have been made at Moncton, N. B., Canada, by Dr. W. Bell Dawson, formerly Superintendent of the Tidal and Current Survey, of Canada, see "Survey of Tides and Currents in Canadian Waters," Ottawa, Ont., Canada, p. 23.

As evidenced from the possible combinations illustrated in the idealized tide curves (Fig. 4), there are of course many other variations of forms of tides. The types described, however, are the principal ones. The type and form of the tides are considerably modified at times by the changing declination of the moon; that is, its position relative to the equator, as well as by terrestrial causes. There are also periodic variations in the range of the tide; that is, the heights to which the tide rises at high water and to which it falls at low water. These variations in range are brought about by astronomical causes.

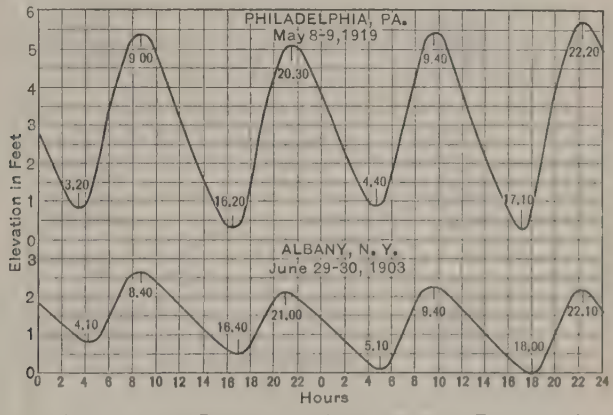

FIG. 5.—TIDE CURVES FROM RECORDS AT PHILADELPHIA, PA., AND ALBANY, N. Y., ILLUSTRATING THE "RIVER TYPE TIDE."

CAUSES OF VARIATION IN RANGE

History does not disclose just when the true relation of the moon to the tides was first recognized; but it is known that as early as the Third Century, before the beginning of the Christian era, Pytheas of Massilia, who had sailed beyond the Mediterranean Sea as far north as the British Isles, and probably to the Arctic Circle, noted this relationship. Pliny, the Elder, four centuries later, definitely ascribed the moon and sun as makers of the tide. The probable reason why history is vague as to the tidal phenomenon is because the people of antiquity who have left a history of their times lived near the Mediterranean Sea where the tidal range is small and its regular fluctuations are frequently modified and at times completely masked by meteorological conditions.

In the sixteen centuries following Pliny, the Elder, no progress was made toward a solution of the problem of the tides. The discovery of the law of gravitation by Newton (toward the end of the Seventeenth Century) furnished a rational explanation of the forces exerted by sun and moon. Newton showed that the tide was a natural consequence of the law of gravitation; having proved this he did not carry his investigations further, but left the development of the different theories to the scientists following him.

It is now well known, of course, that the tides are caused by the attraction of sun and moon on the rotating earth, the moon being the principal agent,

since it is closer to the earth and since the tidal forces exerted by a foreign body vary directly as its mass and inversely as the cube of its distance from the earth. It is evident, therefore, that any variations in the distance from the earth of these two tide-producing bodies, or any variations in their relative positions with reference to the earth, will bring about corresponding variations in the tidal forces exerted and thus a periodic variation in the range of tide.

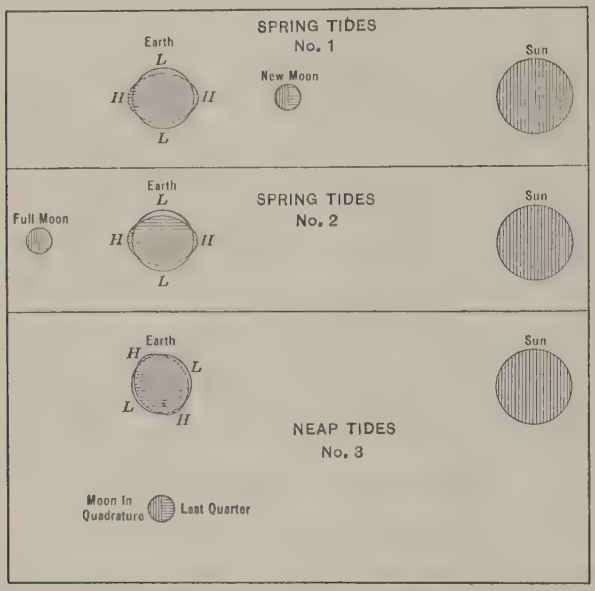

FIG. 6.—DIAGRAMMATIC REPRESENTATION OF CAUSES OF SPRING AND NEAP TIDES AND THEIR DIFFERENCES.

A non-mathematical illustration of these varying astronomical conditions is furnished by Fig. 6 which assumes the earth to be covered with water to a uniform depth. When the moon is over any point its attraction for the water under it is greater than its attraction for the solid earth; the tendency is, therefore, to pull the water away from the earth and thus cause high water. Likewise, the moon's attraction for the solid earth is greater than its attraction for the water on the opposite side of the earth from the moon; its tendency then is to draw the earth away from the water and make high water on the opposite side. The moon, therefore, as it travels around the earth causes in general two high waters each day at a place, one at the upper, and one at the lower, transit, with two low waters in between. While these conditions are not exactly true in Nature, Fig. 6 will serve to illustrate diagrammatically the causes of the so-called "spring" and "neap" tide and their differences. This diagram is untrue to Nature in that high water does not actually follow directly under the moon but has a lag, due to viscosity of water, to friction, and to land masses; and, in addition, in that the tidal forces exerted by the moon and sun are tangential and not vertical, that is, the

direct lifting power of the moon and sun is slight, and the water rather is drawn together from the two sides of the earth under these bodies.

In Diagrams No. 1 (Fig. 6), the moon and sun are in line relative to the earth, and their tidal forces acting through gravity on the earth and oceans are in concert and bring about the large tides which have been designated "spring" tides. In Diagrams No. 2, although the moon is on the opposite side of the earth from the sun, the tidal forces of both bodies are again in unison and produce the spring tides which occurred a fortnight before at the time of new moon, since the moon's two high waters, one on each side of the earth, combine with the two high waters brought about by the tidal forces of the sun. In Diagrams No. 3, the moon is in quadrature. Under this condition the tidal forces exerted by the sun are at right angles to those exerted by the moon, and, therefore, working against one another, each force tending to minimize the force of the other body. This counter-attraction naturally gives rise to small range tides which have been designated "neap" tides. These neap tides occur again in about two weeks when the moon has come to its first quarter on the opposite side of the earth relative to the sun.

The path of the moon in its orbit describes an ellipse, its distance from the earth varying during the course of the lunar month, causing variations in the range of tide. When the moon is in a position closest to the earth (in "perigee"), its tidal forces are strongest; and, conversely, for its position farthest from the earth (in "apogee").

Variations in the range of tide are likewise brought about by the varying distance of the earth from the sun due to its elliptical orbit. At the time the earth is closest to the sun it is said to be in "perihelion"; when it is farthest away it is said to be in "aphelion".

When the spring tides happen to occur at the same time that the moon is in perigee, the range of the tide at some places is increased as much as 40 per cent. Likewise, when the neap tides occur at the same time that the moon is in apogee, the range is less than the mean by about 40 per cent.

An example from Fort Hamilton, New York Harbor, will serve to illustrate these differences.* There the spring, neap, apogean, perigean, and mean ranges are as follows:

Mean	.....	4.7 ft.
Spring	.....	5.6 ft., or 20% greater than the mean range.
Neap	.....	3.8 ft., or 20% less than the mean range.
Perigean	.....	5.8 ft., or 23% greater than the mean range.
Apogean	.....	3.8 ft., or 20% less than the mean range.

The moon was full and also in perigee on July 15, 1916. On July 16, a day later, the tide record from Fort Hamilton shows a range of 6.5 ft., or 39% greater than the average range. This lag of one day in the response of the tide to the tide-producing forces is known as the "age of the tide" and is generally ascribed to the effects of friction.

The moon was in its third quarter and also in apogee on October 16, 1916 The following day the range at Fort Hamilton was 3.2 ft., or 32% less than the mean range.

* "Flood and Ebb in New York Harbor," by H. A. Marmer, *Geographic Review*, Vol. XIII, July, 1923, p. 420.

This subject of types, forms, variations in tidal range, and many other problems have required study and solution by tidal mathematicians before tide predictions could be presented to the engineer and to the mariner in their present accurate state. A study of the different types of tides and the behavior of the tide in different parts of the world played a large part in the conception and in the development of the latest tidal theory—the stationary wave theory of R. A. Harris, a mathematician of the U. S. Coast and Geodetic Survey.

Tidal Theories

Several tidal theories, based on the law of gravitation and Newton's theory, have been advanced since his time,* each looking toward a finally accepted solution of the tidal problem, among them Bernouilli's Equilibrium, or Static, Theory; Airy's Canal Theory; Whewell's Progressive Wave, or Southern Ocean Theory; and, finally, the latest—the Stationary Wave Theory of Harris. Harris' theory is opposed to the older ones. For the idea advanced by previous theories, namely, a single world phenomenon, it substitutes regional oscillatory areas as the origin of the dominant tides of the various oceans, these oscillations being set up and maintained by the periodic tidal forces of the moon and sun.

Clearly, a wave in continuous motion does not imply that the water is moving in the same direction—it is only the forward motion of a shape as evidenced by the kind of wave traveling in from the ocean toward the land. A somewhat similar motion occurs in a rope held in the hand and violently agitated, or a wave in a pond caused by the dropping of a pebble in the water. In the case of the rope a wave will travel its length, the rope itself remaining fixed in so far as progression in direction of travel of the waves. Such a wave is known as a progressive wave (illustrated by the lower diagram, Fig. 7); the older tidal theories depended on the progressive wave as an explanation of the origin of the dominant tides of the ocean. An altogether different kind of wave may travel through a body of water. The upper diagram in Fig. 7 represents a vessel partly filled with water. If one end is raised and immediately lowered, a wave will be started throughout the vessel, and the water put into oscillation, causing a greater depth at one end than at the other, that is, high water at H' and low water at L', with a nodal line, or no change of level, at N. As the oscillation is continued, high water occurs at H and low water at L, and again a nodal line at N. High water will occur at one end when it is low water at the other, and high or low water will occur simultaneously throughout each half of the vessel. This kind of wave is known as the stationary wave.

The period of this wave or oscillation depends on the length of the vessel and the depth of the water. To cause this oscillation to keep on it is only necessary to continue the disturbing force. If this force be applied at regular intervals coinciding with the period of the vessel, the maximum effect

* For general description of the different theories see *Scientific Monthly*, Vol. XIV, No. 3, March, 1922, H. A. Marmer, pp. 209–218; for detailed explanation, see "Manual of Tides," by Harris, Pt. 1, pp. 386–465.

is obtained. Similar oscillations occur in most lakes in which the whole body of water swings back and forth with a period of from 10 min. to 1 hour and with a range of several inches. These oscillations, known as "seiches", are caused by sudden changes in atmospheric pressure or by winds over the lakes. Studies of seiches have been made for a number of lakes and given in detail in various publications.*

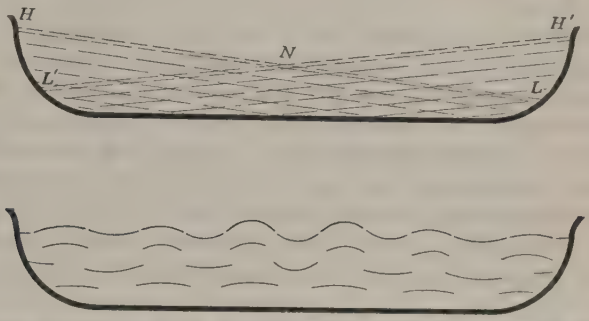

FIG. 7.—GRAPHIC ILLUSTRATION OF STATIONARY AND PROGRESSIVE TIDE WAVES. UPPER DIAGRAM IS BASIS OF A STATIONARY THEORY OF TIDES.

In brief, therefore, such a system of waves forms the basis of Harris' stationary wave theory—that the dominant tides of the world are the results of stationary waves, these oscillations being set up and maintained in the various parts of the oceans by the periodic tidal forces of moon and sun.

In most bodies of inland water connected with the ocean the tidal wave is a progressive wave thrown out by a near-by oscillatory wave in the ocean. The rate of advance of such a progressive wave up an inland body of water, such as Chesapeake Bay, is expressed approximately by the formula, $r = \sqrt{g\,h}$, in which, r is the rate of advance; g, the acceleration due to gravity which is about 32.2 ft. per sec.; and h, the average depth of the water.

If the size and depth of a body of water are such as to maintain an independent stationary wave, its tides may be caused by its own stationary wave; or again in some bodies of water the tide may be caused partly by a progressive wave and partly by a stationary wave, as, for example, in Long Island Sound and in the Bay of Fundy. The period of a body of water having a stationary wave is expressed in the formula, $T = \frac{4\,L}{\sqrt{g\,h}}$, in which, L is the length of the body in the direction of oscillation. In such a body high (and also low) water occurs almost simultaneously throughout its length and the range of the tide increases toward and is greatest at the head; in a body with a progressive wave high and low water advance at a rate dependent on the depth, and the range of tide generally decreases toward the head. The tides in the Bay of Fundy are the best example of the wave of the stationary type.

* "The Tides and Kindred Phenomena in the Solar System," by G. H. Darwin, p. 21, and "Effects of Winds and Barometric Pressures on the Great Lakes," by the late John F. Hayford, M. Am. Soc. C. E., Carnegie Inst. of Washington, 1922.

The Bay of Fundy may be considered as a part of the vessel of water shown in the upper diagram, Fig. 7, the tide occurring almost simultaneously throughout the length of the Bay, the range at the mouth being from 6 to 10 ft., and increasing up the Bay to about 20 ft., and, finally, at the head of the Bay to more than 40 ft. At Nantucket, off the coast of Massachusetts, the range of tide is 3.3 ft., at Monomoy Point, Mass., 3.7 ft., at Nauset, Mass., 6.0 ft., increasing gradually to 20.9 ft. at St. Johns, N. B., and to 41.2 ft. at Moncton, N. B.

The stationary wave theory, then, would have the tides in the various oceans distinct problems. They may be due to a progressive wave thrown out by a near-by oscillatory area of the open ocean, or if the size and depth of the body are such as to maintain an independent stationary wave, its tides may be caused by its own stationary wave; or, again, in some bodies of water, the tide may be caused partly by a progressive wave and partly by a stationary wave. According to the stationary wave theory the configuration of the bottom, the size of the body of water, and the relation of the period of the tidal forces to the period of the body of water make the tide more a local phenomenon.

While from astronomical considerations a mathematical expression for the tide-producing forces may be derived, from which a theoretical tide may be obtained, the actual tides of Nature are so modified by land masses that they have little or no resemblance to these theoretical tides. For the prediction of tides at any place, therefore, it is necessary first to make actual observations, extending over a period of a month to a year or more. From these observations constants are derived which may be introduced into the theoretical expressions for predicting tides as they actually occur in Nature.

Prediction of Tides

In the days of shallow-draft vessels advance knowledge of the state of the tides was of little importance, but as the draft of vessels approached the depth of water over bars and in harbors, such knowledge became of importance to the navigator. It has also become of value to the engineer in the placing of bridge spans, and in a number of similar engineering operations; to watering places for the convenience of the bather; to the fisherman in planning his fishing trips; and to a number of diverse interests too numerous to mention. Figs. 8 and 9, showing high and low tides at Anchorage, Alaska, forcibly impress the need of tide predictions in places having a considerable range of tide and comparatively shallow water at the time of low tide.

The first tide table of record is in the Library of the British Museum. It is a manuscript written in the Thirteenth Century, and gives the time of the tide at London Bridge relative to the age of the moon and not for calendar days. Each of the leading maritime nations publishes tide tables, and since the Coast and Geodetic Survey is the Bureau of the United States Government charged with the furnishing of information to the mariner, the important function of predicting and issuing tide tables naturally devolves on this Service. Tide tables were first published by the Survey in 1853. For the first fourteen years they consisted of a somewhat elaborated means for

enabling the mariner to make his own predictions as occasion arose. In 1867 tables were issued for a few ports on each coast of the United States. They have since been considerably increased in size and scope until now they cover the entire maritime world.

While approximate predictions of the time of high water for a particular day can be made by adding 50 min. for each day since the full and change of the moon to the lunitidal interval (known as the Establishment of the Port), so many factors are involved in the prediction of tides that for accurate results a tide-predicting machine is necessary.

Prior to 1885 the predictions of the tides were computed by means of empirical tables and graphs. Beginning with that year the predictions were made by use of an ingenious machine* devised by Mr. William Ferrel, of the U. S. Coast and Geodetic Survey. This machine differed somewhat from that of Lord Kelvin, who conceived the idea of such a machine and who devised the first one in 1872. When predictions were extended, however, by the Survey to cover the world, it was found that the Ferrel machine was not well adapted to the prediction of certain types of tides, and since 1910 the predictions have been made on a new machine, also designed and constructed in the office of the Survey. This machine is shown in Fig. 10.† By its use a tide table for any single port can be made in about 10 hours, giving the time and height of every high and low water for every day of the year.

For the purpose of predictions the tide is assumed to be composed of a number of elementary constituent tides, each due to the motions of the sun and of the moon and to their relative positions during the year; and, since the tides are local phenomena, the first step in the making of a tide table for any port is to obtain continuous tidal observations at that port. These observations are then subjected to the harmonic analysis which resolves the tide into its constituent simple harmonic waves, or harmonic constants, the periods of which have astronomical definitions, while the amplitudes and phases are derived from actual observations of the tide.

Before beginning the predictions for any port the amplitudes (semi-ranges), and the phases (times of occurrence of high water reckoned from a fixed origin), as obtained from this analysis for each constant, are set on the proper cranks and dials of the machine. These cranks and dials are arranged so that when the machine is put in motion by a handle and gears, it will sum up the effects of all these elementary waves into a single wave representing the tide of Nature. Further, the machine is so constructed that this summation is indicated on a large dial (Fig. 10) as high and low water, and also the time of occurrence is given in standard civil time. The U. S. Coast and Geodetic Survey machine will take account of thirty-seven of these elementary tides.

It is obviously impracticable to predict the tides for all ports. To obtain the state of the tide at a place where no full predictions are made, it is referred to some other port having a similar type of tide for which predictions have been made as a standard port. The Survey makes full predictions for eighty-

* Appendix No. 10, U. S. Coast and Geodetic Survey Report, 1883, p. 253.

† "Description of the United States Coast and Geodetic Survey Tide Predicting Machine No. 2," pub. by the U. S. Coast and Geodetic Survey.

three standard ports, and furnishes a table of data from which predictions may be obtained expeditiously for about 3 500 subsidiary ports, covering the entire maritime world.

Accuracy of Tide Tables

In the prediction of tides (also for mean ranges and lunitidal intervals) for any port, the data used are based on the longest series obtainable at that place, except that, in general, due to the labor involved in the summing of hourly ordinates of the tide and in the harmonic analysis, one year's observations are considered sufficient for all practical purposes. The average of these observations will give the times and heights of the astronomical tide under average or normal conditions. Exact agreement, however, cannot be expected between predictions and actual times of occurrence, since the times and heights of the tide will be modified by the prevailing meteorological conditions which may not be normal. This is particularly true of upper reaches in rivers subject to freshet conditions, and also of comparatively shallow bays with a small range of tide.

In some bodies of water in which the range of tide is small and the depth comparatively shallow, the water will be banked up or blown out by a strong wind, causing considerable differences between predictions and actual tides, and in extreme cases completely masking the normal tide. In Chesapeake Bay, for example, a stiff northwest wind blowing for a few days will cause the tides to be later and the heights lower than those predicted. Then, again, a heavy northeast storm piles up the water in the Bay causing tides higher than predicted.

The necessity for long series of observations to obtain final values in tidal data in a river subject to freshets is brought out by the tidal curves in Fig. 11, from actual observations at Albany, N. Y. The periodic tidal fluctuation in the lower graph (May 27) is only slightly modified by fresh-water run-off, low water reading about 2½ ft. on the staff and the range being 3 ft. The tidal fluctuations on the upper graph, although regular on March 27 and 28, are decreased in range and the whole mean river level raised on the tide staff, until on March 29 the tidal fluctuation has been completely masked by the freshet, and the level of the river has risen to 11 ft. on the staff. A similar condition is illustrated on the middle graph (April 11) when there was a slight periodic tidal fluctuation with the river level raised to 11 ft. on the staff. This fluctuation is completely masked by 8:00 P. M., April 12, with the river level up to 18 ft. on the staff. These conditions, however, are extreme. Most tide predictions are made for bodies of water that are not so greatly influenced by existing meteorological conditions, either because of large tidal range or of considerable depth of water.

As an illustration of the close agreement of these predictions with the tides as they actually occur at stations not influenced to such a marked degree, observations and predictions at San Diego, Calif., and Fernandina, Fla., have been compared for the months of March and August, 1923. At San Diego, the tide is of the mixed type and has a range varying from 2 to 6 ft.; at Fernandina, the tide is of the semi-daily type and has a range of 4 to 9 ft.

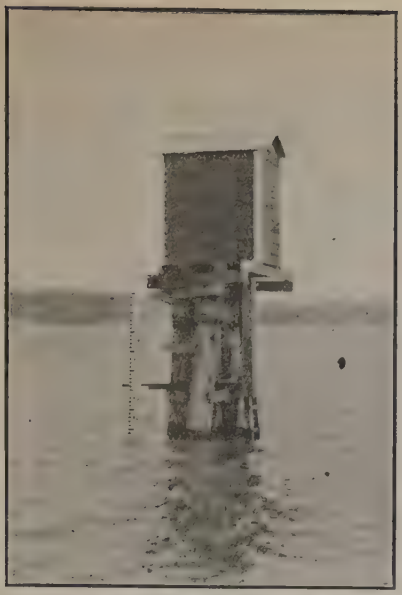

FIG. 8.—HIGH WATER AT TIDE STATION, ANCHORAGE, ALASKA, READING 41.3 FEET.

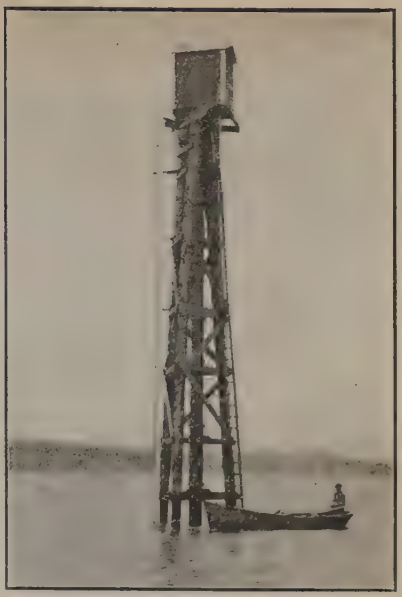

FIG. 9.—LOW WATER AT TIDE STATION, ANCHORAGE, ALASKA, READING 7.5 FEET.

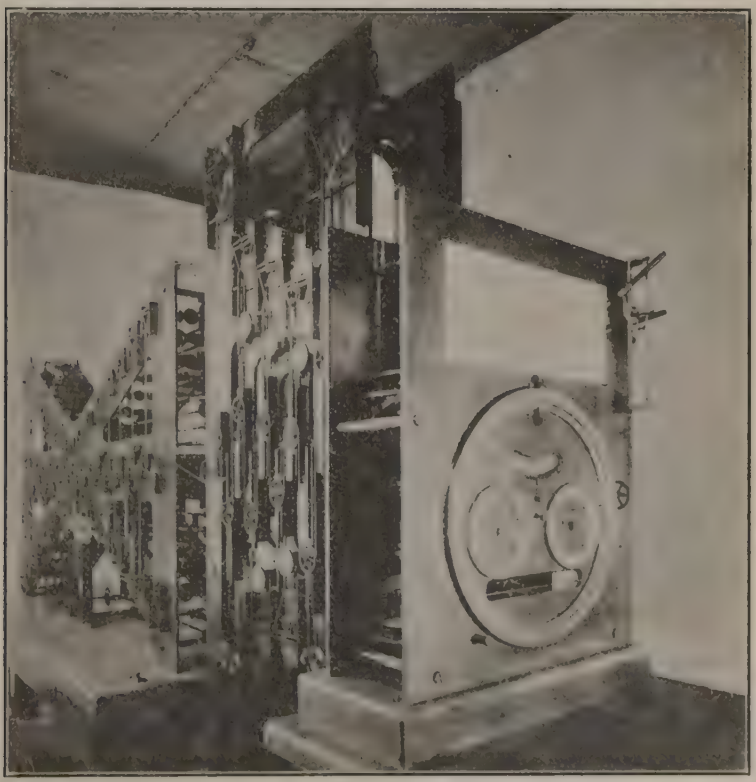

FIG. 10.—FRONT VIEW OF TIDE-PREDICTING MACHINE OF THE U. S. COAST AND GEODETIC SURVEY.

At San Diego for the whole month of March, 1923, 60% of the predicted times differed by not more than 0.1 hour from the observed, and 87% by not more than 0.2 hour. For August, at this station, 48% of the predicted times differed from the observed by not more than 0.1 hour, and 75% by not more than 0.2 hour. The greatest difference in each month between the predicted and observed times of tides was 0.8 hour, or about 50 min.

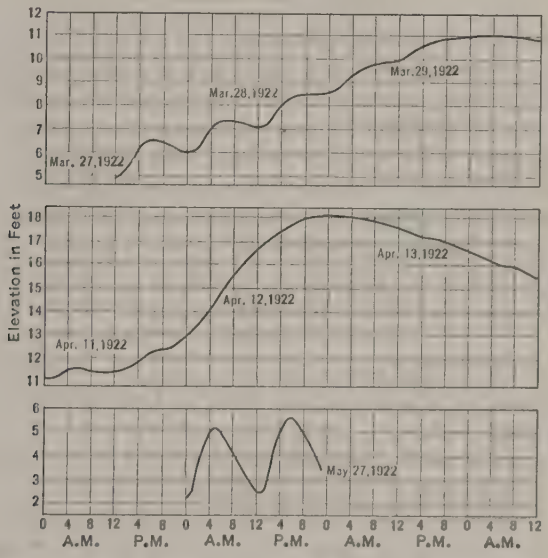

FIG. 11.—TIDE CURVES FROM RECORD AT ALBANY, N. Y., ILLUSTRATING RIVER TYPE TIDE AND EFFECTS OF FRESHETS IN UPPER REACHES OF RIVER.

At Fernandina for the whole of the month of March the percentages are as follows: 36% of the predicted times differed by not more than 0.1 hour from the observed tide; 59% by not more than 0.2 hour; and 76% by not more than 0.3 hour. During the month of August, 39% differed by not more than 0.1 hour from the observed; 55% by not more than 0.2 hour; and 79% by not more than 0.3 hour. During the month of March the greatest difference was 0.7 hour, or about 40 min., and for August the greatest difference was 0.6 hour, or about 35 min. It should be borne in mind, however, that no corrections were applied to the predicted times of tide for meteorological conditions; and, further, that near the times of high and low water the height of the tide is changing slowly and, therefore, it is not practical to determine the time of the observed high or low water with a precision greater than 0.1 hour.

It is quite evident, therefore, why a continuous record at different places of the rise and fall of the water, brought about by the tides, early became of importance to modern life. Not only were these data necessary for commerce in the advance predictions of the future state of the tides in harbors and for the reductions of soundings in hydrographic surveys, but they were of impor-

tance to the theoretical study of the tides in general. These records are also of considerable value to the engineer for defining datum planes; to the geodesist in connection with his level nets and the reduction of his large-scheme triangulation systems to mean sea level; and to the geologist for testing the stability of coast lines by reference to accurately determined mean sea level.

Use of Tide Tables

For those who may not be familiar with the tide tables and their use the following examples, together with the facsimiles of pages* of tide tables (Figs. 12 and 13), will illustrate the facility with which the predicted times of high and low waters may be obtained for any port listed in the tables, as a standard port, or as a subsidiary port in Table 2 of the Tide Tables (see Fig. 13).

As an example: What is the predicted time and height of high water at New York (Governor's Island) on the afternoon of December 25, 1926? Referring to Fig. 12, opposite December 25, in the double column, "High", it is found that the afternoon high water occurs at 12:20 P. M., and that the height is 3.5 ft. above the datum of soundings on U. S. Coast and Geodetic Survey charts.

If predictions are desired for a subsidiary port for which full predictions are not listed among the standard ports, Table 2 of the Tide Tables (Fig. 13), furnishes the necessary data.

As an example: What is the predicted time and height of high water at West Point, N. Y., on the afternoon of December 25, 1926?

The time of high water just found for New York, the standard port under which West Point is listed in Table 2 of the Tide Tables, is used to obtain that for West Point as follows (Fig. 13):

	Time.	Height.
High water at New York	12:20 P. M.	3.5 ft.
Tidal difference	+3:25 P. M.	—1.8 ft.
High water at West Point	15:45, or 3:45 P. M.	1.7 ft.

It might be well to explain briefly the remainder of the columns in Table 2 of the Tide Tables (Fig. 13). It is evident that the first and second narrow columns are the latitudes and longitudes of the ports, and the third and fourth narrow columns, the time and height differences to be applied to the standard port predictions to obtain those for minor ports. In Fig. 13, the column, "Ratio of Ranges" gives the ratio of the rise and fall of the tides at the standard and at the secondary ports. For example, the mean rise and fall of the tide at West Point is 0.6 of that at New York. The column headed "High Water Interval", gives for West Point 11 hours and 30 min., which means that high water occurs there on an average 11 hours and 30 min. after the moon crosses the meridian of West Point. The last two columns refer to the ranges, the "mean range" being the mean of all the ranges of the tide, and the "spring range", the mean range of the spring tides.

FIG. 13.—Reproduction of Part of Table 2 of Tide Tables, Showing How Secondary Ports Are Referenced to Data Shown in Fig. 12.

Instruments for the Observation of Tides

As a means toward labor-saving and time-saving, automatic or self-registering devices give continuous observations of natural phenomena over long periods for use in planning engineering works. Thus, as the importance of series of tidal observations became apparent, the plain tide staff was replaced by automatic gauges.

The earliest automatic tide-gauge* was devised by an English civil engineer, Henry R. Palmer, to obtain a continuous record of fluctuations in the River Thames for getting the effect on the tidal regimen of the river by the removal of London Bridge, "free", as expressed by Mr. Palmer, "from the inaccuracies and doubts which the frequent and long-continued observations of individuals through nights and days must be liable."

* A paper descriptive of this gauge appears in *Philosophical Transactions*, Royal Soc., 1831.

The fundamental principles embodied in this first automatic gauge are still used and although there are many forms of these gauges, the principle is a simple one.* A float is connected by a fine bronze wire or tape with a self-recording pencil or pen, which moves at a reduced scale backward and forward across a paper record which is wound on a cylinder, either vertical or horizontal. This paper revolves by means of a clock movement, thus causing the pencil to trace a curve that accurately represents the tide for that locality.

The U. S. Coast and Geodetic Survey at its primary tide stations makes use of the automatic tide-gauge shown in Fig. 14.† Its principal features are the motor clock which drives the main cylinder regulating the motion of the paper—a roll, 13 in. wide and 66 ft. long, sufficient for a month's record; the time-clock, similar to an ordinary striking clock, trips the recording pencil, making a mark on the tide graph or curve every hour; a system of pulleys and wires connects the mechanism with a tide-float which rises and falls in a well having a small opening for the entrance of the water. Usually the well is made of 2 by 12-in. planks, but at outside ocean stations it is composed of ordinary 12-in. water pipe. The opening in the well is about 1 in. to 1½ in. in diameter for a float-well, 10 in. square, or 12 in. in diameter. The wave action is thus damped, but the hole is large enough to obviate any lag in the rise and fall as compared with the water outside the well.

To fill the need for a more portable gauge for field use, the Survey has recently developed a new automatic tide-gauge (Fig. 15). This can be used to advantage by hydrographic and tidal parties in the field at stations where it is necessary to obtain tidal observations extending over only a few days, or weeks, for the reduction of soundings taken during the survey, or for comparative purposes. In designing this instrument, the main objects were ease of installation and minimum size, commensurate with the desired accuracy.

The essential features of the gauge are its small size, its single drum on which the paper record is fastened by a spring clip, a single clock movement installed within the drum, a cast base fitting on top of a float-tube of stock iron pipe. This pipe, in addition to serving as a float-well, acts as a support for the instrument, thus obviating the necessity of providing an elaborate platform and a cumbersome float-well. This feature alone renders the gauge adaptable for use by field parties, particularly in remote localities where wharves and docks are not available. Another departure from the usual design of automatic gauge is the use of a spring instead of weights as a counterpoise for taking up the slack of the float wire on a rising tide.

The instrument is 10 in. square on the base and, with its weather-proof metal cover in place, is 11 in. high. This cover is held by a padlock, so that the mechanism cannot be tampered with when the gauge is installed in exposed places.‡

* Special types of pressure gauges have been designed for special purposes, such as the Favé "Marégraphe Plongeur," described in *Annales Hydrographiques*, 1908–10, pp. 383–437, and 1921, pp. 193–237. Various other types of automatic gauges have been described by R. A. Harris, in his "Manual of Tides," Pt. II, p. 480.

† This gauge is described in detail in *Special Publication No. 26*, "General Instructions for the Field Work of the U. S. Coast and Geodetic Survey," p. 113.

‡ This gauge is described in detail in *Special Publication No. 113*, U. S. Coast and Geodetic Survey, "A Portable Automatic Tide Gauge."

For comparison of the marigraph curve with the height of the actual tide it is necessary that a fixed zero of staff be maintained over long periods. For this purpose a standard staff and staff support has been devised, which is firmly secured in a vertical position to a wharf or pile, and carries metal guides into which the graduated staff is inserted for the readings. For accurate observations the wave action is damped by a glass tube ½ in. in diameter, in which floats a thin cork disk. This glass tube, attached to the face of the staff by spring clips, is partly closed at the lower end. A brass stop is securely fastened to the back of the staff at an exact foot mark, and a brass plate is set into the top of the staff support, the stop on the staff resting firmly on this plate as the observation is made. The staff support is covered with sheet copper in waters infested with teredos.

Mean Sea Level*

One of the important phases of the tidal work of the U. S. Coast and Geodetic Survey is the determination and establishment of datum planes based on tidal definition. Surveyors and engineers find necessity for these planes as rational datums for vertical control of their operations just as they have need for geographic positions for their horizontal control. Formerly, they used arbitrary or local datum planes which frequently made it impossible to compare the results of recent with previous surveys, and the practice led to confusion in the junction of contiguous surveys.

Formerly, the matter of rational datums was given little or no consideration, but since the extension of highways and railroads, the mapping of whole countries, and, in fact, the joining of surveys of one State or country with those of its neighbor, considerable confusion has been brought about by the use of various datums, both vertical and horizontal. To obviate the confusion resulting from such practice the Survey has been establishing and furnishing to engineers vertical datum planes, based on tidal definition, along the entire coast line of the United States. As an example, all the datum planes shown in Fig. 16, except mean sea level, are arbitrary. In order to make these arbitrary datums permanent throughout the country, the Survey is connecting by precise level nets all those used in the past by organizations, States, and municipalities. Thus, any of these various planes may be reproduced years hence through their connection with mean sea level, even if all bench-marks are destroyed.

For example, the datum plane at the Boston Station determined from a long series of observations, was lost some years ago through destruction of all bench-marks. This plane has since been accurately reproduced by a later series of observations. By a comparison with near-by long series, the second plane was reproduced by a much shorter local series of observations than was necessary for the first, as illustrated by Fig. 17, showing sea level by yearly means over the period, 1912 to 1923, for four primary tidal stations along the Atlantic Coast.

* For a more detailed discussion, see "Mean Sea Level and Its Variations," by H. A. Marmer, *Annals*, Assoc. of American Geographers, September, 1925.

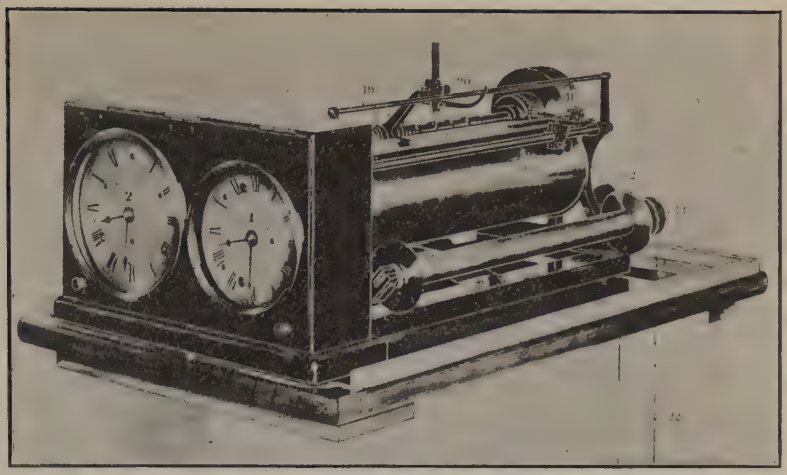

FIG. 14.—FRONT VIEW OF STANDARD U. S. COAST AND GEODETIC SURVEY MODEL AUTOMATIC TIDE-GAUGE FOR USE AT PRIMARY TIDE STATIONS.

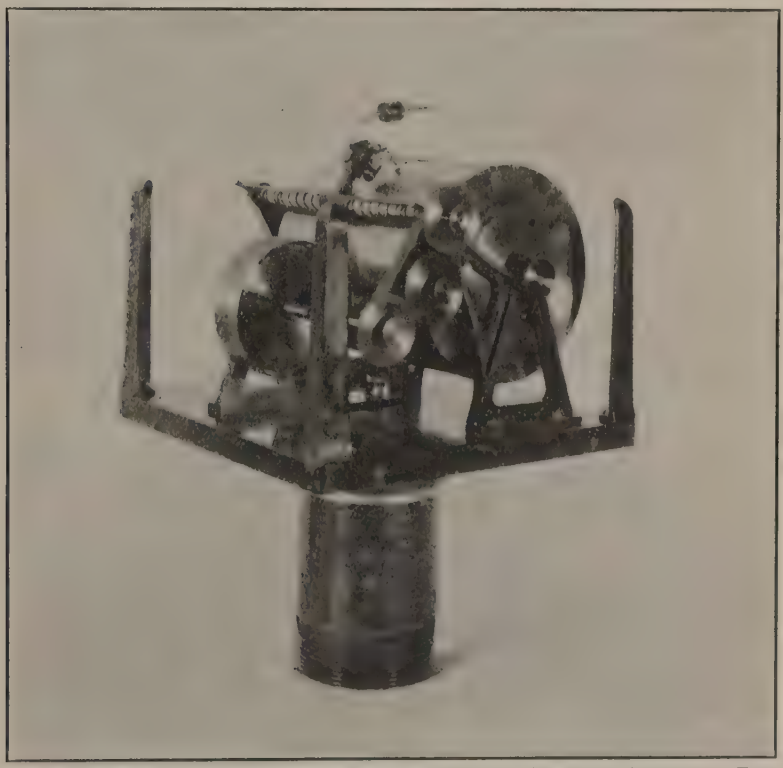

FIG. 15.—VIEW OF U. S. COAST AND GEODETIC SURVEY PORTABLE AUTOMATIC TIDE-GAUGE (WITHOUT COVER).

This graph brings out the interesting fact that the causes for a yearly variation from a mean sea level are not local; but extend, for example, along the entire Atlantic seaboard. For 1919 (the year of largest variation), the

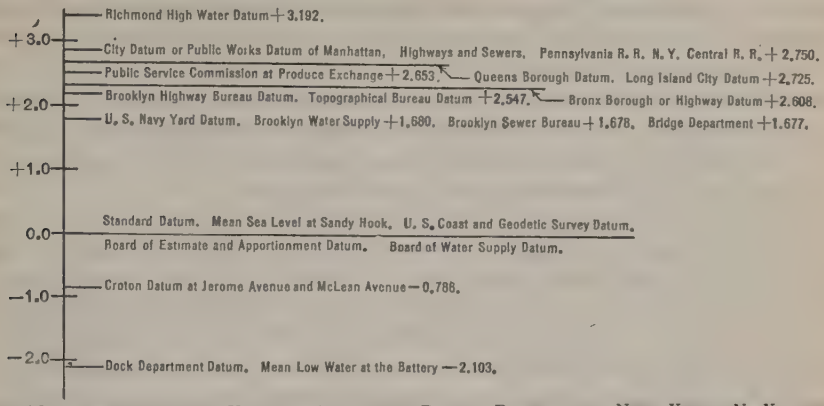

FIG. 16.—COMPARISON OF VARIOUS ARBITRARY DATUM PLANES FOR NEW YORK, N. Y., WITH MEAN SEA LEVEL. PREPARED BY SPECIAL COMMITTEE ON DATUM PLANES OF THE MUNICIPAL ENGINEERS OF THE CITY OF NEW YORK (SEE ITS *Proceedings*, 1915).

sea-level determination at Portland was 0.13 ft. above the long-period mean sea level; 0.22 ft. above at Fort Hamilton; 0.17 ft. above at Atlantic City, N. J.; and so on down the entire coast to Fernandina, Fla.

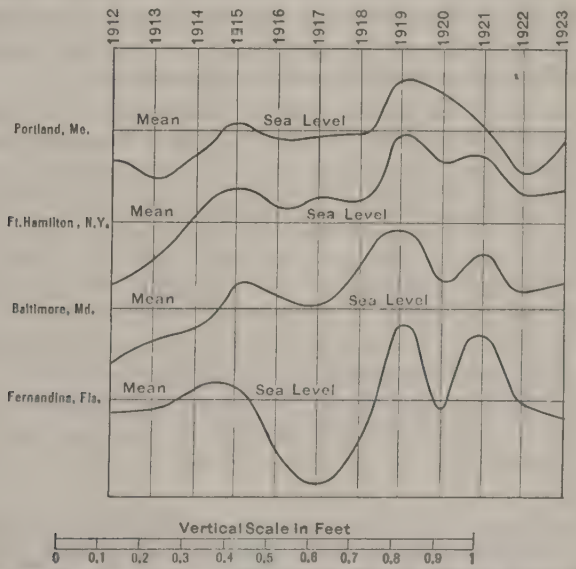

FIG. 17.—GRAPH OF SEA LEVEL DETERMINED FROM YEARLY MEANS (1912–23) AT PRIMARY TIDE STATIONS, COMPARED WITH LONG PERIOD MEAN SEA LEVEL.

The uniformity of these variations over a large area is used for practical purposes in the accurate determination of mean sea level from a short series by comparison with long series at near-by stations. For example, the nearest value to a mean sea level at Boston may be desired from local tidal observations during 1919.

Since it is clearly evident from Fig. 17 that sea level along the entire Atlantic Coast of the United States was above the long-period mean sea level during that year, this may safely be assumed to have been true also at Boston. The mean of the sea levels that year at Portland and at Fort Hamilton was 0.17 ft. above the long-period mean. Including Atlantic City, the average of the three also gives the value, 0.17 ft. above. Taking the average of the variations from the mean for several near-by ports, it is quite probable, therefore, that for all practical purposes a very close value of mean sea level for Boston may be obtained by subtracting 0.17 ft. from the determination from the observations made locally in 1919.

As a test of the accuracy of a datum obtained by reference with primary stations, the comparison may be made separately with two near-by stations at which long series have been observed.* For use in checking a line of precise levels a mean sea level determination was desired for Anacortes, Wash. A tide-gauge was established and maintained for a three-year period; an uncorrected mean sea level determination of 19.73 ft. on the tide staff was obtained from these observations. The Canadian Government furnished the U. S. Coast and Geodetic Survey the hourly readings for Victoria, B. C., for the same three-year period. These data from Victoria, with similar data from the United States Tide Station at Seattle, were used for correcting the three-year determination at Anacortes to the mean sea level datum determined from long series at the other two stations by comparison of simultaneous observations.

Victoria is distant about 70, and Seattle, about 35, nautical miles from Anacortes. The following are the results of correcting the Anacortes datum by reference to the two ports by separate computations:

Anacortes mean sea level on tide staff determined by averaging the hourly readings of the tide from 3 years of observations	19.73 ft.
Anacortes mean sea level on tide staff, corrected to a 17-year determination of mean sea level at Victoria, B. C., from comparison of 3 years of simultaneous observations	19.81 ft.
Anacortes mean sea level on tide staff, corrected to 23-year determination of mean sea level at Seattle, Wash., from comparison of 3 years of simultaneous observations	19.82 ft.

A shorter period than a year may be used with fairly satisfactory results. It was desired to make temporary use of the determination of a mean sea level datum for Anacortes before the full three years of observations had been obtained, so the mean sea level as determined at Anacortes for 19 months of observations was corrected to the 22-year determination at Seattle with the following results:

Anacortes mean sea level on the tide staff, corrected to a 22-year determination of mean sea level at Seattle from comparison of 19 months of simultaneous observations	19.84 ft.

From these examples it is evident that primary tidal stations with long series along a coast line are of prime importance to tidal control of regions of which they are representative.

Therefore, primary determinations of mean sea level at various places along the coasts are important for comparison with short series of tide observa-

* *American Journal of Science*, April, 1926.

tions at near-by stations to reduce the results of the short series to mean values. These primary observations should continue over long periods, to bring out all the variations in mean sea level and to obtain mean values for all tidal constants. A period of 19 years is considered a full tidal cycle and results over such an interval are regarded as constituting mean values. Therefore, sea level derived from 19 years of observations has been generally taken as constituting a primary determination of mean sea level. Unfortunately, observations have not been continued long enough at any station to determine the difference in sea level as found from two or more full 19-year periods.

Thirty years of observations are available for the primary tide station at Fort Hamilton, N. Y. For the two overlapping 19-year periods—1893 to 1911 and 1904 to 1922—a value for sea level of 5.96 ft. on the staff is derived for the first period and 6.02 ft. for the second period.* The mean value for the entire period of 30 years is 6.00 ft. on the tide staff.

For practical purposes, however, it is hardly possible to obtain 19 years of observations at a station. Moreover, it has been found that the principal variations in sea level from year to year are cyclic in character, the level rising for a period of several years and falling for a period of years. Observations are not available for a sufficient number of years, however, to determine accurately the periods of the cycles, but there appears to be one with a period of 4 to 5 years and also one with a period of 8 to 9 years.† The variation with the period of about 9 years is quite prominent and for practical purposes, therefore, sea level determined from 9 years of tide observations may be considered as a primary determination of mean sea level.

Through the work of the Geodetic Division of the U. S. Coast and Geodetic Survey a network of precise level lines has been carried to many parts of the interior of the United States (Fig. 18). These lines have as their initial and "tie-in" points a mean sea level plane determined at the primary stations along the seaboard. Eventually every locality will be within 50 miles of a bench-mark on this net. On the Atlantic Coast long series of observations are being obtained at Portland, Boston, New York, Philadelphia, Atlantic City, Baltimore, Charleston, S. C., and Daytona, Fla.; on the Gulf Coast, at Key West and Pensacola, Fla., and Galveston, Tex.; and on the Pacific Coast, at La Jolla, Calif., San Francisco, Seattle, Ketchikan, Seward, and Valdez, Alaska. All the observations at these stations are connected with permanent bench-marks for the use of engineers locally, or for connection with precise level nets.‡

* U. S. Coast and Geodetic Survey *Special Publication No. 111*, "Tides and Currents in New York Harbor," p. 32.

† U. S. Coast and Geodetic Survey *Special Publication No. 135*, "Tidal Datum Planes," by H. A. Marmer. (See this publication for full discussion of determination of mean sea level and other tidal datum planes.)

‡ In this connection the Coast and Geodetic Survey has recently issued a publication containing the descriptions and elevations of about 1 800 tidal bench-marks in New York State, and also one of the District of Columbia containing about 85 descriptions and elevations of tidal bench-marks in the City of Washington. These publications will be followed by similar ones for other sections of the coasts and should prove of considerable value to engineers engaged on the construction of docks, bridges, harbor and river improvements, and other marine work.

Datum Planes

The simplicity of its definition, as well as the certainty with which it may be reproduced at some future time, gives value to the tidal datum as a plane of reference. In general, the most satisfactory plane is that of mean sea level, since the other tidal planes may be derived from it by knowing the range of the tide and its diurnal inequality.

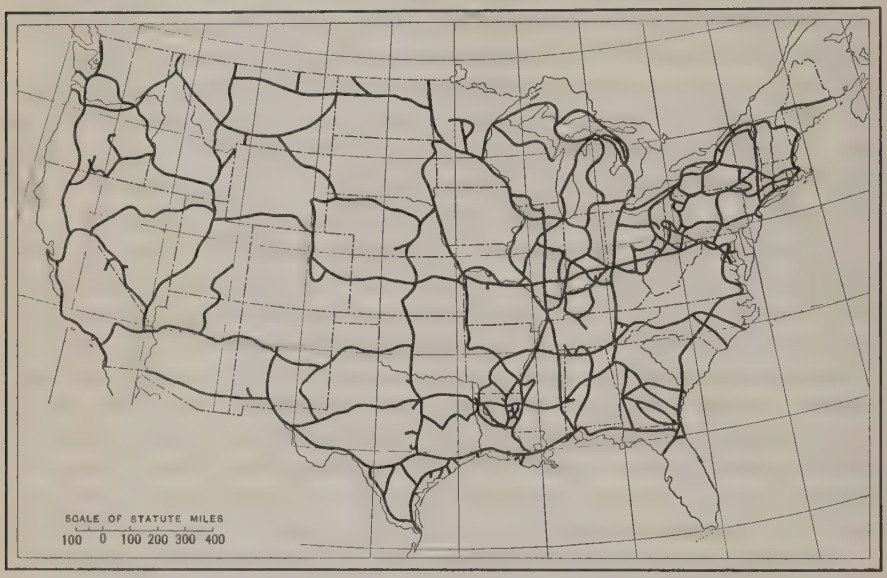

Fig. 18.—Precise Level Net of the United States. This Level Net Is Based on Mean Sea Level Datums Established at Primary Tide Stations.

Mean sea level may be defined as that level about which the tides oscillate. Since no fixed plane exists in Nature, it is necessary to devise some means for determining and for giving concrete value to this plane, above and below which the tide oscillates. The only means for making this determination is by observations of the rise and fall of the tide. It is impracticable to make use of the entire tidal curve, so that, instead of integrating the full curve, recourse is had to averaging the hourly heights of the tide. These hourly heights, tabulated from the record of the observations, are averaged over the entire period. The result is known as mean sea level, and the final accuracy of its determination is defined by the length of the series of observations. The series must be of sufficient length to have passed through varied meteorological conditions and atmospheric pressures, or must be corrected by comparison with other stations having periods of observation of sufficient length to have passed through these varied conditions.

For navigation a low-water plane is the most satisfactory because by its use the soundings on a chart will show the least depth to be expected, regardless of the state of the tide at the time the soundings were made in the hydrographic survey. A plane of mean low water, therefore, has been adopted for

the whole of the Atlantic Coast; on the Pacific Coast, because of the diurnal inequality in the tides, the plane of mean lower low water is used; that is, all soundings shown on charts of the U. S. Coast and Geodetic Survey have been reduced, no matter what the stage of the tide at the time the survey was made, to the plane of mean low water on the Atlantic Coast, and, in general, to mean lower low water on the Pacific Coast and Alaska.

For other engineering purposes planes determined by high waters, higher high waters, or extreme high waters, are adopted at times. All these other tidal planes, however, are local, since they depend on the range of the tide at a given place; that is, when extended from place to place along the coast, these planes would, if visualized, be a wavy or rolling surface, while mean sea level may be considered as an equi-potential surface, forming for practical purposes a continuous smooth plane.

The purpose for which it is to be used governs the length of the series, and, therefore, the accuracy, for the determination of any tidal plane. For practical purposes a tidal plane obtained from a month of observations may be considered as being fairly well determined. Planes determined at different times, however, may differ considerably because of long period tides or seasonal changes and differences of atmospheric pressure from month to month or year to year.

These conditions make it necessary to have long-continued observations at primary stations for general tidal control. Fig. 19 shows that the determination of mean sea level is not an altogether simple matter, nor can it be obtained by a short series of observations. It will be seen that the variations from month to month are as much as 1½ ft. The seasonal variation, too, is quite evident, being much higher in summer than in winter for each year throughout this period.

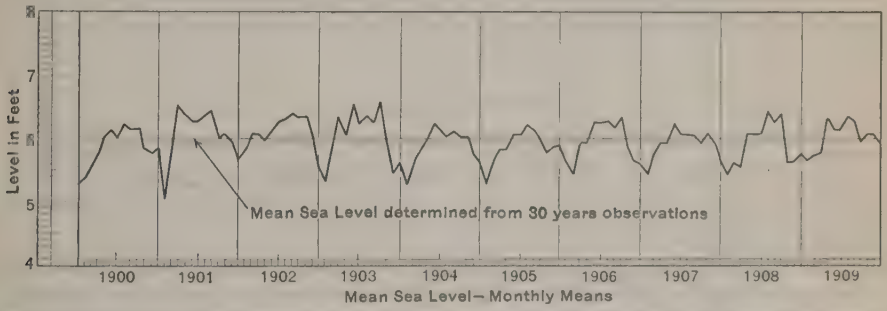

FIG. 19.—DIAGRAMMATIC REPRESENTATION OF THE PLANE OF MEAN SEA LEVEL PLOTTED FROM MONTHLY MEANS, 1900 TO 1909, AT FORT HAMILTON, N. Y.

Sea level as determined by a series of observations extending over only a month may differ as much as 1 ft. or more from that determined for another month. Even the level as determined by observations extending over a year may differ as much as ¼ ft. from a level determined during another year, so that for geodetic and other scientific work, even a year is not sufficient.

There is a distinction between the terms, "mean sea level", "mean tide level", and "mean river level". Mean sea level is obtained by integrating the

tide curve, at least to the extent of taking the average height of the curve at frequent intervals; mean tide level is the plane exactly half way between the high and low waters and is obtained by taking the half sum of all high and low waters; and mean river level is the mean height of the river surface as influenced by the tide, freshets, and bottom slope, and obtained in the same manner as mean sea level.

If the tide curve were a simple sine curve the plane of mean sea level and mean tide level would coincide; actually the larger part of the curve may be above or below the mean level of the water. The difference between the two, however, is small, and if the series of observations is short the two planes may be considered for practical purposes as coincident. On the Atlantic Coast the plane of mean sea level lies above the plane of mean tide level—at Portland, 0.03 ft.; at New York, 0.05 ft.; at Atlantic City, 0.03 ft.; and at Fernandina, 0.10 ft. On the Pacific Coast, mean sea level is the lower of the two—at Seattle, 0.01 ft.; at San Francisco, 0.06.; and at San Diego, 0.05 ft. below. The planes of mean sea level and mean river level coincide at the mouth of a river, but gradually separate toward the head.

A very accurate determination of this natural standard, mean sea level, is also of considerable value to the scientist in furnishing the only means for a quantitative measure of a possible emergence or subsidence of land areas. When the determination of mean sea level has been extended over centuries quantitative evidence will be available as to the stability of coast lines of continents by reference to permanent bench-marks connected with this mean sea level datum. The primary tide stations of the U. S. Coast and Geodetic Survey are placed so as to be representative of certain regions and to furnish tidal control for these regions for practical purposes. In addition to serving these purposes, however, the continuous observations covering a long period of years bring out the variations in mean sea level, thus furnishing data for a quantitative determination of any relative change in elevation of land and water.

Earthquake Waves

The "tidal wave" of the press is a misnomer. While these waves are superimposed at times on curves of tide record, vitiating the records during the time they are recorded, they are in no sense due to tidal forces but rather to seismic disturbances.

If the submarine disturbance be due to a horizontal slip along a fault line, practically no distortion occurs in the regular tide curve; but an earthquake caused by vertical displacement produces waves of considerable magnitude. The San Francisco earthquake of 1906 was caused by a horizontal slip along an old fault line, and the tide record at Fort Point in the Golden Gate showed very little disturbance. In Japan after the disastrous earthquake of September, 1923, a resurvey of Sagami Bay indicated that a considerable vertical displacement had taken place and a wave more than 40 ft. high was reported in a part of that Bay.

Waves 80 ft. in height have been reported in some places near the origin of seismic disturbances. These waves are propagated for considerable dis-

tances over the oceans, at times reaching the shores of other continents, although with constantly diminishing amplitudes. Very destructive seismic sea waves have occurred in regions subject to earthquake disturbances throughout historical times; among others, the destruction of Helike, Greece, in 373 B. C.; at Callao, Peru, in 1724 and 1746; at Lisbon, Portugal, in 1755; Arica, Chile, in 1868; Iquique, Chile, in 1877; and on the Japanese Coast in 1896 and again in 1923.

The sea waves caused by the earthquake which occurred on November 11, 1922, off the coast of Chile were recorded on the tide records at the Survey's primary tide stations at Honolulu, San Diego, San Francisco, and at Zamboanga, Philippine Islands. The marigrams from these stations are shown in Fig. 20, all reduced to Greenwich civil time, November 11-12, 1922. It will be noted that the curve at the beginning of the tidal graph for each station has only minor fluctuations caused by wind wave effects; the remainder of the graphs, however, have distinct fluctuations of considerable amplitude.

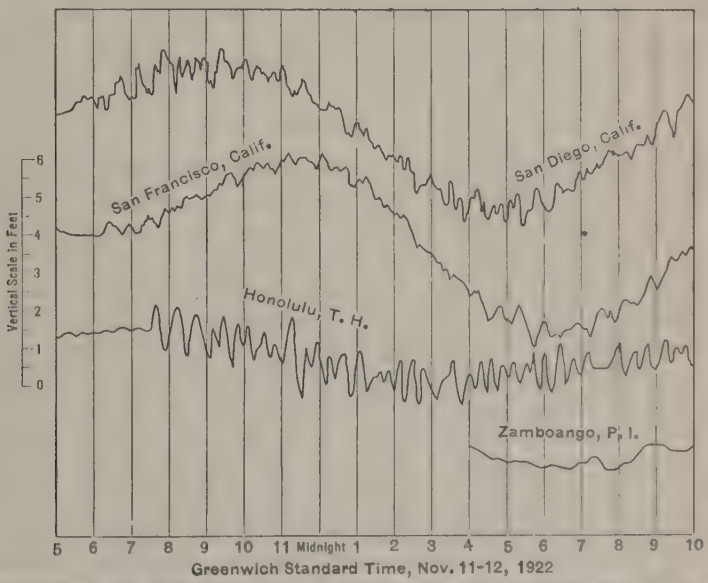

FIG. 20.—RECORDS ON THE MARIGRAMS OF TIDE STATIONS AT SAN DIEGO, SAN FRANCISCO, HONOLULU AND ZAMBOANGA, OF THE SEISMIC SEA WAVES FROM THE EARTHQUAKE WHICH OCCURRED OFF THE COAST OF CHILE, NOVEMBER 11, 1922.

The records from the seismograph stations at Honolulu, Sitka, Tucson, Cheltenham, and Vieques, indicate that the earthquake occurred on November 11 at 4:33 A. M. (Greenwich civil time), and that it originated off the coast of South America in the vicinity of Carrizal, Chile, at about 28° South Latitude. The first fluctuation on the record at San Diego (Fig. 20), began on November 11, at 5:30 P. M. (Greenwich civil time). A maximum amplitude was reached about 2 hours and 20 min. later, with a range of 1.2 ft. and with a period of from 30 to 40 min. Assuming that the propagation of the wave began at the origin of the earthquake simultaneously with the first earth

tremor, its time of transmission from Carrizal to San Diego (4 480 miles) is 12 hours and 57 min., or at the rate of 346 miles per hour for an average derived depth of water of 1 750 fathoms. Table 1 gives similar comparative data for four stations.

TABLE 1.—Sea Wave from Earthquake of November 11, 1922, off the Coast of Chile.

Station.	Distance from Carrizal, in nautical miles.	Arrival of wave (Greenwich civil time).	Time of Transmission of Wave.		Nautical miles per hour.	Derived depth of ocean,* in fathoms.

* Mean depths computed from Table 51, "Manual of Tides," by R. A. Harris, Pt. III.

Tidal Power

Except in rare cases, the engineer is not directly interested in the matter of tidal power, that is, the energy in the gravitational force of moon and sun exerted on the rotating earth, expressed in concrete form in the ceaseless rising and falling of the water of the oceans. While a study of this power is not a function of the U. S. Coast and Geodetic Survey, its Division of Tides and Currents has kept in touch with the subject in order to answer the requests for information addressed to it as the tidal authority in America.

The economical harnessing on a large scale of the energy in the tides has been the dream of the engineer for centuries; but, unlike fire, steam, the water power of streams, and electricity, it is the only force of Nature not enslaved by man. As compared with coal and oil, the initial cost of the necessary construction and installation has rendered the use of tidal power generally out of the question. When nations find it essential to begin by some means to conserve the fuel supply, engineers may find inexhaustible resources in the tides if they are successful in economically harnessing this power. The future may then see projects, introduced by countries or States, situated favorably from a standpoint of wide range of tide. By that time, however, the engineering difficulties will have been completely overcome and the necessary machinery developed to a high state of efficiency.

Plans for the utilization of power from the tides have been rejected by many engineers as involving too great initial cost in the construction of reservoirs in proportion to the power obtained. It must be borne in mind, too, that in practice it is not possible to obtain the full theoretical power, nor to utilize the vast power of all the oceans, but only that small fraction of tidal power available near the coast where natural facilities permit empounding small parts of the sea and constructing power plants.

The Civil Engineering Department of the British Ministry of Transport has prepared plans* for the utilization of tidal power in the estuary of the River Severn, where the range of tide is from 20 to 30 ft. The English propose building a dam for impounding the waters of the Severn, using it also as a bridge for railway and vehicular traffic, connecting South Wales with the remainder of the country. The combining of the two projects will partly lower, of course, the initial cost chargeable to the tidal project; and this initial cost has previously been considered the vital objection.

The utilization of tidal power has also received attention from French engineers, who have proposed a number of plans. The northwest coast of France lends itself to such schemes. The mean ranges along the coast bordering the Bay of Biscay vary from 12.7 ft. at the mouth of the Gironde River to 14.3. ft. at Ushant Island; and along the coast on the English Channel, from 16.6 ft. at Ile de Bas to 26.8 ft. at St. Malo, decreasing to the northward to 16.2 ft. at Cape Griznez, Strait of Dover. A more recent project has been proposed in America in the plan to utilize the large range of tide in Passamaquoddy Bay, New Brunswick, and Cobscook Bay, Maine.

Heretofore, the harnessing of the tides for power purposes has been approached on a much smaller scale than these modern proposals. Tide mills of small power for grinding corn have been in existence in Spain, on the Thames in the Isle of Wight, and on the Bay of Fundy, but having an efficiency of only about 10 per cent. In all these cases the range of the tide is considerable, a necessary factor for the success of any tidal power plan. Means for furnishing power during the time the tide is rising or at a stand is another important factor in tidal power development. In addition, the variations in range during a lunar month add complexities to the problem.

Should engineers be successful in economically harnessing the tides, their use on the Atlantic Coast of the United States would be limited to Northern New England, because of comparatively small ranges of tide elsewhere. At Calais, St. Croix River, Maine, the mean range is 20.0 ft., decreasing gradually southward along the coast to 10.5 ft. at Bar Harbor, Mount Desert Island. In Penobscot Bay, the mean range varies from 9.1 ft. at Head Harbor, Isle au Haut, to 13.1 ft. at Bangor, Penobscot River. South of Penobscot Bay the mean range is less than 10 ft. along the entire Atlantic Coast, with the exception of Wellfleet, Cape Cod, where it is 10.7 ft.

Estuary Tides

Practically all research work on estuary tides has been done by the tidal mathematicians for the purpose of increasing the accuracy of predictions of tides for tide tables. A fertile field remains open for the engineer in a study of the changes in the tidal regimen in an estuary or in a river resulting from changes in topography and depth in harbor and river improvements, in order that dependable quantitative predictions may be made for proposed projects.†

* "One Million Horsepower from Tidal Energy," *Scientific American*, January 22, 1921.

† L. Bonnet's "Contribution a l'Etude Théorique des Fleuves a Marée et Application aux Rivières a Marée du Bassin de l'Escaut Maritime," goes into the theories of estuary tides and their application to the River Scheldt and tributaries.

Apparently the factors entering into the problem differ so widely for each body of water that each case requires individual treatment.

In New York Harbor, for example, where long series of observations are available covering the period during which extensive dredging operations have been carried on, the indications are that little change has occurred in the tidal regimen. The mean ranges, as derived from two overlapping 19-year series, from 1893 to 1922, in 10-year groups,* indicate an increase of 0.1 ft. in a decade, due to the improvement to Ambrose Channel between 1901 and 1914. This increase in range can be ascribed to the widening and deepening of this channel, thus allowing freer access of the tidal wave to New York Harbor.

On the other hand the dredging and development of Delaware Bay and River have made a considerable change in the tidal régime, but of a different effect; instead of an increase the tides of the Delaware have been decreased in range 0.7 ft. in some places,† and the time of the tide retarded by more than ¼ hour. This decrease has been accompanied by the raising of the mean low-water plane, the high-water plane remaining practically constant.

In Fig. 21 are shown the tidal ranges in the entire Delaware Waterway from observations prior to 1890, and from 1900 to 1924. It will be noted that no change occurred in the range from the mouth of Delaware Bay to Woodland Beach. In Delaware River, however, where extensive improvements were made during the period, 1890 to 1900, the curves diverge as much as 0.7 ft. Just below Trenton, N. J., the curves intersect again, and the range at Trenton is now 1 ft. greater than formerly.

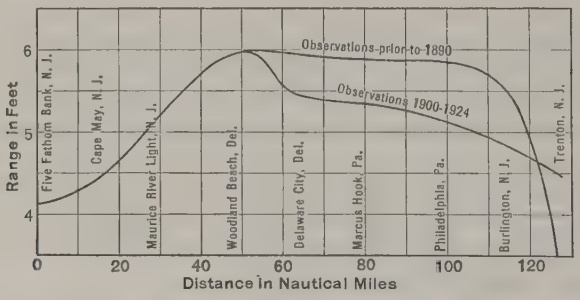

FIG. 21.—RANGE OF TIDE, DELAWARE BAY AND RIVER FOR PERIOD PRIOR TO 1890, COMPARED WITH RANGES FOR PERIOD 1900 TO 1924, AFTER EXTENSIVE HARBOR IMPROVEMENTS.

The physical reasons for this change may be ascribed to the fact that the dredging was not confined to a deepening of the channel, but involved a considerable widening of the waterway by the removal of shoal areas, allowing for a much greater cross-section to accommodate the original tidal prism entering the lower bay where no extensive developments have been made, and also tending to decrease friction in the channel.

* See U. S. Coast and Geodetic Survey *Special Publication No. 111*, "Tides and Currents in New York Harbor," pp. 45–46.

† See U. S. Coast and Geodetic Survey *Special Publication No. 123*, "Tides and Currents in Delaware Bay and River," by L. M. Zeskind and E. A. Le Lacheur.

The increase of the range at Trenton may be ascribed to the same causes that contributed to the increase of the tidal range in New York Harbor. The deepening and widening of the lower channels has given freer access of the tide to the upper reaches of the river and, therefore, increased the range. This accommodation of the upper reaches of the river to a greater part of the total tidal prism entering the whole waterway is another factor, too, in the decrease of the range in the intermediate part of the waterway.

Thus far all interpretations of data from current and tide surveys have been necessarily of a qualitative nature since sufficient data are not yet available for quantitative studies. It may be concluded, then, that in general the deepening and widening of the channels leading from the ocean into an estuary will result in a slight increase in the tidal range of the estuary; that similar operations in upper channels with no increase of the entrance cross-section will result in a decided decrease in range in the improved area, but a decided increase in range in the upper reaches of the river.

In the practical study of the tidal regimen of an estuary or river not broken by abrupt falls, and in the interpretation of the tidal data from scattered observations, a graph similar to Fig. 22 is of considerable value. This diagram has been prepared for purposes of illustration and assumes the slope of the Hudson River to be uniform (which undoubtedly is not strictly correct). Spirit-level connections between the line of precise levels that has been run from New York to Troy and various tide observations made over long periods, would undoubtedly indicate that the river profile is not strictly a straight line. Because of freshets evidently the accurate variations from a straight line can be brought out only by long series of tide observations. However, a graph from observations at relatively few controlling points, furnishes a sufficiently exact approximation of the tidal regimen for the whole river.

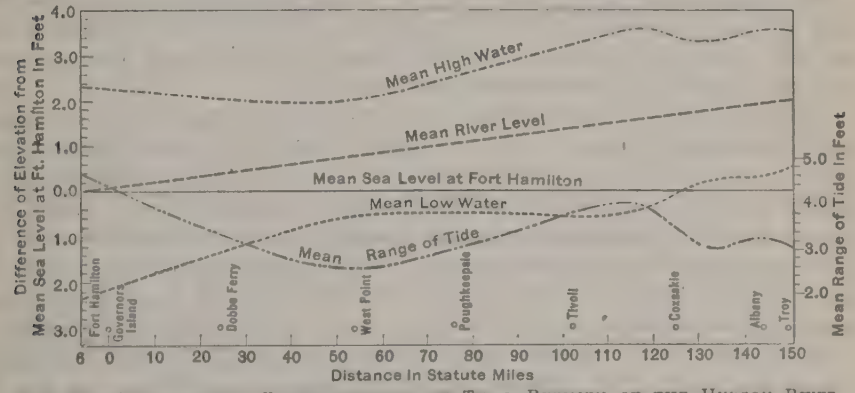

FIG. 22. DIAGRAMMATIC REPRESENTATION OF TIDAL REGIMEN OF THE HUDSON RIVER.

The values of the tidal data, such as mean high water, mean low water, and mean ranges for various places along the river, may be plotted to scale, and smooth curves drawn through the points. In this manner a fair approximation of the tidal regimen is obtained for the whole length of the river from observa-

tions at relatively few controlling points. For example, from Fig. 22 the mean river level at West Point is 0.75 ft. above the plane of mean sea level; 1.01 ft. at Poughkeepsie; 2.06 ft. at Troy, etc.

The velocity, V, of a progressive tidal wave, such as occurs in the Hudson River and Chesapeake Bay, will be:

$$V = \sqrt{g\,h} = 5.67\ \sqrt{h}\ \text{ft. per sec.}$$

in which, $g = 32.17$ ft. per sec. (acceleration due to gravity), and h = depth of water for the average cross-section, in feet.

In order to convert feet per second into nautical miles per hour, multiply by 0.592, and,

$$V = 3.36\ \sqrt{h}\ \text{nautical miles per hour}$$

The time required for the wave is,

$$t = \frac{17.87}{\sqrt{h}}\ \text{min. per nautical mile}$$

$$t = \frac{15.51}{\sqrt{h}}\ \text{min. per statute mile}$$

The character of the wave in a body of water, whether progressive or stationary, can be determined by computing the rate of advance of the tide by this formula and comparing this computed rate with tide observations along the waterway. If the actual rate is considerably in excess of the computed rate and if, in addition, the range as shown from the observations increases toward the head, it may be concluded that the body has a stationary wave tide.

The character of the tide wave may also be determined from the occurrence of the times of the slack and strength of the currents. In a body having a progressive tidal wave the time of slack water occurs about the time the tide is near mean sea level, and the strength of the current occurs near the time of high or low water; whereas, with a stationary wave, slack-water occurs near the time of high or low water, and the strength of the current, at about the time the height of the tide is near mean sea level.

The tide wave in the Hudson is of the progressive type and the range decreases toward the head. In the vicinity of West Point a sharp decrease in range occurs, due to the marked increase in the depth of waterway and the absence of any obstructions to the free passage of the tidal wave. After its passage through this deep, open stretch the tidal wave is obstructed by shoaler water and lateral shoals, and the range, therefore, increases somewhat, with a more marked increase in the stretch between Tivoli and Coxsackie where numerous and extensive middle-grand shoals still further impede its progress.

The general theory that the range decreases progressively toward the head in an estuary having the progressive type tide and increases in one having the stationary wave type, presupposes a body of uniform width and depth. The reason for any departure from this theory will generally be found in the physical characteristics of the body, as seen in the case of the Hudson.

As another example, the tide in Chesapeake Bay is of the progressive type. From the tide tables the mean ranges of the tide at points directly opposite on

the western and eastern shores from the Capes to the mouth of the Patapsco River, are given in Table 2.

TABLE 2.—Mean Ranges of Tide in Chesapeake Bay.

Western shore.	Range, in feet.	Eastern shore.	Range, in feet.
Cape Henry	2.8	Cape Charles	3.0
Near Point Comfort	2.2	Cherry Stone Light	2.3
Stingray Point	1.4	Mouth, Occohannock Creek	1.8
Smith Point Light	1.2	Tangier Light	1.6
Point Lookout	1.3	Holland Island Light	1.6
Cedar Point	1.2	Barren Island	1.5
Chesapeake Beach	0.9	Sharp's Island	1.3
Herring Bay	0.9	Poplar Island	1.2
Sandy Point	0.8	Love Point	1.1
Seven Foot Knoll	0.9	Tolchester Beach	1.3
Average mean range	1.36	Average mean range	1.67

The range decrease progressively up the Bay to Seven Foot Knoll on the western shore and Tolchester Beach on the eastern shore where there is a slight increase. This increase here is to be expected, since the tide wave is retarded just below these places by the constriction of the channel and by the obstruction to the progress of the wave afforded by the shoal areas off the mouth of the Patapsco River. The differences in the ranges on the two shores of the Bay will be explained hereafter.

Still another example is the Potomac River. As shown in Table 3, this river may be divided into sections as to increase or decrease in range toward the head.

TABLE 3.—Changes in Tidal Range in Ascending Potomac River.

First Section—Increase in Range.	
Point Lookout	1.3 ft.
Piney Point	1.6 "
Ragged Point	1.8 "
Blackiston Island	1.9 "
Second Section—Decrease in Range.	
Colonial Beach	1.6 ft.
Lower Cedar Point	1.4 "
Mathias Point	1.2 "
Maryland Point	1.1 "
Third Section—Increase in Range.	
Brents Point	1.2 ft.
Quantico Creek Entrance	1.4 "
Indian Head	1.7 "
Marshall Hall, Md	2.1 "
Alexandria, Va	2.8 "
Washington, D. C	2.9 "

A chart of the Potomac will show that the first section is just below Kettle Bottom Shoals, which furnishes a considerable obstacle to the advance of the wave. It is to be expected that the ranges would increase below this point.

The second section comprises a comparatively deep, free channel and the tidal ranges, therefore, decrease as might be expected.

In the third or upper section the river is practically filled with extensive shoal areas and the channel reduced to a mere thread (relatively). The ranges increase, therefore, toward the head due to the retardation of the tidal wave.

The Bay of Fundy, already mentioned, furnishes a good example of the increase in range toward the head in a body having a stationary wave tide. Table 4 shows the ranges directly opposite on both shores of the Bay from its mouth to its head (taking as the mouth a line between Belfast and Jebogue Point).

TABLE 4.—Mean Ranges in Tide in Bay of Fundy.

Western shore.	Range, in feet.	Eastern shore.	Range, in feet.
Belfast, Me.	9.7	Jebogue Point, N. S.	14.0
Eastport, N. B.	18.2	Annapolis, N. S.	25.1
St. Johns, N. B.	20.9	Port George, N. S.	27.8
Moncton, N. B.	41.2	Minas Basin, N. S.	44.2
Average mean range.	22.5	Average mean range.	27.8

The average mean range on the eastern (right) shore in the Bay of Fundy is greater by 5.3 ft. than on the western (left) shore, as found for Chesapeake Bay.

Fig. 23 shows the ranges on both shores of the Bay of Fundy. The upper curve is drawn directly through the plottings of the mean ranges at several ports on the Nova Scotia shore as taken from the tide tables; the lower curve is for the Maine-New Brunswick shore. These two curves of ranges differ at the mouth of the Bay by about 4 ft., increasing to about 6 ft. half-way up and decreasing to about 3 ft. at the head where a narrowing of the Bay takes place. The greater range is on the right shore.

Fig. 24 illustrates the same feature in Delaware Bay. Beginning at Five Fathom Bank Light Vessel, just outside the entrance to the Bay, the two curves representing the values of the mean ranges on the two shores separate, the greatest difference of 0.8 ft. occurring about half-way up the Bay. Toward the head the two curves again approach each other. Here, too, the greater range is on the New Jersey side, the right shore facing up the Bay.

This interesting phenomenon of the difference in range on the two shores of an estuary is due to the deflecting force of the earth's rotation, acting to the right (and so causing a greater range on the right shore) in the Northern Hemisphere and to the left in the Southern Hemisphere.* The theoretical

* For formula, see *Special Publication No. 111*, U. S. Coast and Geodetic Survey, "Tides and Currents in New York Harbor," by H. A. Marmer, p. 68, Govt. Printing Office, 1925.

value, in feet, by which the ranges on the two shores of a tidal stream differ, is represented approximately by the formula, $\frac{3\,v\,d\,\sin\,\phi}{g}$, in which, v is the velocity of the water, in knots; d, is the width of the body, in nautical miles; ϕ is the latitude; and g is the acceleration of gravity, in feet per second (approximately 32.2).

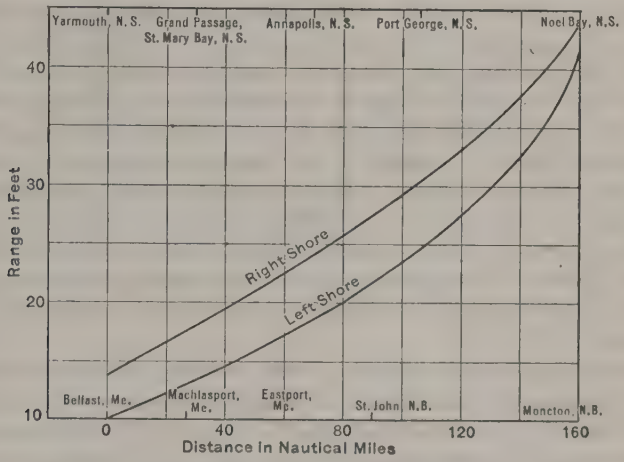

FIG. 23.—COMPARISON OF THE RANGES OF TIDE ON THE TWO SHORES OF THE BAY OF FUNDY.

Another character of tide occurs in short straits connecting two independently tided bodies of water. The movement of the water is largely hydraulic in character. The East River furnishes a good example of this type.* It will be taken up here briefly. Here the tide is derived from the tide in New York Bay, which is due to a progressive wave, and from that in Long Island Sound which is largely due to a stationary wave. These tides differ 3 hours in time and about 3 ft. in range.

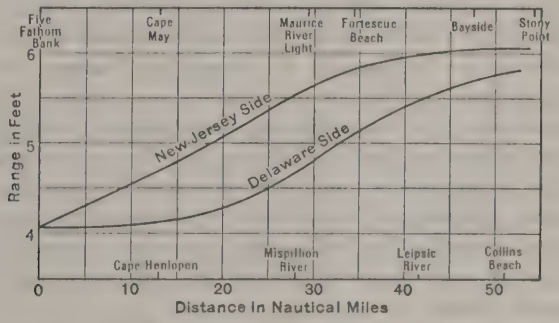

FIG. 24.—COMPARISON OF RANGES OF TIDE ON TWO SHORES OF DELAWARE.

At times the peculiar condition resulting has been ascribed to the interference of two tide waves—one from New York Bay and one from Long

* The tide in the East River is covered in detail in U. S. Coast and Geodetic Survey *Special Publication No. 111.*

Island Sound—whereas it is merely a changing height of water brought about by the changing levels in the two bodies of water which it connects. The stage in the East River at any time is conditioned on the relative heights of the water in the Upper Bay and Long Island Sound—part of the time the water in the Upper Bay is higher than in the Sound and part of the time it is lower. A simple system of slope* lines, found by plotting to suitable scale the simultaneous heights of the water levels above mean sea level at the two ends of East River for each hour of the tidal cycle, will indicate quite conclusively that the tidal movement in the river is primarily hydraulic, since the range of the tide, and the high and low-water intervals, as scaled from these slope lines, agree very closely with actual observations at any place in the river. Of course, this simple slope line will furnish only an approximation to the tidal conditions since it is based on the assumption that the river channel runs straight through its length with unvarying width and depth and does not take into consideration the varying depth, the changes in direction, nor the effect of fresh water entering the East River from the Hudson by way of the Harlem. Deception Pass, Washington, and Seymour Narrows, British Columbia, are other examples of this kind of tide with hydraulic characteristics.

The difficulties that often arise in connection with the harmonic prediction of estuary tides are due principally to hydraulic elements—to freshet conditions, to the restriction of the channel at low water, to the effect of the non-tidal current on the propagation of the tide wave, and to bottom and lateral friction. The Canadians have overcome the difficulty to a considerable extent in the St. Lawrence Estuary. Correct tide tables are unusually important for Quebec, because the tides at up-river points are derived from them. The tides are predicted by the harmonic analysis for Father Point, which is near the ocean and which, therefore, has a tide answering well to the harmonic treatment; for the predictions at Quebec variable empirical corrections are applied to these Father Point predictions, varying for the synodic, the anomalistic, and the declinational months. By this method the average error in the predictions, as compared with observations, has been lowered from 26 min. by the harmonic method to 6 min. by this combined method.

The tide curves for Albany, N. Y. (Fig. 11), illustrate the difficulty in making tidal predictions for upper reaches of rivers subject to freshet conditions and the necessity for long series of observations to obtain final values.

In short straits, such as the East River, New York, the harmonic analysis answers well for predictions, although the characteristics of the tides in such bodies are largely hydraulic. The hydraulic elements are brought about by periodic tidal movement in the bodies which the strait connects, and the tidal conditions, therefore, may be predicted with the same ease as the tidal movements in the main bodies.

Tide Reductions

The methods used in reducing tidal observations may be grouped under two heads: Harmonic and non-harmonic. The harmonic method's principal

* U. S. Coast and Geodetic Survey, *Special Publication No. 111*, p. 77.

use is for tidal predictions; by this method the tide wave is decomposed analytically into a number of constituent simple harmonic waves, the periods of which have astronomical definitions, while the amplitudes and phases are derived from observation. The non-harmonic is essentially a statistical method, by which the tides are tabulated for any desired argument. These reductions are made in order that the data may be in convenient form for practical use in chart-making, surveying, and general engineering work; for the prediction of tides they also include the determination of the harmonic and non-harmonic constants.

After tabulation, the high and low waters and the hourly heights are treated in a separate manner for reduction, that for the hourly heights being known as the harmonic, and that of the high and low waters as the non-harmonic. The harmonic method of reduction employing the highly refined mathematical process of the harmonic analysis, is used principally for the determination of harmonic constants for the prediction of tides for the tide tables. It is of little use in practical engineering.

At any place the times of high and low waters have approximately fixed relations to the time of transit of the moon. The relation for high waters is called the high-water lunitidal interval, or the establishment of the port, and that for low water, the low water lunitidal interval. The intervals for each place are determined by comparison of the times of the tabulated high and low waters with the times of the corresponding moon's transits.

The datums, mean high and mean low waters, are also obtained by averaging all the tabulated heights of high and low waters. The difference gives the mean range of tide at the station, and the half-sum, the half-tide level. For stations on the Pacific Coast, because of the large diurnal inequality in the heights of the high and low waters, the average of the higher high and lower low waters are also obtained, the results being the datum plane of higher high water and lower low water.

In like manner all other planes and data may be determined, such as spring range, neap range, perigean range, apogean range, mean duration of rise, mean rise interval, mean high water diurnal inequality, mean low water diurnal inequality, mean great diurnal range, etc.*

Currents in General

To the engineer, particularly the military engineer detailed to harbor and river development, the subject of currents is of equal or greater importance than that of tides. In general, currents are caused directly by tidal action, so that a clear understanding of such action is essential to a knowledge of tidal flow. They are intimately related phenomena, or may be considered as different phases of the same phenomenon, since, accompanying the vertical movement of the water caused by the tidal forces of moon and sun, a horizontal movement also takes place, giving rise to currents.

In addition to those currents due to astronomical forces working through the tides, others are brought about by meteorological conditions and physical

* The reduction of tidal data and explanations of the forms used are given in detail in U. S. Coast and Geodetic Survey *Special Publication No. 26*, "General Instructions for the Field Work of the U. S. Coast and Geodetic Survey," pp. 128–150.

differences in sea water in different parts of the oceans. These astronomical forces, combined with topographical features, as in the case of the tides, give rise to five types of currents:

(1) The rectilinear or reversing type, illustrated by the current in most inland bodies of water, such as the Hudson River, Chesapeake Bay, Delaware Bay, etc.;

(2) The so-called hydraulic type, illustrated by the currents in straits connecting two independently tided bodies of water; for example, the East River, New York, Deception Pass, Washington, and Seymour Narrows, British Columbia;

(3) The rotary type, illustrated by the currents in the open ocean and along the sea coast;

(4) The wind-driven currents of a temporary nature, produced by the friction of local winds on the surface of the water; and

(5) The permanent currents comprising the main oceanic circulation, illustrated by the Gulf Stream of the Atlantic and the Kuro Siwo of the Pacific.

The first three types are of tidal origin and are, therefore, periodic, while the last two are non-periodic and are due to meteorological conditions, dominant winds, variations in barometric pressures over the oceans, and differences in temperatures and densities of the sea water in different parts of the oceans.

Rectilinear or Reversing Type Currents

The progression or rate of advance of a tidal wave and the velocity of the current should not be confused. The velocity of the current is the actual speed of a moving particle. On the other hand the progression or rate of advance of a tidal wave is the forward motion of a shape or wave motion. Usually this is many times greater than the velocity of the current.

Except possibly in shoal channels of varying widths the rate of advance, r, of the tide wave of the progressive type is, approximately, $r = \sqrt{g\,h}$, in which h is the depth of the body of water. The velocity of the current, however, or the actual speed with which the particles of water are moving, depends on the volume that must pass a given point and the cross-section of the channel at that point.

In a rectilinear current the distance traveled by the water particles or by a free float during a full tidal cycle may be found approximately by the following equation:

(Velocity of current at strength, in knots) $\times$ (0.6366) $\times$ (duration of period of cycle, in hours and tenths) = distance, in nautical miles, floating object will be carried.*

The form of current known as the rectilinear or reversing type occurs in all inland bodies of water connected with the ocean. These currents come to a slack and reverse, the direction being designated "flood" when referring to the horizontal movement of the water in the ocean toward the land (or "up

* For greater detail, see U. S. Coast and Geodetic Survey *Special Publication No. 111*, p. 18.

stream" in inland waters), and "ebb" when referring to the movement in the ocean away from the land (or "down stream" in inland waters).

This current is intimately related to the tidal regimen of the body of water. In a body in which the tides are due to a progressive wave the time of the reversal of the current (slack-water) occurs at about half-tide, and the strength of flood and ebb at about the time of high and low water, respectively; in a body with a stationary tidal wave, slack-water occurs at about the time of high and low water, and the greatest current velocity at about the time of half-tide.

This time relation for a current station in the Hudson River, which has a progressive tidal wave, is illustrated in Fig. 25. The upper diagram is a graph of current observations on July 24, 1922, at a station in the entrance to the Hudson River. The lower diagram shows the tidal curve at the Fort Hamilton Tide Station for the same date. In rectilinear currents it is evident that any shifting up or down of the zero current line, resulting from a steady non-tidal current, would affect the periods of duration of the flood and ebb, and make them of unequal length. Such a shift would also change the times of slack-water, but would leave unchanged the times of flood and ebb strength.*

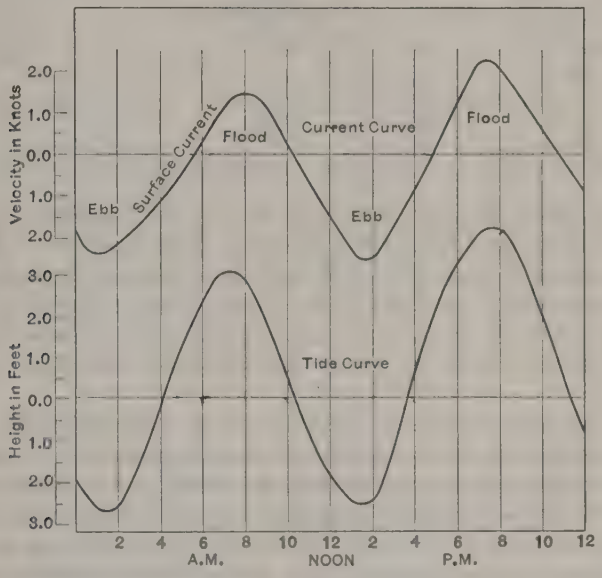

FIG. 25.—COMPARISON OF TIDE AND CURRENT CURVES, NEW YORK HARBOR.

An added advantage of such a graph for the interpretation of current data is the facility with which the duration of slack-water may be determined graphically; that is, the period during which the current velocity is less than 0.1 knot, which is becoming to mean "slack-water", although theoretically the time of slack-water is only an instant.

* For more detail, see U. S. Coast and Geodetic Survey *Special Publication No. 111*, p. 17.

The parallelism of the two curves in Fig. 25 indicates the intimate time relation between the tides at Fort Hamilton and the currents at the entrance to the Hudson; for example, the times of slack-water (upper diagram, Fig. 25), occurring at about 5:40 A. M., at 10:15 A. M., at 5:00 P. M., and at 10:45 P. M., agree very closely with the times of half-tide of the lower diagram, half-tide occurring at 4:15 A. M., 10:20 A. M., 3:40 P. M., and 11:15 P. M. This occurrence of slack-water at the time of half-tide is one of the indications that the tides of the Hudson are due to a progressive wave and not to a stationary wave.

A graph of this character has the advantage of furnishing the relation (which may be instantly detected) of the velocities of the currents at different depths. Fig. 26 is a graph of the current velocities obtained from observations at three depths, 9, 24, and 38 ft., on August 3, 1922, at a station in mid-stream, at the entrance to the Hudson.

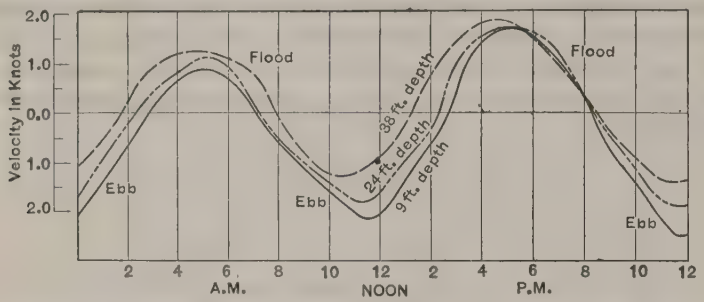

FIG. 26.—GRAPH OF CURRENT VELOCITIES AND DIRECTIONS FOR THREE DEPTHS AT STATION IN MID-STREAM AT MOUTH OF THE HUDSON RIVER, AUGUST 3, 1922.

It will be noted that the slacks from flood to ebb (between 6:00 and 8:00 A. M.) occur much more closely together than those from ebb to flood (about 2:00 A. M., and again about 2:00 P. M.), all slacks between flood and ebb, however, occurring first at the 9-ft. depth, a little later at the 24-ft. depth, and still later at the 38-ft. depth. It is again true for the afternoon slacks from flood to ebb about 8:00 P. M., except that the times are more nearly simultaneous.

An inspection of the graphs for a month of observations at this station indicate that when there is considerable diurnal inequality in the velocities of the morning and afternoon currents, the slacks of the afternoon currents from flood to ebb occur almost simultaneously, while the morning slacks at different depths from flood to ebb are separated somewhat in time; and as the diurnal inequality disappears when the moon's declination is nearing a minimum, the difference in the times of slack-water at different depths from flood to ebb become very nearly equal. The average interval between the surface and bottom slacks from flood to ebb at this station has been found from a long series to be about 12 min.

From ebb to flood, however, the times of slacks at different depths have a wider range and occur first near the bottom (1:40 A. M.), next at mid-depth (2:30 A. M.), and last near the surface (3:00 A. M.). These relations again

hold for the afternoon slack from ebb to flood—occurring first at the 38-ft. depth (1:15 P. M.), next at the 24-ft. depth (2:20 P. M.), and last at the 9-ft. depth (2:50 P. M.). Thus, the time between slack-water near the bottom and that on the surface differs by about 1½ hours. This interval has been found to average 1½ hours at this station from long series of observations.

To sum up for this station when there is diurnal inequality evident in the velocities of the current the slack-water following the weaker flood occurs first on the surface, a few minutes later at mid-depth, and last at the bottom; the slack-water following the stronger flood occurs almost simultaneously at all depths. At the time of the month when there is little diurnal inequality in the flood velocities, the slack-water following both floods occurs almost simultaneously at the three depths. The slack-water following an ebb shows very little diurnal inequality in the times of slack at all depths, occurring first at the bottom, next at mid-depth, and last on the surface. The average difference between slacks at the three different depths from flood to ebb is found to be 12 min., and the average difference in slacks at the three depths from ebb to flood is found to have an average interval between of 1½ hours.

This difference of intervals for slacks at different depths following a flood current from that following an ebb, is due to the fact that on the flood the dense ocean water is flowing into the harbor against the lighter fresh-water run-off of the river, and is thus causing a commingling of the water. This action, having a tendency to bring about a uniform density of the water from top to bottom, causes the change in direction to occur practically simultaneously at all depths. On the other hand, during an ebb current, with no force to cause a mixing of the water, the dense salt water seeks the bottom and the lighter fresh water seeks the surface. When the flood water first begins running into the harbor from the ocean the dense ocean water hugs the bottom and under-runs the fresh surface water coming down on the ebb. This lower layer of heavy flood water, therefore, retards and brings to a slack, first, the lower layer of ebb current, gradually gaining sufficient momentum finally to offset the inertia of the over-running, less dense surface water.

Hydraulic Type Currents

The so-called hydraulic type currents are those occurring in straits and canals, connecting two independently tided bodies of water. They are reversing currents, although they are due primarily, not to tidal action of the purely stationary or progressive type, but rather to a temporary difference in head between the two bodies brought about by tidal action. The currents in the East River, New York, and in Cape Cod Canal, are examples of this form, and a brief description of those of the East River will serve to illustrate the type in general. Although these currents are due primarily to the hydraulic gradient, the indications are that some tidal propagation is evident; but, in general, its effects may be neglected. For purposes of predicting, for example, the time of slack-water and the velocity of the currents in such straits and canals for current tables, satisfactory results are obtained by considering only the hydraulic gradient.

The East River connects Long Island Sound with New York Bay, and the tides in these two bodies of water are decidedly different, the tides in Long Island Sound being due to a stationary wave, and those in New York Bay to a progressive wave. The tides in Long Island Sound, therefore, increase in range from the mouth toward the head, from 2.0 ft. at Montauk Point (east end) to 7.2 ft. at Willets Point, at the west end of the Sound; the tide in New York Bay, however, decreases in range from 4.7 ft. at Sandy Hook to 4.4 ft. at Governors Island. This difference in range of tide at the two ends of the East River is sufficient in itself to produce a hydraulic gradient; but, in addition, the time of the tide at Willets Point at the north entrance to the East River is 3 hours or more later than the time of the tide at Governors Island. This difference in time is the larger factor in producing the temporary difference in hydraulic head to which the considerable velocity of current in the East River is due.

As examples, high water occurs at Willets Point when the tide is about at mean sea level at Governors Island, and, therefore, the current at this time sets to the southward through the East River; and at the time of high water at Governors Island the tide at Willets Point is about mean sea level and the current then sets toward Long Island Sound. This difference of tidal conditions in Long Island Sound and New York Bay, at times causing a hydraulic gradient of 4 ft. in the distance of 17 miles from Willets Point to Governors Island, gives rise in Hell Gate to currents which attain a mean velocity, at strength, of about 5 knots; and occasionally currents have a velocity of 8 knots.

While it is a comparatively simple matter to predict the time that the heads at the two ends will be equalized and that slack-water should occur, account must be taken, with conditions such as these, of the momentum of this mass of water and of the time of the continuance of the flow after equalization of head. This information can be obtained only from observations, and to obtain mean conditions these observations should be continued over a considerable period, since the range of the tide between springs and neaps varies more than 20%, and, therefore, the current velocity at the different phases of the moon varies proportionately.

If a long series of tidal observations at a suitable place near-by are available, short series of current observations may be reduced to mean values by comparison with these tide observations, since the currents are intimately associated with the tidal regimen of the bodies of water and vary during the tidal month proportionately with the range of tide. The procedure is explained hereafter under "Current Reductions".

The hydrodynamic problems that arise in a canal connecting two large bodies of tidal waters are of so involved a nature that even where solutions have been found they necessitate a great deal of complicated numerical work. Since, however, the engineer is interested chiefly in the maximum velocities, or those that occur at times of strength of the current, simpler formulas that will give approximate results are used.

Ocean Currents

The along-shore currents of the coast have considerable importance in coast erosion and accretion studies, and since these are intimately associated with the general ocean circulation, engineers should have a general knowledge of this circulation.

Little of a quantitative nature has been done in the study of oceanic circulation by direct observations of currents. The set and drift of ocean currents have been mapped in a general way; but the principal information on which these results are based is of a qualitative nature obtained from a record of the drift of bottles and of wrecks, and from a difference between the true and the dead reckoning positions of vessels, the determination of which does not permit of a high degree of accuracy. All these, however, furnish qualitative data and quantitative data can come only from systematic observations either directly of the current or of densities and temperatures, all of which may be considered an international, rather than a national, problem.

Three reasons may be assigned for this near neglect of a phenomenon so closely associated with the subject of tides: Obviously, tidal observations may be made more economically than current observations, for which expensive vessels with full complement of officers and crew are necessary. Secondly, associated with periodic tidal currents are non-tidal currents which, in general, are produced by the wind and by differences in temperatures and densities of sea water. Data for predictions of tidal currents, since they are periodic, may be obtained from observations extending over a comparatively short time, while for non-periodic non-tidal currents a much longer series of observations is required to furnish average conditions and to permit of predictions of any degree of accuracy. Another reason is that the oceans may be considered the highways of commerce for all nations, and, therefore, the study of its problems an international rather than a national undertaking.

The subject of ocean currents is now receiving the attention of physical oceanographers, particularly in the North European countries in their fisheries conservation studies—Bjerknes, Helland-Hansen, Nansen, and Pettersson, in Europe, and McEwen, of the Scripps Institution of Oceanography, in America.

Dynamic oceanography provides a method for mapping currents over extensive ocean surfaces, and it is by these methods, rather than by direct current observations, that the present meager knowledge of ocean currents will undoubtedly be supplemented. Given the temperature and salinity observations from several known depths at stations systematically located over an ocean area, then the direction and velocity of the current are readily predicted and mapped by the physical oceanographer. Studies made at Bergen, Norway, covering density and temperature observations obtained by the International Ice Patrol, indicate the probability that, from a sufficient number of observations of density and temperature over an area, current charts can be prepared to show the probable direction and velocity of the relatively deep-seated ocean currents several weeks in advance.

The principal maritime nations have made current observations, however, on their inland waters and along their coasts. Within the last few years the U. S. Coast and Geodetic Survey has given attention to the study of coastal currents, both tidal and wind-driven. Recently, current tables have been issued containing data of importance on this subject which are vital to the safeguarding of life and property in coastwise shipping. This is particularly true on the Pacific Coast in that its currents, like its tides are more complex than those on the Atlantic; and, in addition, in that its coast harbors are many miles apart, the sailing courses long, and the periods of foggy and stormy weather of comparatively frequent occurrence.

Although the total coastal current is made up of a combination of two components, the periodic, or tidal, current and the non-periodic, or wind-driven, current, analysis of a long series of current observations made at any station serves to separate the two, so that the proper correlation can be made between each component and its causes. That is, the velocity and direction of the tidal current may be referred to the predictions at some standard port, and the velocity and direction of the wind-driven current correlated with the force and direction of the local wind prevailing at the time. These two coastal currents, although combined, are of distinct characters and will be taken up separately.

Coastal Tidal Currents.—The current observations, on which these studies of coastal tidal currents have been made, have been obtained on the light vessels along the coasts, through the co-operation of the Lighthouse Service. While the data obtained relate chiefly to the vicinities of these vessels, general laws of the action of these currents can be deduced, which, usually, will apply to other sections of the coast.

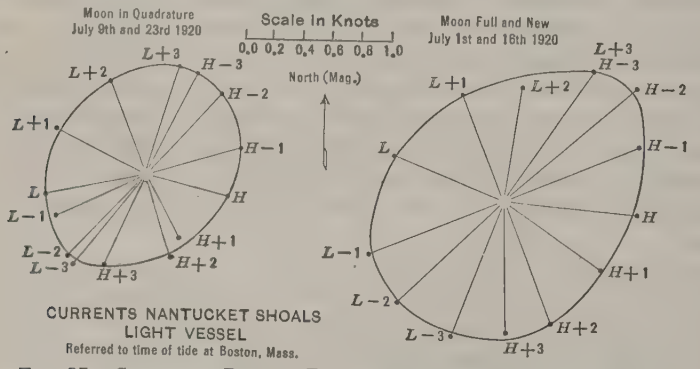

FIG. 27.—GRAPH OF ROTARY TIDAL CURRENTS, NANTUCKET SHOALS LIGHT VESSEL, ATLANTIC COAST, AT TIMES OF DIFFERENT PHASES OF THE MOON.

On the open coast the tidal current is not of the rectilinear or reversing type with its period of slack-water; nor is the current ever slack—its direction changes constantly in a rotary movement. The varying velocities throughout a tidal cycle when plotted to scale on polar-co-ordinate paper approximate an elliptical shape illustrated by Fig. 27. This shows velocities and directions

of current at Nantucket Shoals Light Vessel referred to the time of tide at Boston. For example, from the left diagram at $H-2$, that is, 2 hours before high water at Boston, the current sets about south by east with a velocity of 0.6 knots.

It should be noted that the current is constantly changing direction clockwise at the rate of about 15° per hour from H (high water) through each hour to L (low water) and so on to H again; and that the velocities are such that a curve through the extremities of ordinates approximates an ellipse. The velocity of the tidal current along the Atlantic Coast varies with the times of neap and spring tides (compare the right and left diagrams of Fig. 27). The direction of the set of the current, however, is in general the same at any time of the month for the same tidal hour at a standard port; for example, in both diagrams, H is in the same general direction from the origin; at L-3 (3 hours before low water at Boston), the direction is the same for both diagrams, and likewise for each tidal hour.

A graph of the tidal current at Five Fathom Bank Light Vessel (Fig. 28) illustrates that toward the coast tidal currents assume more nearly the character of the rectilinear or reversing type, the ellipse becoming more elongated than those for Nantucket Shoals Light Vessel, which is about 40 miles offshore.

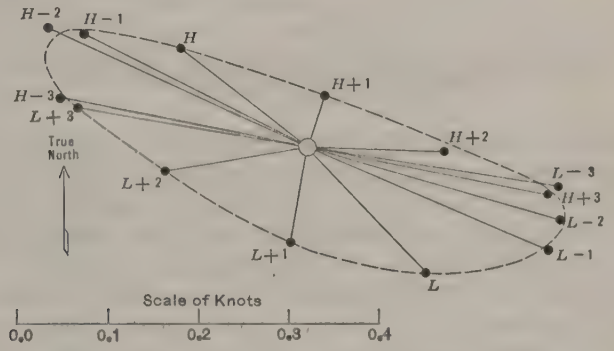

FIG. 28.—GRAPH OF ROTARY TIDAL CURRENT AT FIVE FATHOM BANKS LIGHT VESSEL, ATLANTIC COAST.

The coastal tidal currents on the Pacific Coast are also rotary, but, like its tides, they have considerable diurnal inequality. The current velocities on the Atlantic Coast vary principally with the changing phases of the moon (Fig. 28), while on the Pacific Coast the variations are principally due to diurnal inequality brought about by the declination of the moon.

The current graphs from the observations for 1919 at Swiftsure Bank Light Vessel at the entrance to the Strait of Juan de Fuca (Fig. 29), are representative of the type of coastal tidal current on the Pacific. They are referred to the times of the tide at Astoria, Ore., H representing the time of lower high water, L the time of higher low water, $H\ H$ the time of higher high water, and $L\ L$ the time of lower low water.

The left-hand diagram (Fig. 29) is made from observations at the time the moon was farthest north and farthest south of the equator, illustrating

the variation in velocity due to diurnal inequality; that is, at the time the daily tidal forces are at a maximum, when the moon is at its greatest declination. It will be seen that on the Pacific the velocity of the coastal tidal current, like the range of the tide, is greater during one tidal cycle than during the next. For example, one hour after lower high water at Astoria the current at Swiftsure Bank Light Vessel has a velocity of about 1 knot; whereas one hour after higher high water the current has a velocity of only about ¼ knot. On the Atlantic Coast the two ellipses of a tidal day are practically the same, whereas the ellipse through one tidal cycle on the Pacific Coast is considerably different from that of the next tidal cycle.

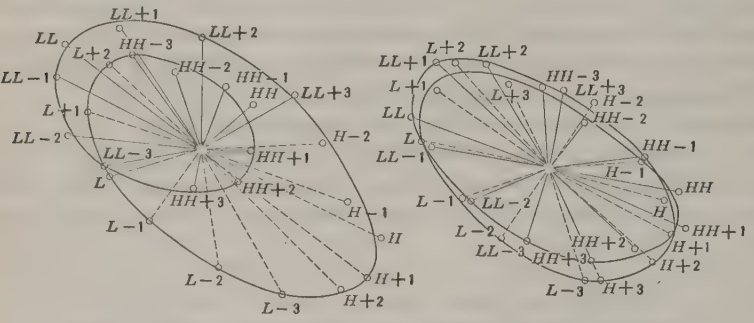

FIG. 29.—GRAPHS OF ROTARY TIDAL CURRENT, SWIFTSURE BANK LIGHT VESSEL, PACIFIC COAST, AT TIMES OF DIFFERENT DECLINATION OF THE MOON.

The right-hand diagram, Fig. 29, is a graph of a current at Swiftsure Bank Light Vessel at the time the moon is nearing the equator; that is, when the moon has its least declination. The semi-daily forces at this time predominate as in the tides, and the diurnal inequality practically disappears from the current graph as it does in a tide curve at this time.

The permanent set of the current at a station due to causes not tidal may be readily obtained by this method of plotting the tidal current graph. In Fig. 30 the velocities and directions of the tidal current, as averaged for the particular period desired, are plotted from a common origin (focus of the rays) and the true center of the ellipse, *C*, is then determined. The direction and distance to scale of *C* from the origin represent the permanent set of the current; that is, superimposed on the tidal currents there was a constant set during the month of August, 1919, passing Swiftsure Light Vessel at a rate of almost ½ knot in a direction N. 40° W. This permanent set may be ascribed to the fresh-water run-off from the Strait of Juan de Fuca, the light vessel being stationed just off the entrance to the Strait; it may be due to several causes, among which are prevailing winds, fresh-water discharge from a strait or river, and permanent sets like the Gulf Stream.

Since the rotary tidal currents along the open coast are so closely related to tidal action, it is evident that those components due to tidal action alone may be readily and accurately predicted as to their velocities and directions by comparison with the times of high or low water at some standard port.

The problem, however, is not so easily solved, for this tidal current is only one of the components of the total coastal current. The other, due to local winds, is not only non-periodic, defying accurate predictions a long time in advance, but, in general, is of greater velocity than the tidal currents, and, therefore, proportionately of greater importance.

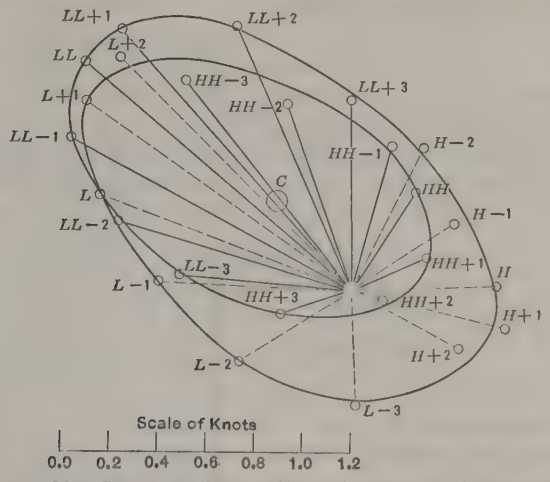

FIG. 30.—GRAPH OF ROTARY TIDAL CURRENT AT SWIFTSURE BANK LIGHT VESSEL, PACIFIC COAST.

Coastal Wind Currents.—It has been brought out that the rotary tidal-current ellipse may be displaced from its origin by a permanent set due to fresh-water run-off; at times, the current produced by heavy winds, however, retards the regular tidal current to such an extent that the origin is displaced considerably outside the ellipse. At Frying Pan Shoals Light Vessel from observations made during a northeast storm from January 29 to February 2, 1920 (Fig. 31), the wind velocity varied during the five days from 15 to 60 miles per hour, averaging 34.6 miles; the wind direction varied from north-northeast to northeast.

The origin of the graph is at P. The direction of the current varied throughout the tidal cycle from south to west and back to south; that is, from $H+1$ to $L+3$ by way of $L-2$, and then from $L+3$ to $H+1$ again by way of $H-1$. The velocities also varied because of the tidal forces throughout a tidal cycle and the curve through the extremities of the velocity ordinates approximates an ellipse; that is, the current, although setting to the southwestward during the entire duration of the storm varied in velocity by the amount of the acceleration and retardation due to the tidal component.

In an ocean of infinite depth it may be shown* from theoretical considerations that a current produced by winds should be deflected on the surface 45° to the right of the wind in the Northern Hemisphere and 45° to the left in the Southern Hemisphere, due to the deflecting forces of the earth's rotation.

* "On the Influence of the Earth's Rotation on Ocean Currents." *Arkiv for Mathematik, Astronomie, och Fysik*, Vol. 2, No. 11, 1905.

Near the coast it is to be expected that this deflection should be considerably modified by the configuration of the shore. Recent investigations from the comparatively long series of continuous current observations obtained during the past few years at different light vessels have verified this theory and brought out the important fact that, contrary to the belief of the mariner, a local wind creates a current setting not in its own direction, but in a direction about 20° to the right of the wind.

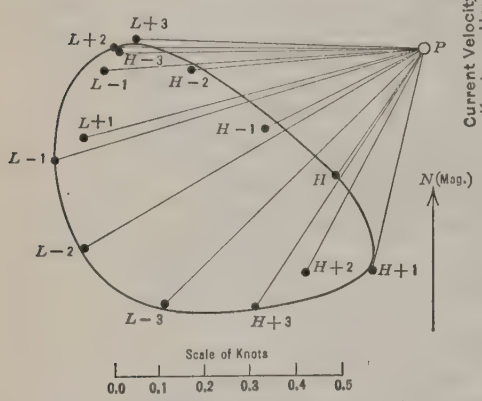

FIG. 31.—GRAPH OF CURRENTS AT FRYING PAN SHOALS LIGHT VESSEL, ATLANTIC COAST, FROM OBSERVATIONS MADE DURING NORTHEAST STORM, JANUARY 29 TO FEBRUARY 2, 1920.

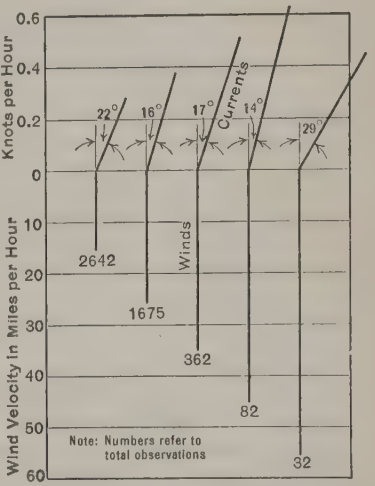

FIG. 32.—RESULTS OF OBSERVATIONS OF WIND-DRIVEN CURRENTS, DUE TO NORTH-NORTHWEST WINDS AT BLUNTS REEF LIGHT VESSEL, PACIFIC COAST.

Since a large number of observations of this character are necessary for averages of any degree of accuracy, and also for the elimination of tidal current in the resulting data, it is evident that observations of wind-driven currents have to be made over a considerable time in order to get a number of winds of 10 miles per hour, 20 miles per hour, etc., blowing from various directions. In Fig. 32 are represented diagrammatically the results from a number of observations over a period of two years (1919-20) for a north-northwest wind at Blunts Reef Light Vessel, Pacific Coast, for velocities from 10 to 60 miles per hour. The deflections of the slanting lines from the vertical indicate the deflections of the resulting currents to the right of the wind direction.

While the general law applies to the average current produced by any given wind velocity, observations are necessary at intervals along the coast, particularly well inshore, to determine the actual velocities for that particular locality. For coastwise navigation, however, the general law will hold with sufficient accuracy for practical results within 5 to 20 miles offshore; it has been found that the velocity varies fairly proportionately with the wind velocity and is about 2% in knots of the wind velocity in miles per hour on the Pacific Coast and 1½% on the Atlantic Coast.

In practice, it is necessary to take into consideration the combination of this wind-driven current with the periodic tidal current, the tidal current being obtained from predictions and the wind-driven current estimated from the local wind at the time. In actual practice the resultant current may be readily obtained from a diagram drawn to suitable scale showing the velocity and direction of each component, tidal and wind-driven, the resultant direction and velocity being scaled from this graph.

At times, however, wind-driven currents of considerable velocity appear to precede the wind to which they are due. The writer during two winters, 1915-16 and 1916-17, took current observations from the Carolinas well down the Florida Coast and from the shore out to the Gulf Stream. A number of times these showed a strong set from the southwestward during moderate weather, displacing considerably the regular tidal current ellipse from the origin of the current graphs. In every case this condition was indicative of a heavy southwest blow which followed within a few hours. At times, of course, a long swell, preceding the wind, may accompany this strong current, but sometimes even this warning of treacherous currents is absent.

While the main oceanic circulation involves a study of currents which, in general, are produced by predominant winds, such as the trades, and by differences in barometric pressures, densities, and temperatures over the oceans, little of a quantitative nature has been done toward a systematic study of these phenomena. In fact, what has been done may be considered as reconnaissance work only and volumes may be devoted later to obtaining the quantitative data necessary to such a study.

Reduction of Currents

Mean Values.—Since the tidal currents in bays and estuaries are so intimately connected with the tidal regimen in these bodies, a short series of current observations may be reduced to mean values by means of tidal data.

In the non-harmonic analysis of current observations the times of slack-water and greatest velocity are referred to the times of high and low water of the tide at some suitable place near-by. In this method the time of current is reduced to approximately mean values, since the changes in the time of current approximate the changes in the time of the tide. It is necessary, however, to reduce the velocities to mean values.

The velocities of a short series of ordinary current observations of the rectilinear or reversing type, caused by a progressive or stationary wave, may be reduced to mean values by multiplying by a factor equal to the reciprocal of the range of the tide for the same period of time during which the current observations were made, divided by the mean range of the tide for the place. The velocities of hydraulic currents, however, vary as the square root of the head (that is, of the difference in the height of water at the two ends of the strait); and to reduce the velocities of a short series of hydraulic type currents to mean values, it is necessary to multiply by a factor which is the square root of that used for ordinary tidal currents referred to heretofore.

Before multiplying the velocities of currents of both types by the suitable factors to reduce them to mean values, the non-tidal current, due to fresh-

water run-off, must be eliminated. This may be done by taking as the tidal current the half sum of the observed flood and ebb strengths, and this half sum is multiplied by the correction factor in each case.

The relations as to time existing between currents and tide apply as to the moon's changing phases and also as to the moon's changing distance from the earth; but as to the moon's changing declination, the current and tide do not respond alike, the diurnal variation in the tide at a place usually being greater than the diurnal variation in the current. In regions where the tide has considerable diurnal inequality, as on the Pacific Coast of the United States, the time relations between tide and current are subject to variations. In such cases, however, it is possible to refer the current at any place to the tide at some other place that has a comparable diurnal inequality.

Instruments for Current Observations

The instruments made in the United States for the observation of currents have been devised principally for shallow depths and for use in rivers. Little attention has been given, therefore, to attachments for furnishing the direction of the current.

There are a number of types of meters, described in the catalogues of American instrument manufacturers; practically all, however, are made on a principle somewhat similar to the anemometer used by the meteorologist—several metal cups on a carriage revolving in the current and making an electric contact at each revolution of the carriage. This contact, making an audible "tick", is transmitted through an insulated cable and telephone receiver to an observer on a vessel.

The Price current meter (Fig. 33) illustrates this type. The meter is suspended on station by a triple-strand insulated cable, 0.133 in. in diameter, made up of three enameled wires, one of which is piano wire, 0.0335 in. in diameter, for carrying the weight of the meter, and the other two, copper wires, No. 20 B. and S. gauge, for the electric circuit to the telephone receivers on board the observing unit.

To hold the meter from a davit of the observing vessel vertically on station in strong currents, a spherical 200-lb. cast-iron weight is suspended near the bottom on a ½-in. steel wire cable, and the meter lowered and raised along this cable by means of its own suspending cable and two small shackles (Fig. 33). The meter is rated before and after a survey lasting several months, so that the revolutions may be reduced to exact velocity.

Since the meters furnished by manufacturers in this country do not have a means for determining the direction of sub-surface currents—an important matter in current surveys for local peculiarities of currents in large ports off piers and slips—the U. S. Coast and Geodetic Survey has developed a device for this purpose. It is known as a "Bifilar Suspension Current Direction Indicator", and appears to have solved in a simple and inexpensive manner the problem of the determination of the direction of these currents in the smooth waters of a harbor. The determinations, however, are vitiated in rough water, where the rolling of the vessel causes the comparatively heavy device to swing.

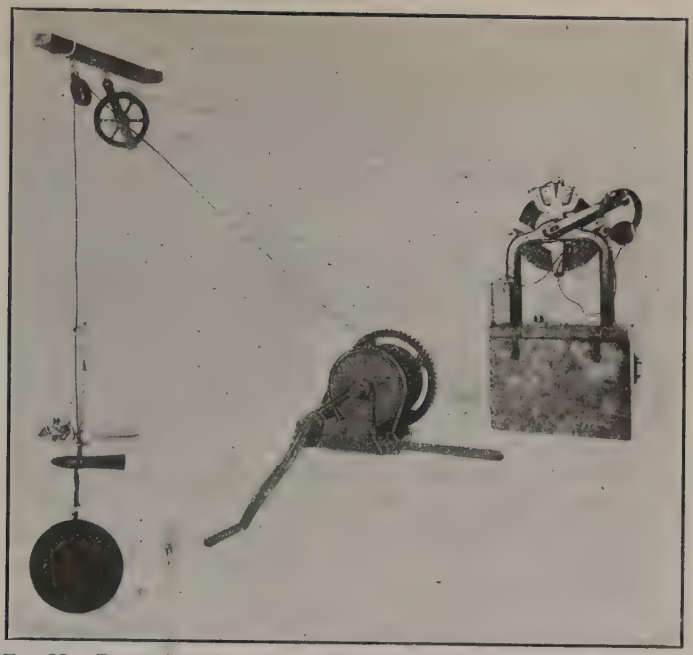

FIG. 33.—DETAILS OF INSTALLATION ON THE CURRENT SURVEY VESSEL OF THE PRICE CURRENT METER.

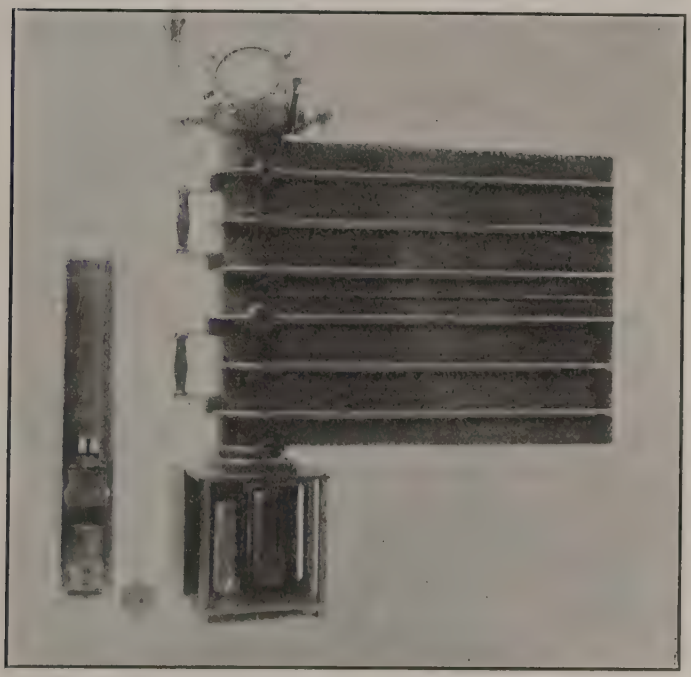

FIG. 34.—VIEW OF THE PETTERSSON SELF-RECORDING CURRENT METER.

Briefly, the device consists of a pipe, with rudder attached, free to turn in azimuth by virtue of a ball-bearing joint at its connection with an outrigger or davit on a vessel. The pipe is lowered to any moderate depth desired. A graduated pelorus at the davit indicates by a pointer the direction the bar is forced to take by virtue of the rudder acting through the taut aircraft wires.

A later development of the device (Fig. 35) permits not only of simultaneous observations at three depths, but also lessens the labor of operation by obviating the necessity of continually lowering and raising a single rudder for observations at various depths.

Foreign instrument makers have given consideration to attachments within the instrument for the determination of direction. Among others are the Ekman meter* and the Pettersson meter.† The former accomplishes the purpose by allowing metal balls, the size of ordinary shot, to drop into different compartments, one for each of the principal points of the compass, as the meter swings in azimuth; the latter by photographing on a narrow, sensitized film the graduated periphery of a glass disk, which is held in azimuth by a magnetized steel bar.

The Pettersson type (Figs. 34 and 36) is a self-recording meter and makes a photographic record each half hour of the total current passing the meter during the preceding half hour, and, in addition, of the magnetic direction of the current. The metal cartridge (left, Fig. 34), containing the recording device, is inserted into the heavy brass cylinder (right, Fig. 34), and the cap screwed down in place on top of the cylinder by heavy lug screws. A rubber gasket in the face of this cap prevents any water entering even at pressures of considerable depth.

The whole apparatus is supported on a ball-bearing shackle, permitting of a free movement in azimuth. The vane or rudder to the right (Fig. 34) forces the meter to head into the current.

The details of its operation are shown in Fig. 36. There is no mechanical connection between the current vanes, *W W*, which are wholly outside the cylinder, and the recording device on the inside of the cylinder. The vanes, *W W*, through a train of gears, turns a permanent magnet, M_1. This magnet in turn causes Magnet M_2, on the inside of the cylinder, to rotate in synchronism; Magnet M_2, through a train of gears and vertical shaft, causes the glass disk, D_1, to revolve. This glass disk is graduated on its periphery and the number of graduations past a given point in an half hour gives the number of revolutions made by the vanes, *W W*, and thus the current velocity, during that half hour. The glass disk, D_2, graduated on its periphery to every 10°, carries on its surface a magnetized needle, which holds it in azimuth.

The clock-work causes a sensitized photographic film to move at a uniform rate past an opening just above the two glass disks, D_1 and D_2. The clock-work also causes a light, L_1, to flash each half hour, thus making a record on the film of the graduations on both disks opposite the initial line, across the opening, at that instant. B_1 and B_2 are two ordinary dry cells and J is of

Swedish soft iron, breaking the magnetic field between the magnets and the magnetized needle on Disk D_2. The meter is suspended from the ball-bearing shackle, S.

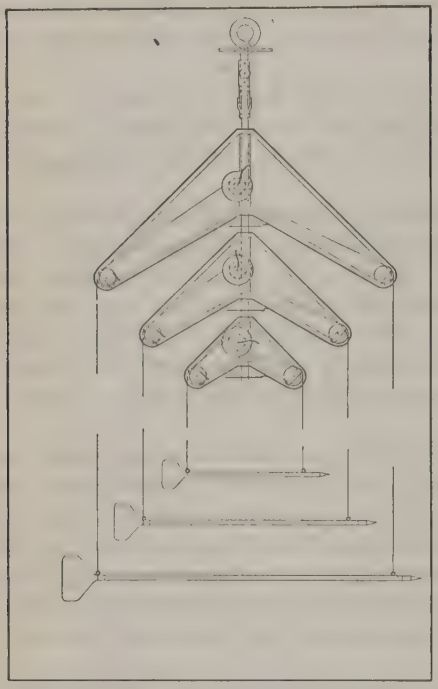

FIG. 35—BIFILAR SUSPENSION CURRENT DIRECTION INDICATOR, GIVING RECORDS AT THREE DEPTHS.

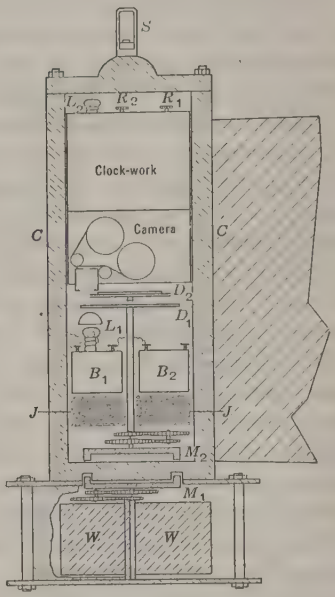

FIG. 36.—SCHEMATIC PLAN OF PETTERSSON TYPE CURRENT METER.

The meter can be lowered to any reasonable depth and left on station, suspended from a buoy, or raft, requiring no attention until the film has run out and the clock run down. The clock will run for 2 weeks and the film will accommodate 700 observations, sufficient for the corresponding record. This meter was tested by the U. S. Coast and Geodetic Survey on the current survey of Southeastern Alaska during the summer of 1925. It gave excellent satisfaction.

The U. S. Coast and Geodetic Survey has obtained good results in the observations of surface current velocities on the light vessels along the coast by the use of the current line. This consists of the ordinary log-line used in the days of the sailing ship for estimating the speed of the vessel, except that it is graduated to a 60-sec. interval for use with a stop-watch instead of a shorter interval as used with the old sand-glass. The sailing ship chip-log is replaced by a pole 3 in. in diameter and 15 ft. long, weighted with lead at the lower end to float upright, with about 1 ft. out of water. The line is graduated for the 60-sec. interval from the proportion, 3 600 sec. : 60 sec. = 6 080 ft.: X, or 101 ft. 4 in. representing 1 knot. The knot is subdivided into tenths by silk fish-line tabs.

The current line and the pole furnish a more reliable record of current velocities obtained from a vessel in rough water on the open coast than the current meter, because of the acceleration of the meter due to the rolling and pitching of the vessel.

Current and Tide Survey of Harbors

Prior to 1922 the current data available for the harbors of the United States consisted of short series of scattered observations made at various times. Thus it was impossible to reach conclusive results of the circulation throughout the harbors. Congress made additional funds available for current work in 1922 and the comprehensive current and tide surveys of the harbors of the country are being taken up in the order of their military and commercial importance. Such a survey was made in 1922 of the Harbor of New York, jointly by the U. S. Coast and Geodetic Survey and the U. S. Army Engineers, First District; in 1923 the Survey made a similar survey of San Francisco Harbor; in 1924, of Delaware Bay and its tributaries; in 1925 of Southeastern Alaska; and in 1926 of Boston and Portsmouth Harbors.

A thorough knowledge of tides and currents is necessary to a proper understanding of conditions under which harbors and rivers may be developed, in connection with sewerage problems, and in marine constructions of all kinds. Since the Harbor of New York is one of the most complicated from a standpoint of its tide and current conditions, a brief résumé of this survey will show its scope and the results obtainable. An interpretation and discussion of the tide and current observations made during this survey, together with scattered observations made by various organizations at intervals since the early Fifties, has been published.*

The Harbor of New York (Figs. 37 and 38) is made up of an outer bay, a narrows (at Fort Hamilton), an inner bay, a tidal river, a sound, and two straits, connecting independently tided bodies of water. Since the tidal and current conditions in all sections of the harbor are so intimately and vitally connected, continuous simultaneous observations throughout the entire harbor, of course, would make for an ideal survey. Unquestionably, it was uneconomical and impracticable even to approach this ideal and the problem was met by dividing the harbor for the purpose of the survey into different major sections and linking together the observations at one or two principal stations of one section while observations were in progress in the contiguous section. The actual observations continued day and night for about three months.

The dense traffic in the harbor, particularly in the East River and in the Lower Hudson, presented a rather troublesome question. The constant danger of collision to the observing units of the Survey, particularly at night and during thick weather, made it advisable in the parts of the harbor where the traffic was most dense, to utilize large flat-bottomed barges instead of the light 60-ft. launches generally used on this class of work.

The times of slack-water are of importance to shipping in a harbor in which the current velocity is considerable and the vessels entering the harbor,

* U. S. Coast and Geodetic Survey *Special Publication No. 111*, "Tides and Currents in New York Harbor."

of large tonnage. This is likewise true of exact information on local peculiarities of the currents in the vicinities of piers and slips in connection with the berthing of large vessels. The engineer engaged on marine work in the harbor, while not so vitally interested as the mariner in the predictions of the times of slack-water, must have a complete and accurate knowledge of the conditions of the current at various depths in order to plan intelligently. For example, this survey was not fully completed when a request was received from an engineer for information on the current velocities at various depths in connection with the proposed tube from Brooklyn to Staten Island.

Since the periods of slack-water in New York Harbor are short, particularly in those parts where the currents attain the greatest velocity, the predicted times of these slacks, to be of value, must be accurate. These predictions are made several years in advance and observations as furnished by this current survey are necessary to the preparation of accurate tables of current predictions. Likewise, in Admiralty Courts the time of slack-water and the velocity of the current at different times play important rôles in the settlement of cases involving collisions and suits for damages. Without accurate data on which to base computations and conclusions no authoritative statements are possible. This recent survey covers a large part of the harbor with current series of sufficient length to warrant authoritative statements for the majority of cases that will arise.

The results are also important in the studies of sewage disposal for New York City, and in the improvements to the waterways, particularly the East River, Harlem River, and Little Hell Gate. Engineers and commissions have been studying for many years these problems of sewage disposal. At the time of the creation of the New York Pollution Commission in 1903, the duties of which were continued by the Metropolitan Sewerage Commission in 1906, the question was serious and has become more so each year. Extensive float tests have been carried on from time to time to determine the final resting places of objects set adrift in the harbor. While these tests demonstrated that at times some of the floats would finally reach the ocean and others strand on the shores of the Bay, they did not furnish quantitative data on the circulation of the harbor as a whole. This recent survey, although made in five sections, has been so linked together as to make possible the study of simultaneous conditions of flow. Figs. 37 and 38 show the tidal movement in New York Harbor at the time of high water, and also at the time of low water, at Fort Hamilton.*

In general, floats are of little use for obtaining quantitative current data, except to show the different current threads in some classes of studies, such as oyster culture. For an interpretation of the entire circulation in a harbor, definite stations, with simultaneous observations, scattered over the harbor at selected points, are necessary.

In view of the purpose of the survey, it was considered of advantage to divide the current work into two parts: (*a*) Observations for determining

* U. S. Coast and Geodetic Survey *Special Publication No. 111*, in which the data from this survey are discussed, contains thirteen such diagrams of the harbor as a whole, showing the generalized tidal movement throughout the harbor each hour of the tidal cycle.

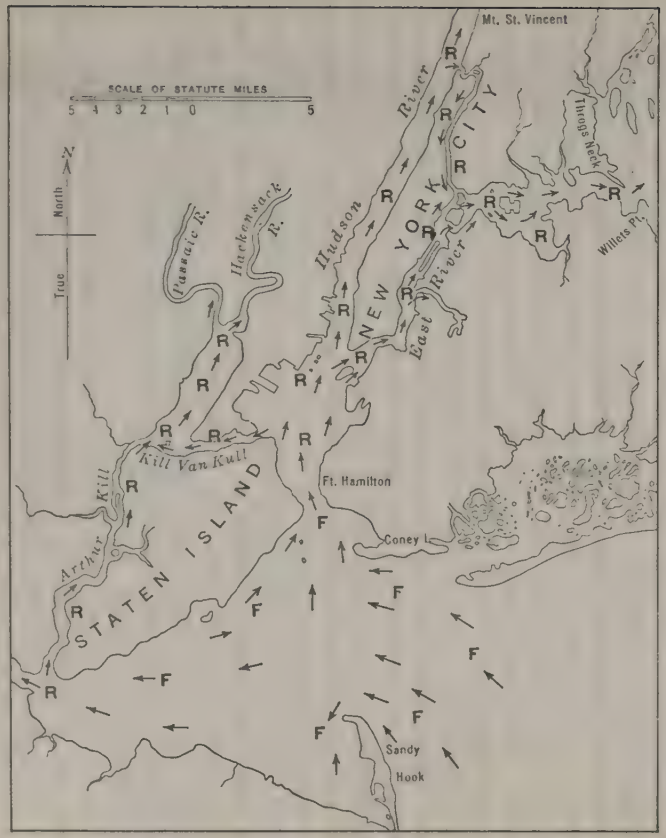

FIG. 37.—TIDAL MOVEMENT IN NEW YORK HARBOR AT TIME OF HIGH WATER AT FORT HAMILTON, N. Y. R INDICATES RISING TIDE.

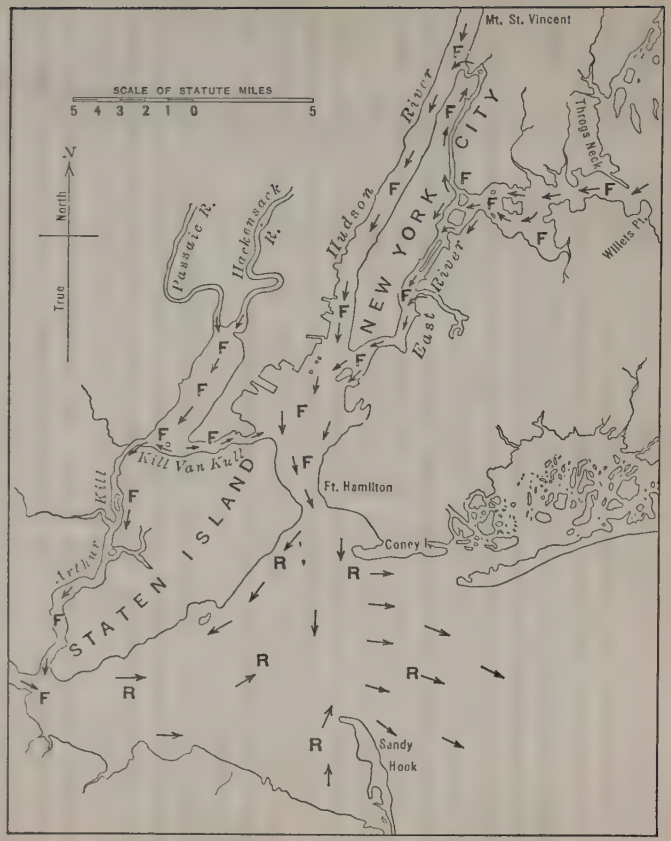

FIG. 38.—TIDAL MOVEMENT IN NEW YORK HARBOR AT TIME OF LOW WATER AT FORT HAMILTON, N. Y. F INDICATES FALLING TIDE.

circulation; and (*b*) observations for determining local conditions. The first comprised making observations as nearly as possible simultaneously throughout the harbor for the purpose of obtaining data on the full circulation of the harbor water, and after the completion of this work, re-occupying the principal stations and obtaining Data (*b*) at secondary stations off the piers and docks regarding local peculiarities of the currents.

Harbor Circulation.—The impracticability of carrying on current observations simultaneously in a harbor of such extent as that of New York is evident. The harbor, therefore, was divided into five sections for the purpose of planning and carrying on the survey for circulation. For each section the principal stations were planned so as to provide an overlapping of simultaneous observations in contiguous sections, in order to link one section to the next.

In addition to the principal stations, each area was covered by a number of secondary stations of either 13 or 26 hours each. A number of these stations were arranged so as to furnish observations of three to five units at a cross-section.

Local Conditions.—The observations at the stations of the various sections completed the operations for harbor circulation. For the observations for local conditions in the vicinities of piers the harbor was divided into three sections: The East River from Governors Island to Blackwells Island; the Hudson River from the Battery to 37th Street; and the Upper Bay. During the time the current observations, both for circulation and local conditions, were in progress, observations were being made on the three light vessels stationed off the entrance to New York Harbor, Fire Island, Ambrose, and Scotland Light Vessels, and also on Cornfield Point Light Vessel in Long Island Sound.

When the survey of New York Harbor was made the Pettersson meter had not been thoroughly tested. Price current meters solely were used for obtaining current velocities and, in addition, the ordinary current lines and current poles, already described, were used for check observations of surface velocity. The "single count" contact of the Price meters gave better results than the "Pentahead" for the currents encountered.

The chemicals in the water of the harbor at times had a deleterious effect on the points of the fine contact wires of the meters, and it was necessary to replace these at intervals. A supply of this wire was furnished by the manufacturers of the meter and new contact points were made and soldered on in the field without causing delay in the observations, since a number of spare meters were kept on hand.

The observations at the current stations were made, with some exceptions, from large flat-bottomed barges or scows, which were moored from four anchors, one from each corner, to hold them exactly on station. In those parts of the harbor where traffic was not sufficiently dense to constitute a danger to the units, the observations were made from launches, 60 to 75 ft. long, moored fore and aft.

At each station the current observations were made half-hourly with the meter, and checked hourly as to surface velocities by observations with the pole and current line. The direction of the surface current was determined by laying the current line, attached to the current pole, across a graduated

brass plate secured to the taffrail of the launches, or to the deck of the barges, and referred to a compass; the direction of the sub-surface current was determined by the Bifilar suspension current indicator.

Velocities were determined with the meters by observations near the surface, at mid-depth, and near the bottom. In general, readings were taken at two-tenths, five-tenths, and eight-tenths of the depth at each station, beginning with the one near the surface, followed by the mid-depth and near-the-bottom observations. Then the order was reversed and, before the meter was drawn up, the observation near the bottom was repeated; then the mid-depth; and, finally, the one near the surface.

Special weights of 60 lb. each and special hangers were provided for the Price meters because of the strong currents. This weight, however, was not sufficient to keep the meters in a vertical position below the vessel. In an attempt to overcome this difficulty a small winch was installed on the deck of each of the observing units for carrying a ½-in. wire cable holding a 250-lb. concrete block, which was hung just clear of the bottom. The meter was lowered and raised along this cable by a small shackle secured to its hanger. Subsequent experience, however, on later surveys has demonstrated that a 200-lb. spherical cast-iron weight, with its smaller surface (Fig. 33), is the more satisfactory.

In Hell Gate the velocity of the current and the traffic prohibited the anchoring of launches or barges. To obtain observations in this important waterway one of the concrete blocks was lowered from the Hell Gate Railroad Bridge by a ¾-in. cable and the meter run up and down this cable. After a series of 6 hours' observations, a tow ran into the cable and carried away the whole apparatus. The observations were then continued for a period of 13 hours from a drillboat of the Army Engineers moored off Hallets Point. The drillboat was run down a few hours later.*

Conclusion

The foregoing furnishes a brief outline only of the subject of tides and currents. Extensive further references are available.†

The finished products of the tide and current work of the U. S. Coast and Geodetic Survey for the use of the engineer and mariner appear in several forms: In tide tables and current tables which foretell the state of the tide and current for future years; in publications on tidal bench-marks, which definitely fix for the engineer the various datum planes over all the coasts of the United States; and in special publications devoted to a detailed interpretation of the tide and current phenomena of the various ports of the country.

* For more detailed discussions of the data from comprehensive tide and current surveys and of the methods and procedure used on these surveys, refer to the following publications of the U. S. Coast and Geodetic Survey: *Special Publication No. 111*, "Tides and Currents in New York Harbor"; *Special Publication No. 115*, "Tides and Currents in San Francisco Harbor"; *Special Publication No. 123*, "Tides and Currents in Delaware Bay and River"; *Special Publication No. 127*, "Tides and Currents in Southeastern Alaska"; and *Special Publication No. 124*, "Instructions for Tidal Current Surveys."

Y., and "Tides and Kindred Phenomena in the Solar System," by G. H. Darwin, Lond., 1911. For a mathematical treatment of the subject he should consult "Manual of Tides," by R. A. Harris, 1894 1907, Govt. Printing Office, Washington, D. C. These publications carry additional references to published material on the subject.

DISCUSSION

Lewis M. Haupt,* M. Am. Soc. C. E. (by letter).—This comprehensive paper, by Commander Rude, describes one of the most important factors in the interchange of the world's products. His statement of the complex nature of this problem, created by agencies which are constantly modifying the operation of tidal elements, is prefaced by sixty-four definitions of its many phases. Celestial and terrestrial gravitation, temperature, light and darkness, hills and valleys, continents and islands, winds, waves, and currents, are all factors which affect tidal fluctuations.

"All the rivers run into the sea; yet the sea is not full; unto the place from whence the rivers come, thither they return again". This is due to celestial and terrestrial gravitation (formulated by Newton), yet it is the returning streams that deposit the bars at the mouths of the rivers, thus affecting transportation, limiting the interchange of products, and increasing its cost. It is, therefore, a vital factor in the general welfare of humanity.

It is also worthy of note that, although on some coasts the tides are very feeble and diurnal, in others they are of great amplitude and semi-diurnal while, as the author shows, they are ever varying and are affected by other terrestrial agencies such as winds, waves, and currents.

Another factor in navigation is the form of the channel and the velocity and sectional area of the vessel, causing displacement in canals or aqueducts and creating a crest in advance with suction in the rear, which seriously affect the banks of narrow channels. These, however, are not "tides", strictly speaking.

As the tides are important factors in the erosion, transportation, and deposition of the sandy barriers which enclose the coasts and imperil navigation, it is important that they be carefully analyzed and utilized as remedial measures, as has been done by the U. S. Coast and Geodetic Survey and many foreign authorities. It has been demonstrated by maritime engineers the world over that tides may be utilized so as to create ample channels across ocean bars for the largest vessels, but in many instances these channels are being maintained by dredging to remove the drift carried in by the tides from adjacent coasts.

As an instance of vital moment, attention is called to the re-entrant angle in the coast between Long Island and New Jersey, where the inlets on both flanks have been moving toward the bar covering the 7-mile gap between Sandy Hook and Coney Island. Its greatest navigable depth at Gedney's Channel was 21 ft. until the Ambrose Channel was dredged to meet the imperative demands of commerce, but no permanent works have been constructed to check this littoral drift from Long Island. The Jamaica Bay Bar has now crossed the 50-ft. basin and is encroaching on the existing channel. It is believed that the exhaustive report made by the Coast Survey under Professor Henry Mitchell in 1858-59 has not been published, but it is an important document looking to the creation of a permanent entrance

* Cons. Engr., Physical Hydrography, Cynwyd, Pa.

to the City of New York. The problem has been under consideration for many years, and is quite feasible, but as yet has received no permanent solution, reliance being placed on dredging.

In this connection, and as a matter of record, it seems pertinent to cite a demonstration of the utility of tidal action in the creation and maintenance of an automatic channel which was inaugurated by Mr. Brewster Cameron* in 1899. He succeeded in persuading Congress to undertake the establishment of a navigable channel by constructing an offshore barrier to check the littoral drift and admit the 14-in. diurnal tides. All previous efforts had failed and the inlet has been abandoned, with the remains of the previous Government work lying across the bar at a depth of 3 to 8 ft. In 1906, after many delays, the detached offshore, curved or "reaction jetty", was reported to Congress to have been completed at a cost of only $389 203 and the Superintendent of the U. S. Coast and Geodetic Survey stated that the predicted automatic channel was in evidence, without dredging or bar advance. In January, 1910, it was desired to secure a depth of 25 ft., and it was proposed that a second jetty should be built and the offshore breakwater connected with the island. The cost was estimated at $2 028 125, with $60 000 additional to be used for annual dredging, which was not permitted under the former work, the automatic channel having been created by the 14-in. diurnal tides. A second jetty was constructed, however, and it reduced the depth immediately to 13.3 ft. at the outer end, where it was more than 25 ft., and diminished the tidal influx passing through this 2-mile entrance, thus reducing its efficiency.

Again, in 1912, another project was submitted to secure greater depths by the extension of both jetties and by dredging. The estimate submitted† was "for $2 325 000 to be completed in three years", but the diurnal tides continued to deepen along the concave reaction jetty so that this sum was entirely saved.

This example indicates the relative efficiency of purely tidal scour, due to a curvalinear directrix so well presented by H. C. Ripley, M. Am. Soc. C. E., in his paper,‡ "Relation of Depth to Curvature of Channels", in which reference is made to this reaction breakwater, which he built under authority of Congress and which is believed to be the only one in existence.

The Mediterranean Sea is regarded as tideless, yet in certain bays there are tides equal to those of the Gulf of Mexico. The Bay of Rio de Janeiro, Brazil, is notorious for the "resacas" which rise to more than 100 ft. at times, depending on the winds.

These are only a few of the main factors imposed by the tides as they affect the problems of the engineer in the creation of channels or the reclamation of beaches so vital to the welfare of the Nation.

H. de B. Parsons,§ M. Am. Soc. C. E. (by letter).— The work being done by the U. S. Coast and Geodetic Survey, as described by the author, is most

§ Cons. Engr.; Prof. Emeritus, Rensselaer Polytechnic Inst., New York, N. Y.

useful to the profession. Some years ago, the writer undertook a study of the tidal phenomena of the Harbor of New York,* and appreciated the help that he received from the Survey.

There are only a few engineers who comprehend tidal phenomena and the regimen of the rise and fall of tidal waters. Structures are frequently erected in the beds of tidal waters and streams, and, when they are, a comprehensive knowledge of tidal ranges and of current velocities is most essential. Many engineers are prone to consider the tidal rise and fall as being approximately harmonic, and do not make proper allowance for hydraulic conditions that affect the range and the irregularities of recurring high and low waters.

It is unfortunate that engineers and surveyors use so many different datums as reference planes for engineering works. The result has been confusing because it has made it difficult to co-ordinate surveys based on different datums. In many instances, the datum used is an arbitrary assumption, and then co-ordination is impossible. The establishment of precise mean sea-level datum bench-marks throughout the United States is a development of the work of the Coast and Geodetic Survey that engineers and surveyors in civil practice should utilize, as it will eliminate confusion and make it possible to co-ordinate surveys made at various times and under different conditions. The universal use of a standard datum would be especially beneficial for hydraulic developments, railroads, highways, water supplies, sewage disposals, river regulations, and flood protection works. These are often interstate problems, and the advantage of a standard reference datum, correlating all adjacent surveys, must be evident. It frequently happens that questions relating to elevations arise in cases under litigation. Such cases would be clarified if a standard elevation had been used for the different surveys that are the bases of the questions under dispute.

The U. S. Geological Survey uses mean sea level as the datum for its topographical maps of the United States, as also does the U. S. Lake Survey for its studies of the waters of the Great Lakes. Perhaps, in the course of time, the U. S. Coast and Geodetic Survey will state the land heights on its charts as feet above mean sea level, instead of in feet above high water, or will print the correction on the charts. These charts and topographical maps are used extensively for preliminary studies of important engineering works.

In contributing this discussion, the writer has in mind the hope that engineers and surveyors will use mean sea level as determined by the U. S. Coast and Geodetic Survey when selecting their datums. When an arbitrary datum is in local use and cannot be readily changed, a note should be placed on drawings giving the correction required in order to refer the datum to mean sea level.

The writer was pleased to find that the engineers of the Board of Transportation of the City of New York had placed a note on a recent drawing, referring the arbitrary datum representing mean high water at New York, to mean sea level as established by the U. S. Coast and Geodetic Survey at Sandy Hook.

* *Transactions*, Am. Soc. C. E., Vol. LXXVI (1913), p. 1979.

Engineers interested in erosion of beaches and in harbor improvement will find the records of coastal currents extremely enlightening. This work is being carried forward by the Coast and Geodetic Survey and data (supplemented by the records of the U. S. Weather Bureau) are being accumulated that will give good pictures of normal and abnormal conditions along the shores of the United States.

The public, as well as the profession, is indebted to the engineers of the U. S. Coast and Geodetic Survey for the careful and painstaking work that is being done and published for general use.

R. L. Faris,* M. Am. Soc. C. E. (by letter).—The paper brings out well the various aspects of tides and currents as they concern the engineer. As yet the engineer has not contributed to this subject as much as might be desired, notwithstanding the fact that as regards certain phases, for example the changes in tidal régime brought about by river and harbor improvement, he is in a position to make contributions of a fundamental character.

If any one branch of the subject may be regarded as of basic importance to the engineer, it is undoubtedly that having to do with datum planes, for they are a matter strictly within his domain. It is not so many years ago that it was customary for the engineer to start with some arbitrary bench-mark as "datum" and refer all elevations within a given locality to this datum. If the bench-mark originally defining this datum were lost, or its elevation accidentally changed, no means were at hand for re-establishing it accurately at its original elevation. Furthermore, with the growth of urban communities, characteristic of the past decades when lines of levels based on such arbitrary datums met, confusion was inevitable. Datum planes based on tides represent a step in the direction of standardization.

With the adoption of datums based on the tides the engineer is in a position to recover such reference planes even if all bench-marks are lost. Furthermore, these tidal datums furnish natural, instead of arbitrary, bases which are related to physical phenomena with the concept familiar not only to the engineer but to the intelligent public.

It is to be observed that while tidal datum planes possess the advantages of simplicity of definition, accuracy of determination, and certainty of recovery, their determination is not a simple matter. The laws governing the rise and fall of the tides are such that, together with the effect of wind and weather, any phase of the tide chosen as a datum plane, as, for example, mean sea level, mean high water, lower low water, etc., changes from day to day, from month to month, and from year to year.

Despite these variations, however, as is brought out by the author, methods have been developed to reduce to mean values the results of short series of observations. By the use of these methods, in general a datum plane may be derived from a month of tide observations correct to within 0.1 ft. and from a year of observations correct to within 0.05 ft.

Even limiting the matter to that which may be of concern to the engineer, the subject is one of wide extent. Necessarily, therefore, the author has been

* Asst. Director, U. S. Coast and Geodetic Survey, Washington, D. C.

obliged to deal with the various phases of the subject in a brief manner. The full references, however, add to the value of the paper. With the improvements of tidal waterways which the growing water-borne commence will make necessary, the engineer will be called upon to solve problems that demand a knowledge of tides and currents. Such knowledge this paper gives.

Earl I. Brown,* M. Am. Soc. C. E. (by letter).—This paper is an excellent statement of present-day scientific knowledge of tides, and of the practical uses made of such knowledge. In reading it one cannot fail to be struck most forcibly by the thought that tidal phenomena are too much neglected in textbooks on hydraulics. Papers like this go a long way toward supplying the deficiency. As the author points out, a practical working knowledge of the theory and application of tidal hydraulics is a necessity for any engineer engaged in the maintenance or improvement of channels in tidal waters. A lack of understanding of tidal mechanics has been responsible for many of the mistakes and failures made by engineers in planning and executing maritime works.

In practice, the engineer is not ordinarily concerned with the tides or currents in the open sea, far off the coast. He is interested in those adjacent to the coast, and in the inland waters, and it is these that will be understood in what follows.

There is not much in the paper to which the writer would take exception. It might be well to point out that the author's classification of waves into progressive and stationary waves is a purely arbitrary one, as there is no basic difference between them. All waves are fundamentally progressive, but when a progressive wave is reflected back upon itself at points one-half or one full wave length (or multiples thereof) from the origin, a stationary wave results from the interference of the components. The resultant wave derived from such a reflection will show characteristics more closely approaching those given as defining each class of wave, depending on how closely the point of reflection coincides with the half-wave length or its exact multiple in distance from the origin.

As the author shows, the propagation of the tide from the sea into inland waters gives rise to so many apparently confused and conflicting manifestations of heights of water, and directions and velocity of currents that to bring order out of the chaos and to deduce general laws seems to be impossible. Nevertheless, it has now been found possible to account for almost all these phenomena by considering the tidal wave entering inland waters, as a progressive wave of translation, acted upon and modified by friction of the bed, depth and width of the channel, and combined with entire or partial reflections at those points where a change of energy of the wave is effected by the bed.

The author has classified the currents flowing through a narrow strait connecting two larger tidal bodies of water as being hydraulic currents, meaning by this term a current flowing under the influence of a surface slope.

The writer has had experience on many canals connecting such bodies of water along the coast, at points ranging from Delaware to Texas. He has also

* Col., Corps of Engrs., U. S. A.; Engr., Eighth Corps Area, Fort Sam Houston, Tex.

observed many inlets connecting the sea with large inland bays, in which the connecting channel was of varying lengths from a few hundred feet to several miles. He has always found the flow through such channels, when of considerable length, to be far from hydraulic. The surface slope is not uniform, nor are the current velocity and rate of discharge uniform for the whole length of the canal. All these phenomena vary from point to point, and the current may be strongest where there is no slope or even an opposed slope. As the connecting channel or canal becomes shorter, these manifestations of true tidal propagation are less evident, but still persist, and it is only when the canal is very short indeed that true hydraulic flow may be said to prevail. The author is correct, however, in stating that the simpler hydraulic solution of problems arising in some cases may suffice for all practical needs. The engineer must bear in mind, however, that such a solution is a mere approximation, and it should be used only for very short canals or straits.

Edward Godfrey,* M. Am. Soc. C. E. (by letter).—The writer agrees with Commander Rude that the subject of the tides is one that ought to be discussed by engineers, particularly that phase that deals with their cause. Some scientists deal chiefly with speculation. They are not concerned with producing results; nor are they concerned with rigid proofs that certain results will be produced by certain causes. A motor, or engine, or turbine must deliver the power for which it is designed. Hence, the engineer must know definitely, what certain elements, when brought together under certain conditions, will do.

The foregoing remarks are a preliminary to a challenge of the universally accepted theory of tides, which omits mechanical principles that govern the movement of bodies, and glides over adverse facts that nullify the theory completely. Forces of gigantic magnitude are ignored, and secondary forces are given the leading, in fact, exclusive, consideration.

The theory of tides, as expounded by George Howard Darwin,† at greater length perhaps than by any other writer, is that they are the result of the gravitational pull of the moon on the water of the oceans. This is explained by the author, except that it is the centrifugal force of the earth's rotation, combined with the moon's lessened pull, that causes the tidal rise on the opposite side of the earth from that where the moon is on the meridian.

Writers on tides, including Commander Rude, show the bulges representing the high tide, directly under the moon and on the opposite side of the earth. They also state, as Commander Rude has said, that in Nature it is different, diametrically different, so to speak. The tides are perpetually low on the sides of the earth where the moon is pulling for high tide, and *vice versa*. The only explanation of this astounding nullification of the theory is that the tide lags or is retarded, presumably by the wave trying to catch up with the force which produces it. It is here that a study of engineering mechanics would be a good thing for the scientist. It would be interesting to have him answer the following questions:

* Structural Engr., Pittsburgh, Pa.

† "The Tides and Kindred Phenomena in the Solar System," by George Howard Darwin.

(1) Is the force of gravitation itself so sluggish that it takes 6 or 8 hours for it to be felt across the distance from the moon to the earth?

(2) Does not the tidal wave traverse the circumference of the earth in about 25 hours?

(3) Why does this wave not synchronize itself with the force that produces it?

(4) If gravitation is instantaneous, or nearly so, when and how is a tidal wave initiated and what keeps it going, since the force is admittedly always in an entirely different direction from that in which, mechanically, it would have to be to raise the water?

(5) Is there any action in a tidal wave analogous to flywheel action?

(6) Would a wave continue to travel around the earth from east to west, the crest and trough being 6 000 miles apart, if the moon's force were suddenly to cease?

(7) Would not that wave divide and seek a level by traveling both east and west?

A large pendulum can be made to move in wide amplitude by impulses applied by pulling at intervals on a small rubber band, if the timing of the impulses agrees with the swinging of the pendulum, in the same direction as the impulse. However, the pendulum cannot store up impulses applied contrary to its motion to be used later when it is swinging that way. Therefore, it is inconceivable that the ocean could store up, for 6 or 8 hours, a wave-raising force received from the moon and then respond to that force.

If the earth were absolutely rigid, there would be tides due to the moon's gravitational pull, but high tide and low tide would be just about exactly reversed.

The earth is not rigid and does not behave as a rigid body, in spite of the opinion of scientists. If it were a solid steel ball, of the hardest steel known, the gigantic force of the moon would of necessity elongate its diameter in the direction of a line to the moon. The moon's gravitational pull on the near hemisphere of the earth is greater than that on the far hemisphere by about 600 000 000 000 000 tons, a force that would snap a piano wire 30 miles in diameter. Is this a trifling force that can be ignored because some scientist states that in his opinion the earth acts as a rigid body in the face of the moon's tidal pull?

This force distributed uniformly over the entire cross-section of the earth considered as a solid steel bar, 4 000 miles long, would stretch it out 4 or 5 ft. Other metals and rocks do not approach this rigidity. This is not conjecture. There has never been a piece of material found in the earth that is not subject to this law and would not be elongated by this amount or a greater amount under a force of this intensity.

Furthermore, having been elongated by this force, applied in a constantly changing direction, the elongation would not cease when force and elasticity were equal. Inertia would carry the earth several feet more. A high wave, therefore, in the body of the earth itself is carried around by the moon and what is the result? Of course, a wave of water follows in the trough of the

earth wave. This is the ocean tide as it is known, not a wave of water raised by the moon, but a wave of water following and remaining in the trough of the solid earth created by the gigantic differential gravitational pull of the moon.

The tidal pull, rightly understood, accounts for countless phenomena, not otherwise explained in any rational manner. Some of these phenomena are the following:

(*a*).—*Earthquakes.*—The continual kneading of the earth by its satellite accounts for the thousands of earth tremors observed yearly.

(*b*).—*Volcanoes.*—Extra movement with attendant friction below the surface of the earth creates heated spots, where peculiar rock formations exist that are conducive to movement.

(*c*).—*Hot Springs.*—The same process that produces the volcano, working on a small scale produces the hot spring.

(*d*).—*Internal Heat of the Earth.*—The heat of friction due to the continual kneading of the body of the earth by the pull of the moon and the earth's rotation accounts for the internal and absolutely constant heat of the earth. It seems strange to state that the moon and not the sun is responsible for the unfailing supply of heat in the earth, making the planet livable, particularly at night, when radiation of atmospheric heat would leave the air excessively cold.

(*e*).—*Trade Winds.*—The tidal pull of the moon on the earth's atmosphere, apart from land or ocean tides, accounts for prevailing winds, trade winds, etc.

(*f*).—*Ocean Currents.*—Instead of ocean currents being caused as claimed by trade winds, they are doubtless due to the continual travel of a wave of water forced around the equatorial region and deflected by the continents in the manner exhibited by ocean current paths.

The earth's density is several times that of rock. It is, in fact, nearly as great as steel. The interior, therefore, must be metallic. No doubt, it is largely composed of iron or steel.

This great elastic ball, subject to the enormous gravitational pull of the moon, would exhibit inertia in its tidal wave in a manner not possible in a water wave assumed to be actuated by the moon's tide-raising force. Accelerated impulses, such as those of the combined pull of the sun and moon as they approach conjunction or opposition, cause higher and higher tides, and the highest tide, on account of the inertia, would be a little later than the maximum impulse. This accounts for the fact, as pointed out by Commander Rude, that the highest tide occurs a day later than the actual time of new or full moon.

The frictional heat of the earth, due to tides, is generated comparatively near the surface, probably largely where the interior elastic metallic ball joins the exterior rock crust. The temperature at the center is probably not very great; not much if any greater than the temperature a few miles from the surface. Hence, the metallic core is elastic and not fluid.

Volcanoes are the result of heated spots where extra motion and friction are manifest; they are not an indication of the earth's general internal condition.

The moon's excessive low temperature is due to the fact that it does not rotate as does the earth; therefore, it can have no tide. Its atmosphere and water vapor have turned into snow.

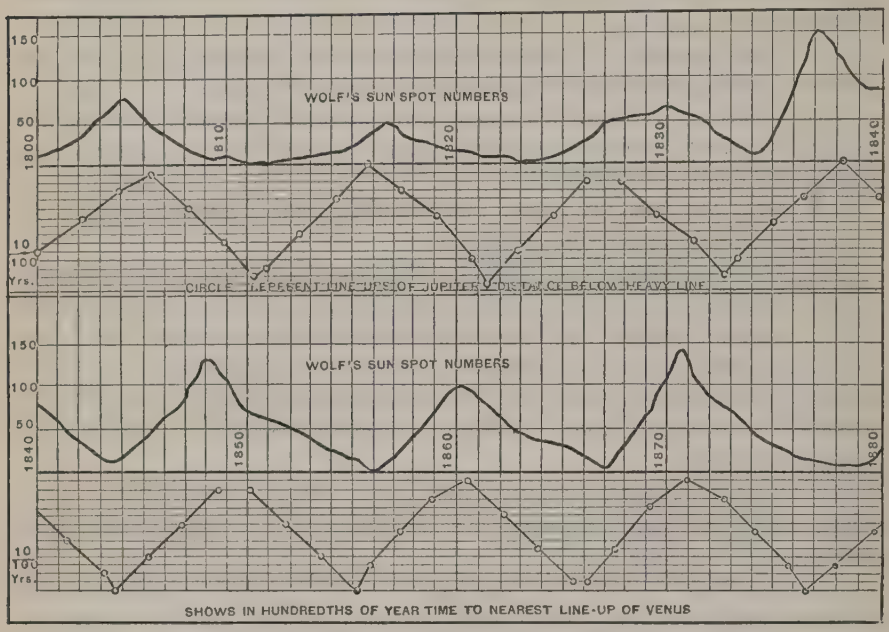

FIG. 39.—GRAPH OF SUN-SPOT INTENSITIES.

The sun is subject to tides of gigantic force. Any one of the four planets, Mercury, Venus, the Earth, and Jupiter, exerts a tidal pull on the sun many times the tidal pull of the moon on the earth. The kneading of its great mass creates heat that is incalculable. It is this that sustains the heat of the sun. A very striking proof of this is exhibited in sun-spot counts for a period of 300 years. Sun spots are volcanoes in the sun caused by excessively heated spots, due, as in the earth, to sub-surface friction.

Astronomers have recognized that there is some general influence, over a long period of years, that intensifies sun spots in a regular period of 11.2 years and some influence that introduces an irregularity, so that the several periods are more or less than 11.2 years. The writer has discovered that there are exactly such influences at work and that the period of high sun-spot intensities agrees remarkably with those influences.

Every 11.2 years Jupiter and Venus and the Earth are almost exactly in line, thus adding their tidal pulls on the sun and intensifying its heat. Fig. 39 shows the agreement between these alignments and the high sun-spot periods. The influence that makes for irregularity is Mercury, which aligns itself with one or two of these planets in short periods.

Forty-one of Jupiter's half synodic periods is 22.387 years and twenty-eight of those of Venus is 22.381 years. Thus, every 22.38 years these planets and the Earth are within 2 days of being exactly in line. In the intermediate period these planets are twice within 7 days of being in line, as will be seen by comparing their synodic periods.

The argument that will be used against this theory is, "What about the law of the conservation of energy?" That "law" was broken down when radium was discovered. Now, however, to cover the face of the law, scientists assert that all matter has potential energy of almost incalculable amount residing in it, although they do not hesitate to calculate how long a pound of metal would run a horse-power engine, in millions of years. Let them turn engineers for a while and try to lift a fly 1 ft. by a ton of this metal in any period without using some regular old-fashioned coal, wood, or other fuel that is said to have potential energy stored in it, or by using sun radiations.

Energy is inexhaustible and is all derived from the moving, impinging, vibrating ether, traveling at the speed of light and penetrating matter without hindrance. On the earth there are limited means of converting this energy into useful work. Nature's great tidal engines must be depended upon to supply and store up the useful energy needed.

It may seem strange to set up a theory that the heat of the earth is derived chiefly from the moon and that the earth contributes immeasurably more heat to the sun than it receives from the sun; but let any one who is skeptical determine the known forces, from the law of gravitation; one that would snap a piano wire 30 miles in diameter and the other that would snap a similar wire about 150 miles in diameter, each exerted on bodies of enormous size in a different direction every hour. Calculate the horse power needed to accomplish this and the heat that would result, and some of the greatest puzzles of science will be at least partly solved. These puzzles are the undiminished supply of heat from the sun, the constant temperature of the earth, the cause and reason for the periodicity of sun spots, the cause of earthquakes and volcanoes, and, in fact, directly or indirectly, all the mechanical manifestations on the earth or sun, as well as the utter absence of them on the tideless moon.

William Barclay Parsons,* Hon. M. Am. Soc. C. E. (by letter).—This paper is an admirable exposition of a very complicated natural movement, on some of the aspects of which scientific men are not in agreement. Engineers, however, are not directly concerned with these differences in opinion in the planning and execution of their work. From the standpoint of science they may be interested in what is supposed to take place in the great tidal movements and oscillations in the deep open oceans, but in practice all they need know is what will occur under various conditions in harbors, estuaries, or other places along a coast exposed to tidal effect.

The most important factor for the engineer thoroughly to understand is that he cannot generalize with safety in respect to what will take place in tidal action in any one locality. He may know, with nice exactness, the effects

* Cons. Engr., New York, N. Y.

and movements at two places, one each side of where he is working, but he must not assume that the result at his site will be a mean of the other two. Local conditions have a tremendous, and frequently surprising, influence. There may be two progressive tidal waves each acting freely and with normal ranges and times, at the other places, but which, meeting and interfering, will give an apparently wholly unrelated result at an intermediate station. Tidal actions are also seriously affected by ocean currents as well as river flow and particularly by the depth and shape of bays and estuaries.

The writer recalls one experience where mean sea level had been previously determined for two places only eight miles distant, one from the other, by measuring high and low-water elevations at both places, taking the mean, and connecting such means with a chain of levels. Being on opposite sides of a peninsula, the places were affected by two tidal waves of different characteristics. Although the levels showed a considerable difference in elevation between the reputed mean sea levels, the elevations had been accepted as accurate. The error was not discovered until the writer had established tide stations, when it became apparent that whereas mean tide at one station was the same as mean sea level, such was not the case at the other. At the latter station there was a large body of comparatively shallow water so that, when the ebb tide was half gone, sufficient frictional resistance began to be developed to retard the flow, and, consequently, the ebbing tide never was able to reach the true low-water level. In this case mean tide and mean sea level were far from being the same.

The engineer should never accept any tidal statements as true unless they are based on accurate observations with self-recording gauges conducted through at least one lunar cycle, properly analyzed and interpreted; and even then he must be on his guard against exceptional tides and prolonged wind effects.

The author refers to the currents in channels joining two bodies of water in which there are tides with different characteristics, and cites as examples the East River, New York, and the Cape Cod Canal. The former, although highly interesting and important, is not a good example from which to draw conclusions, on account of its variable cross-section and sharp turns. The latter on the other hand is almost perfect for study, with its uniform cross-section and only two curves with long radii, well protected from wind influence. Some of the results, as deduced by the writer, were given in his paper entitled "The Cape Cod Canal".* Among other interesting data were (*a*) the curved and not straight line of low-water elevations with an upward central versed sine of about 1 ft., a factor of economic importance; and (*b*) the evident momentum of the moving body of water which causes an actual flow of water up a gradient of measurable slope. This momentum accounts, in part, for the fact that the current in tidal waters does not change direction at the same time as the tide turns.

When the Board of Advisory Engineers, of which the writer was a member, was considering the type of canal for Panama, it refused to discuss or attempt

* *Transactions*, Am. Soc. C. E., Vol. LXXXII (December, 1918), p. 1.

to determine the rate of current that would exist if a canal were built there at sea level without locks, being satisfied with a general statement that the current would not be strong enough to interfere with traffic. So far as the writer is aware no analysis of this question has ever been published.

T. Kennard Thomson,* M. Am. Soc. C. E.—It is fortunate for New York that the State of New Jersey did not have the benefit of Commander Rude's professional services generations ago, when New Jersey claimed Staten Island, because, it was stated, a ship could not sail around it in one day without running aground.

Unfortunately for New Jersey, New York had a captain who knew the tides and channels, and who by starting at the right place, at the right time, was able to get around without landing on a sand-bar.

Fig. 40 shows that the St. Lawrence River, Bay of Fundy, and Long Island Sound are practically parallel, although in opposite directions, and have enormously greater tidal ranges than Chesapeake Bay, Delaware Bay, and the Hudson River, which are also parallel to each other, but approximately at right angles to the first three.

The Bay of Fundy, with no outlet at its upper reach, has the greatest tide, about 47 ft., with an average, as Commander Rude has indicated, of 5 ft. higher tide on the Nova Scotia side, than on the New Brunswick side.

At Quebec, Que., Canada, the St. Lawrence River has a maximum tide of about 20 ft. and the influence of the tide is slightly felt at Montreal, where the surface of the river is about 24 ft. above mean tide level. The St. Lawrence, above Montreal, receives an enormous fresh-water flow of about 300 000 cu. ft. per sec. from the Great Lakes. This is a comparatively uniform flow.

On the other hand, Long Island Sound has two outlets, the East River and the Harlem River, with a maximum average tide of 7½ ft., only about 3 ft. more than the average tide at Governors Island.

It would be interesting to know whether a new East River from Flushing to Jamaica Bay and a new Harlem River from Hell Gate to the Hudson, 2.50 miles long instead of 6.75 miles, would reduce the difference between the tide levels at Governors Island and Hell Gate, if each of the new rivers were, say, 50 ft. deep, and of ample width.

Fortunately for the Cities of New York, Philadelphia, Pa., and Baltimore, Md., they are not troubled with such excessive tides, and it would also be interesting to know whether this good fortune is due to the fact that they are at right angles to the direction of Long Island Sound, Bay of Fundy and the St. Lawrence; and also whether, if all these rivers, bays, and sounds were running parallel to the equator, the tidal ranges would be greatly increased.

Chesapeake Bay has a tide of only 1.2 ft. at Baltimore; Delaware Bay has a tide of about 5.2 ft. at Philadelphia; and the Hudson River, a tide of 4.5 ft. at Governors Island, with an ordinary high tide of 2 ft. at Albany, N. Y. The Hudson River, however, is subject to greater fresh-water flood variations than the others. For instance, the speaker has seen a low-water flow of only

* Cons. Engr., New York, N. Y.

600 cu. ft. per sec. in the Mohawk River near its entrance to the Hudson River, and, at the same place, he has seen a flood flow of 100 000 cu. ft. per sec. At The Narrows, where the normal flow is 76 000 cu. ft. per sec., an exceptional flood flow has amounted to between 300 000 and 400 000 cu. ft. per sec. While the flood-flow elevation is not proportionately great at Governors Island, it amounts to 18 ft. at Albany.

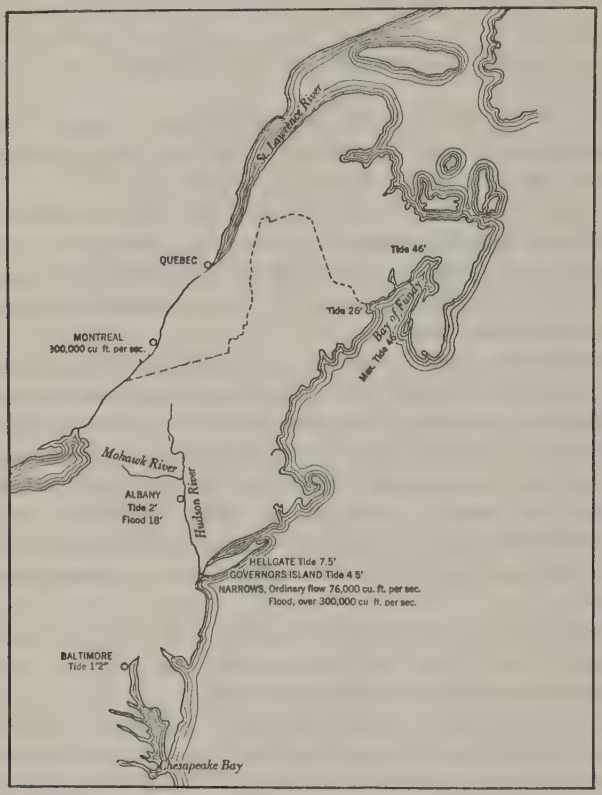

FIG. 40.—GRAPH SHOWING PARALLELISM OF ST. LAWRENCE RIVER, BAY OF FUNDY, AND LONG ISLAND SOUND.

This paper is of great personal interest on account of the plan the speaker has been advocating since about 1910, for a "Really Greater New York". When he first suggested extending Manhattan down the Bay (where it is hoped to reclaim 9 sq. miles), nearly every one thought that the one insuperable objection would be the "tidal prism theory", and it looked as if it might be necessary to construct a model, including New York, New Jersey, Connecticut, and all the fresh and salt-water flows that affect New York Harbor. Such a model, of course, would cost many thousands of dollars, but when a (then) U. S. Chief of Engineers stated that he had no use for the "tidal prism theory" in this respect, the speaker cheerfully discarded the idea of the model.

While in 1911 many laughed at this project for a "Really Greater New York", which included reclaiming a section of the East River, a number of

people have recently proposed it as an original idea of their own. One went so far as to say that he had the approval of the War Department, which, of course, was absurd, because he had omitted the first essential feature of the original plan, that of providing an outlet for Long Island Sound to the Hudson River and Jamaica Bay before attempting to close the East River. He did not even pay any attention to Newtown Creek.

In addition to avoiding the danger of turning Long Island Sound into a Bay of Fundy, it is equally important to provide new docks, etc., for the people before closing off 5 miles or more of the East River.

It may be interesting to record the fact that some of the biggest financial men of the country declared that they would not be interested if the East River section of the plan was omitted. This was due (in 1913) to the fact that they realized that New York can never get enough bridges and tunnels to connect Long Island with Manhattan, and also to the relief which this plan will afford the north and south traffic.

Commander Rude has referred to the hydro-electric features of the Bay of Fundy. Two projects have recently appeared in the daily papers. One plan is for Passamaquoddy Bay between Maine and New Brunswick, of which more than three-quarters would be in Canada, with a maximum tide of 27 ft.; and the other plan is for the upper end of the Bay of Fundy, all in Canada, with a maximum tide of 47 ft.

It is claimed that the latter project would only cost one-half as much per horse power developed as the first plan, but the first promises to develop power at a cost of about four times as high as the speaker's estimates per horse power developed for a "Niagara Falls Junior". There is no immediate prospect, therefore, of the Bay of Fundy developments. However, sooner or later, engineers will have to learn how to utilize these tides economically, storage batteries not being economical; for when all the rivers are fully developed there will still be more coal used than at present, and before that time there is hope of having a new city of 9 sq. miles built in the very heart of New York City, between the Battery and Staten Island, where people will never use a pound of coal, nor any oil or gas.

H. F. Dunham,* M. Am. Soc. C. E.—The author's well organized and excellent paper will be widely read and appreciated. The "Nomenclature" is a fortunate introduction. The definitions offer a slight difficulty to one unaccustomed to these terms, namely, "perigee" and "apogee", termed positions of the moon "in its elliptical orbit around the earth". "Elliptical" as frequently used implies a return to the point or position first occupied by a moving body. In Fig. 41 the lines represent the orbits of the earth and moon on a scale of 2 000 000 miles to 1 in. Is there an elliptical orbit for the moon around the earth in addition to its elliptical orbit around the sun, similar to that of the earth around the sun?

Low-tide elevations alongshore where construction work is going forward are complicated with ground-water heights and do not require extreme accuracy. The limit for timber submergence is rather a matter of good judgment. If sub-drains or subways are to follow, the call is for better judgment.

* Civ. and Hydr. Engr., New York, N. Y.

In 1922, the Carnegie Institution of Washington published "Effects of Winds and Barometric Pressure on the Great Lakes". Tidal influences were not recognized; instead, from many observed gauge readings at various points, the 13-hour rise and fall was attributed wholly to wind and barometric pressures.*

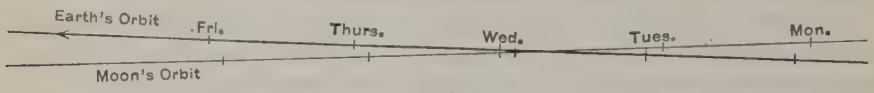

FIG. 41.

In 1903 a tide-gauge was established near the mouth of the Menominee River, on Green Bay, Wisconsin,† where conditions for accurate records were extremely favorable. An unused water intake of metal about 6 ft. in diameter,

FIG. 42.—VARIATION IN WATER ELEVATION, GREEN BAY, WISCONSIN, DECEMBER 29 AND 30, 1903.

perforated with ten thousand $\frac{3}{8}$-in. holes and placed in 20 ft. of water, was connected by a 12-in. pipe line, 800 ft. long, to a vertical 16-in. pipe well having a float carrying a rod and pencil, which traced a line on a vertical clock

* "The Manual of Tides," by R. A. Harris, U. S. Coast and Geodetic Survey Report for 1907, was cited as authority.

† This gauge was set by the speaker. Records from it, faithfully kept for many months by the late J. J. Campbell, have been deposited with the U. S. Coast and Geodetic Survey, at Washington, D. C.

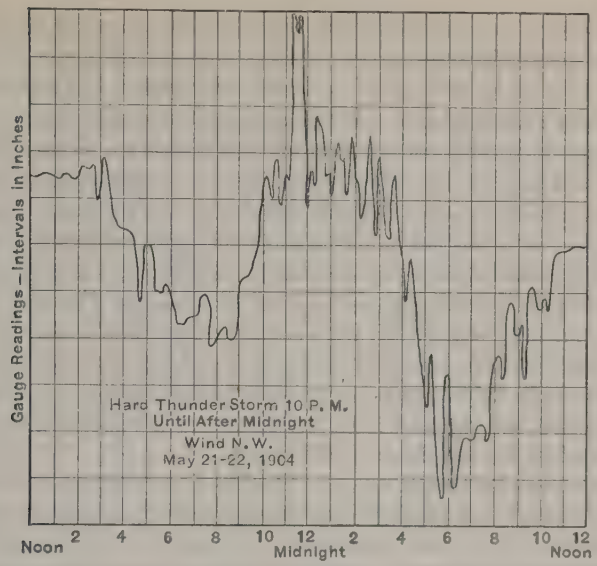

FIG. 43.—VARIATION IN WATER ELEVATION, GREEN BAY, WISCONSIN, MAY 21 AND 22, 1904.

cylinder. The pipe line and well were connected by about 20 ft. of 1-in. pipe. Wave effects, so-called, were not recorded as Fig. 42 will show.

Fig. 43 covering a later date is quite exceptional. While wave action may be inferred at first glance the time intervals of many minutes shown by the inequalities of the curves indicate an up-and-down motion of large areas of the water surface. The U. S. Weather Bureau records at the nearest station, Green Bay, Wis. and Escanaba, Mich., show that the wind was southwest and not in excess of 6 miles per hour during the night covered by the record. This shows that the small irregularities on the chart were due to variable barometric pressure. Still another record is given in Fig. 44 (*a*). Below it (Fig. 44 (*b*)), for comparison, are shown the high and low tides for Sandy Hook covering the identical period. The similarity of the two graphs is marked. It is difficult to accept a conclusion that denies or seriously questions the existence of sun and moon influences as distinct from atmospheric effects on the tides of the Great Lakes.

The illustration of a "stationary tide" by the slight movement of a basin containing water (Fig. 7), seems especially fortunate if it can be extended to ocean basins and checked with astronomical data. Zenith and tower telescopes disclose a failure to fix position on the earth's surface (the latitude, for instance), closer than a fraction of a second of arc, or less than a horizontal distance of 100 ft. It has long been suspected that the earth quivers a little even at the best sites of observatories, usually on mountain ranges. Various suggested causes have included movements of glacial masses hundreds of square miles in extent in the Antarctic; also work done by man in various localities; but if something must be cited or predicted as the basis of a theory, the rhythmic tidal thrust of enormous volumes of water against the shore lines of ocean basins might be given first place.

Ralph Bennett,* M. Am. Soc. C. E. (by letter).—The importance of the current observations outlined by the author is well illustrated by the present and proposed outfall sewers in the vicinity of Los Angeles, Calif.

The City of Los Angeles now maintains a large sewer which discharges near the mid-point of Santa Monica Bay. In this Bay, there are very feeble and variable tidal currents. The variation due to wind and season is seemingly larger than that due to tide stage.

Under the condition that existed while the old outfall in the same location was operated, most of the floating matter and much raw sewage drifted on the adjacent beaches soon after discharge. As these beaches are extensively used for bathing, the City was compelled to make much more complete provision for screening and diffusion than had been the case in the old sewer.

In the absence of any extended data as to the total flow of water past the discharge point, the new outfall was designed to produce dilution of the sewage by the use of numerous distributed outlets. The operation of the sewer is under the control of the State Board of Health and any serious increase in objectionable matter on the beaches will result in orders to treat the discharge fully and to release only clear, sterile, and odorless effluent.

* Cons. Engr., Los Angeles, Calif.

The adjacent areas in Los Angeles County are quite largely sewered by the County Sanitation Districts which propose to discharge in a somewhat similar way into San Pedro Channel.

At the point of proposed discharge there is a more definite tidal flow than in Santa Monica Bay, but here, again, reliance will be placed largely on deeply submerged outlets in multiple. This location has been bitterly fought and only because of necessity has the State Board of Health permitted the construction. The sewer may ultimately be equipped for full treatment.

If, in either case, a continuous record of the direction and velocity of the ocean currents at the discharge points could be obtained, a great increase in accuracy of design might be made.

This is very noticeable in the outfall sewer of the Sanitation Districts which has been located without scientific aid. If records of the channel currents were available, it is entirely possible that a point of high velocity and seaward discharge could be found, at which a better and yet less expensive outlet could be located.

A fully continuous record is required, however, in such quiet waters as those of Santa Monica Bay. The device should be capable of producing an automatic record of both direction and velocity for a long time without attention.

A similar degree of performance has been attained in the modern curve-tracing gauges. Long-distance wind direction and velocity recorders are in use. A similar long-distance equipment, actuating a shore-located recorder from an anchored vane, deflected by the velocity of the current and swinging with the direction, can certainly be developed if the market demands it. The need is obvious. Cannot the demand be met?

Victor Gelineau,* M. Am. Soc. C. E.—This paper is a valuable and illuminating treatise on a difficult but very real and practical subject. It contains a vast amount of information for engineers whose work extends to tidal waters and who are frequently required to determine the elevations of high or low water. The evaluation of tidal ranges and elevations is a vital requirement in land drainage or reclamation works and in the construction of marine works of every kind, such as navigation canals or channels, basins, wharves, sea-walls and jetties.

The author has treated a subject that has assumed great importance in the State of New Jersey; and one that has taken an advanced position in the administration of its waterways and ocean frontage. Among the activities to which this statement applies are: (*a*) The sale and lease of lands flowed by tide water, the proceeds from which, amounting to many millions of dollars, are by constitutional provision dedicated to the support of free public schools; (*b*) the construction of coast-protection structures on which the State has expended large sums; (*c*) the dredging, wherever necessary, in the improvement of an inland waterway route, approximately 120 miles in length, through the coastal lagoon system from Cape May to the Manasquan River; and, (*d*) the opening or closing of ocean inlets.

* Director and Chf. Engr., New Jersey Board of Commerce and Nav., Jersey City, N. J.

In the sale or lease of riparian lands flowed by tide water, one of the first requirements is the location of the mean high-water line (low-water line in some States) that forms the boundary between State-owned and privately-owned property. Since the right to accretion depends on riparian ownership, that is, adjacency to the limiting line of tide water recognized by the laws of the particular State, property rights of the utmost importance depend on an accurate determination of the shore line; that is, the mean high-water line or other tidal plane recognized by the law. The tide line then is a natural boundary, the position of which determines valuable property rights.

In the design and construction of wharves, bulkheads, jetties, or other water-front structures, the determination of low and high-water elevation constitutes one of the first requirements of design. In works of this nature it is the practice to place wales or stringers and other braces at or near low-water level. Serious disputes may arise over the determination of the low-water plane, especially because the contractor has only a short period during low-water slack tide in which to perform the operations at or near the low-water mark.

In the improvement or extension of waterway channels and the construction of navigation canals, the determination of the plane of reference is the first duty of the engineer. It is the object of improvements of waterways for navigation to provide a minimum depth of water at a given stage of tide, usually local mean low water, to be available when the project is completed.

The elevation of local mean low tide that is established before dredging a channel of relatively large cross-section through a tidal lagoon region, will differ in greater or less degree from the elevation of the mean low-water plane determined after dredging. The engineer must estimate in advance of dredging just how much this disparity will amount to because the enabling legislation or other regulation prescribes the minimum depth to be obtained in the channel after dredging.

This shifting of the low-water and high-water planes, which follows and is a result of the dredging operations, depends on various hydraulic factors. The disparity between the old and the new planes amounts, in some places, to a considerable proportion of the entire mean tidal range. If the dredged channel cuts through reaches of congestion, such as shoals and tortuous minor channels, relatively extensive changes in the tidal regimen of the inland waterway are to be expected.

The establishment of mean low water or other tidal datum planes is effected usually by one of several different methods, as:

(*a*) A relatively short series of comparative readings of tidal swings at the unknown station simultaneous with readings at an established primary tide-gauge station. This method, which disregards any correction factor, requires for applicability a close similarity of tidal regimen at the two stations of comparison.

(*b*) Simultaneous comparisons during a relatively short period of time at the new or unknown station and at the primary or reference station, utilizing

an adjustment factor to correct for dissimilarity in the tidal regimen at the two stations of comparison; this is virtually an adaption of Method (*a*).

(*c*) Continuous independent readings of the tidal oscillations for a sufficiently long period of time.

The choice of methods will depend on many conditions, such as the degree of accuracy to be obtained and the time and equipment available. The chief defect of the method of comparative readings is the fact that the effects of strong winds which modify the tidal swings may not be felt with equal force at the two stations of comparison.

All these methods have been used in the surveys by the New Jersey Board of Commerce and Navigation. The experience gained in these operations has convinced the speaker that whenever practicable the third method, namely, that of independent establishment of tidal planes, should be resorted to frequently and should be applied for each section of waterway that differs appreciably in tidal range from the adjacent station.

Experience in New Jersey has demonstrated that continuous readings of the tidal range for one lunar month may be, and usually are, utterly inadequate for the independent establishment of the mean high or low-water plane at any station. The error in the result will probably exceed the limits permissible in projects to dredge inland waterway channels.

W. M. Black,* M. Am. Soc. C. E. (by letter).—This subject is one of great importance to all engineers engaged in any work affected by tidal action. The paper is opportune and valuable. As stated by the author, the tides of the seas have been the subject of investigation for centuries, and their action is now well known. Tidal action in estuaries and in tidal rivers is not so well understood. The best discussion of tidal action in estuaries, known to the writer, is that of L. Bonnet.†

Due to Commander Rude's well-known reputation as an expert in tidal movements, and his position in the U. S. Coast and Geodetic Survey, his paper must be considered authoritative. However, it contains a few statements which the writer, from the standpoint of an engineer who has had to deal practically with tidal action in estuaries and tidal rivers, deems likely to be misleading.

The theory followed by Commander Rude divides tidal waves into two classes, namely, progressive waves and stationary waves. This classification is not universally accepted. The classification of waves in fluid bodies as given by Bonnet seems to lend itself better to the solution of the problems of tidal action in confined tidal waterways, than that of Harris.‡

According to Bonnet, wave movements may be divided into two great classes: Waves of oscillation and waves of translation. Waves of oscillation are produced when a vertical force, such as the attractions of the heavenly bodies, or the fall of a heavy body, acts on a body of water, producing a

† "Contribution à l'Etude Théorique des fleuves à Marée et Application aux Rivières à Marée du Bassin de l'Escaut Maritime."

‡ "Manual of Tides."

momentary elevation or depression of the surface over a limited area. These waves have the characteristics of the progressive tidal waves described by the author.

Waves of oscillation may be periodic or ordinary. Periodic waves follow each other as ordinary waves, but the periodicity of movement follows periodicity of action, each action causing the formation of a wave. Ordinary waves are those produced by a force which acts once, or at irregular intervals.

The tidal wave of the ocean is a periodic wave of oscillation. Waves formed by a stone falling into water are ordinary waves of oscillation. These waves may be divided into two other classes: Those which seem to travel along the surface of the water, named in French, "ondes houlouses", which may be translated into English as "swells"; and those which seem to remain in one place, "ondes clapoteuses", for which the word "chops" seems the best English equivalent. The "chop" is formed in liquid masses confined by walls. Under such conditions a "swell" is reflected from the walls, with the angle of incidence approximately equal to the angle of departure and with the direction of propagation reversed. It superposes itself on the direct wave. The "swell" is the natural movement in open and deep seas when perturbing influences are negligible in amount, while the "chop" is formed in confined waters, such as rivers and small lakes.

If a force acts horizontally on a liquid mass, a wave of translation is formed. This is propagated above or below the original water surface. In the first case, it is termed positive; in the second, negative.

Positive waves of translation were first investigated by Scott Russell.* They are formed in a channel by a rapid elevation of the water surface, as manifested down stream by the opening of a movable dam, or in advance of a moving canal-boat. The forward movement of a flood crest in the Mississippi, in advance of the waters causing the flood, is another example. Negative waves are produced by the rapid creation of a depression in a liquid mass, as in the upper pool of a canalized river by opening a movable dam.

The distinction between waves of oscillation and waves of translation is of importance to engineers. In the former class, slack-water, which marks the change of current direction, occurs nearly midway between high and low water; in the latter class, it occurs at or close to high and low water. The tidal waves of estuaries and tidal rivers of the United States at the entrance are generally waves of oscillation which gradually change into waves of translation in their course toward the limit of tidal action. If it is desired to control only an ebb current at any point, and this current is produced at that point by a wave of oscillation, it is evident that the training wall need only be built to about the level of mid-tide, while if the tidal wave at that point is a wave of translation, the work must be built to high-water level.

A wave is formed through the expenditure of energy from some source, and once formed, it must continue until its energy is exhausted. The energy

* "Wave Action in Relation to Engineering Structures," Gaillard, p. 23.

of a wave is measured by the work it can do in coming to rest. The total energy comprises the potential energy due to height and the kinetic energy, or half the living force, due to the velocities of its fluid molecules. The energy of a wave of oscillation in deep water has been shown to be approximately equal to the product of the liquid mass contained in the orbit of the surface molecules by the square of the velocity of propagation of the wave.

In open and deep waters, when resistances due to friction and obstructions may be disregarded, the theoretical velocity of wave propagation approaches closely to the true velocity. This theoretical velocity is given by the formula, $v = \sqrt{g\,h}$, in which, v equals the velocity of propagation; g is the acceleration due to gravity (32.17 ft. per sec.); and h is the depth, in feet. In shallow and crooked channels this formula does not give results sufficiently accurate to be of great value to an engineer.

When a wave of oscillation approaches a coast obliquely from the open sea, the end of the wave nearest the shore is retarded by the shoaling waters, while the other end continues to advance with its original velocity. Waves thus seem to swing toward the coast line. When such a wave is propagated through a broad channel, deep in the middle, and with shoal areas along the sides, the same phenomenon is observed.

When a wave enters a widely opened mouth of a bay normally, the two extremities nearest the shores, where the water is shoal, advance more slowly than the central portion. The wave then extends into a fan-shape which becomes more marked as it progresses into the bay. In a funnel-shaped bay, with its mouth seaward and with decreasing depths landward, waves entering are shortened and become higher and higher. On the contrary, when waves enter a broad, shoal bay through a narrow channel, they become longer and diminish in height.

In estuaries and tidal rivers, the tidal wave is due to the ocean tidal wave at the mouth. After entrance, the wave is acted on by the forces which produced the ocean wave, very slightly, if at all. The energy of an estuary, or river, tidal wave at the entrance is that of the incoming ocean wave. After entrance the energy gradually is exhausted by the work of friction on the bottom, and by the resistances caused by bends or obstructions in the channel. Since this tidal energy is the source of the currents by which the navigable channels are maintained, it is the task of an engineer engaged in the formation and maintenance of such channels to see that the works constructed by him are such as will conserve this tidal energy as much as possible, for the benefit of the parts of the waterway lying beyond; and, further, to see that he does not make undue demands on the energy available by forming channels with dimensions too great for it to maintain, or by obstructing, unduly, the free passage of the wave.

Commander Rude mentions the increase of the range (and, therefore, of the energy) of the tidal wave of New York Harbor due to the opening of the Ambrose Channel across the outer bar. He shows also the effect on the Delaware River tidal wave of the work done in the channel of the Delaware River below Philadelphia, Pa., but above the entrance channels to the river, as con-

trasted with the effect at Trenton, N. J. A similar change in the tidal range of the Hudson at Troy, N. Y., resulted from the enlargement of the channel between Troy and Hudson, N. Y. In 1876, the tidal range at Troy was 0.8 ft., with the mean low-water plane 3.43 ft. above the Barge Canal datum. In 1910, the range was 2.06 ft. with the mean low-water plane 2.2 ft. above the same datum.

The writer is in hearty agreement with the statement that,

"A fertile field remains open for the engineer in a study of the changes in the tidal regimen in an estuary or in a river resulting from changes in topography and depth in harbor and river improvements, in order that dependable quantitative predictions may be made for proposed projects."

Commander Rude's paper, as well as other papers by officials of the U. S. Coast and Geodetic Survey, give clear statements of current action in estuaries under the physical conditions which existed when the investigations were made, and when data are available, of tidal changes following changes in channel dimensions; but they do not attempt to state what changes would occur in the velocity of wave propagation, in the tidal range, and in the currents produced by the tidal wave action if extensive changes should be made in the physical conditions of the channel by works of river and harbor improvement. It is of maximum interest to engineers engaged in such works to know what such changes would be. In so far as is known to the writer, M. Bonnet is the only engineer who has gone into this subject extensively. He has been able to deduce formulas by which can be predicted the effect of physical changes in channel dimensions of the Scheldt River on the tidal action in that river.

In restricted tidal waterways, the tidal wave is always propagated at a velocity which is greater than the velocity of the currents produced by the wave. In such waterways the character of the wave frequently changes in its course from the entrance to the upper limit of tidal action. In the Hudson River, for example, the tidal wave when passing the Battery, in New York City, has the characteristics of a wave of oscillation, with the ebb slack-water occurring about midway between low and high water. As the wave progresses up the Hudson, the times of slack-water approach more and more closely to the times of high and low water, until above the City of Hudson, the times of slack-water coincide with the times of high and low water, a flood current beginning at low water. The wave there has the characteristics of the progressive type (Bonnet's nomenclature). The same is true in the East River where the wave of oscillation entering at the Battery becomes transformed into a progressive wave between the Brooklyn Bridge and Blackwells Island.

Bonnet states with truth that it is not easy to define, offhand, the exact nature of a river tidal wave, "for it is one of the most complex of the phenomena of river hydraulics." He gives the following theory to account for the formation of river tidal currents.*

* "Fleuves à Marées," Bonnet, Pt. II, Chapter II.

At the instant of low water at the mouth the portion of the wave in advance which is in the river, or the entire wave in advance as is the case in the Amazon and St. Lawrence, has a certain discharge toward the sea which is a function of the resistances of the watercourse and of the volume of flow from above.

The ebb current thus formed is increased, as the tide rises, by the volume of water left behind by the portion of the new wave advancing in the river; at the same time, this new wave itself tends to produce an up-stream current, which tendency is continuously augmented and finally neutralizes the counter down-stream current completely. At this instant, low-water slack occurs. When the manner in which this slack is produced is considered, it is seen that it must always take place when the tide is rising, even when there is no discharge from up stream. The length of the period which elapses between the time of low water and the time of ebb slack will depend on the resistances offered by the river channel and on the volume of the fresh-water discharge. After the time of ebb (low-water) slack, the counter (down-stream) current is less powerful than the current of the tidal wave, so that the resulting velocity is a flood (up-stream) velocity.

This phase of the tidal action persists until the volume of water left behind by the tidal wave in a unit of time, added to the fresh-water discharge, becomes again equal to the up-stream flow produced by the tidal wave. At this instant there is produced a new slack-water, known as flood (high-water) slack. The position of this slack with respect to high water, is no more definitely fixed than is that of low-water slack with respect to low water; but observations made on the Scheldt and its tidal tributaries show that high-water slack is always found after high water, except in the upper reaches of the tidal rivers, where, under the influence of the fresh-water discharge, the flood slack precedes high water. Close to the limit of tidal action a reach is found where the flood slack coincides with the ebb slack. Above this point, nothing but an ebb current is found, and the rise of tide is caused entirely by water from up stream.

These conclusions are the same as those reached by Van Brabant in his note on the changes of current in the river tidal wave.* After flood slack, the sections of the tidal wave growing smaller and smaller, the flow of the counter current is greater than that of the tidal wave; so that an ebb current prevails in the river. This phase of the tide persists until the subsequent ebb slack, after which a new cycle begins. The existence of a counter current explains the abnormal reduction of the velocity of propagation of the river wave and the rising of the mean level of the river in an up-stream direction.

To summarize, it can be stated that the river tide is a resultant of the combined action of a tidal wave, which goes up the course of the river, and of a return current, which is formed as the effect of the work of the river-channel resistances and of the fresh-water discharge.

* "Fleuves à Marées," Bonnet, Pt. III, Chapter II.

M. Bonnet makes a mathematical analysis of the effects of the frictional resistances encountered on the energy of a unit length of a tidal wave advancing up the river, and deduces formulas by which the tidal action in the Scheldt can be found. These formulas contain certain constants, the values of which vary for different streams, being dependent on the physical features of the river beds, which values must be determined by observation for each tidal stream.

It is to be hoped that future investigation will show the relation between these constants and the physical conditions of the tidal channel clearly enough to enable formulas to be deduced which will have a general application.

With reference to the practical application of the formulas to the problems of the improvement of any tidal stream, the writer agrees with M. Bonnet that:*

"When a project for the improvement of a tidal river is being prepared, the first task to be accomplished is the study of a mean tide of the river by means of direct observations and the computation of volumes. This preliminary study will give accurate data on the high tide cross-sections, the mean depths at mid-tide, the tidal ranges, the volumes of the flood currents, the fresh-water discharge, the mean level of the river, the velocities of the propagation of the tidal wave, the velocities of the flood and ebb currents, the periods of tidal rise and fall and of ebb and flood flow; in a word, on all of the important elements which make up the regimen of the river.

"When this preliminary study shall have been made, a possible longitudinal profile of mean depths at low tide can be determined. This profile should be selected so that there may be assured a good tidal propagation, the extinction of the river wave at the limit of tidal action in the river, the safe discharge of freshets, and the navigable capacity desired. Generally, the selection of the series of proper mid-tide mean depths will be a simple matter, since the river in its natural state gives sufficiently exact indications in its good and bad reaches of the depths to be preserved or to be modified."

From the foregoing, one of the river tide phenomena, which for a long time puzzled the writer, can be understood readily; that is, how the changes of direction of the tidal currents occur. In the Hudson, the tidal wave is more than 100 miles long, and the waves follow each other at intervals of about 12 hours, but the ebb and flood currents have a movement of only 10 to 15 miles before they change. The description of tidal wave action previously given shows that the ebb and flood slack waters, which mark the times of the changes in current direction, occur at definite periods after low and high water. As the wave progresses up a river, the slack-water phases arrive successively from point to point, so that an ebb or a flood current starts at successive points. The slack-water phases succeed each other at intervals of from 4 to 7 hours, the periods of ebb flow being the longer. At the end of each period, at each point along the river, the current direction is reversed. Since the current velocities are usually less than 2.5 miles per hour, the total distance through which a float will be moved by the current is from 10 to 15 miles. Such a float, started near the head of tidal action, will pass down the

* "Fleuves à Marées," Bonnet, Pt. IV, Chapter I.

river with the first ebb; will return to within a few miles of its starting point with the following flood; will then again start down the river; and thus gradually, after many tides, will reach the sea.

While, in a tidal waterway, for long reaches the longitudinal profile of mid-tide levels is approximately a straight line, the longitudinal profiles of the local mean high and mean low-water levels are irregular curves, as indicated in Fig. 22. This shows the necessity for establishing tide gauges as reference points at comparatively short intervals along a waterway, for the reduction of soundings in hydrographic surveying. Otherwise, true mean low-water depths cannot be found. Another phenomenon frequently found in such waterways is that at certain points, during certain phases of the tide, the surface slope of the water is up, measured in the direction of current flow; or, in other words, the water seems to flow up hill.

Referring again to Fig. 22, in his study of the Hudson River, the writer found that the longitudinal profile of mid-tide levels was formed approximately by three straight lines. Starting from the Battery, at New York, the profile had but a slight inclination upward until above Spuyten Duyvil, where a break occurred and the inclination from the horizontal became slightly greater. Thence, to a point above Hudson, the profile was a straight line. Another break occurred at this point, and thence to Albany, the inclination up from the horizontal was markedly increased. In the writer's judgment, the break above Hudson marks the change from estuary to tidal river conditions.

In the course of his duties the writer has had occasion to study the data available on the tidal action and the resulting currents in the Cape Cod Canal and to make a careful survey and study of the complicated tidal conditions at Hell Gate in the East River, New York. An analysis of conditions in the Cape Cod Canal as they existed shortly after the Canal had been opened, has been published.* The surveying methods used at Hell Gate, and the conclusions of the writer have also been published.†

The writer's experience with respect to currents formed in a narrow strait which connects two larger bodies of tidal water, is in agreement with that of Colonel Brown, as given in his discussion. Commander Rude's statement that, "The movement of the water is largely hydraulic in character," is incorrect if it means that the laws governing the ordinary flow of water in open channels are applicable in making predictions as to the effect of changes which will result in the currents of a channel connecting two bodies of tidal water, when the length, curvature, and dimensions of that channel are changed. From the standpoint of an engineer, the term used by Commander Rude is so broad as to be misleading. The hydraulic character of the movement through Hell Gate is the effect of tidal actions. To be able to modify this movement in the interest of navigation, an engineer must seek the cause.

* "The Cape Cod Canal," by William Barclay Parsons, Hon. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1.

† H. R. Doc. 188, 63d Cong., 1st Sess., "Survey of East River and Little Hell Gate, New York, and Resurvey of Hell Gate"; also, *The Military Engineer*, Vol. XVIII, July-Aug., 1926, p. 266, "Needed Harbor Improvement."

The writer is convinced that the conditions at Hell Gate are the result of the combined action there of two tidal waves, one reaching that point through Long Island Sound and one through Lower and Upper New York Bays and the East River. The rates of propagation and the progress of each wave can be traced clearly from the Tide Tables of the U. S. Coast and Geodetic Survey as far as Hunt's Point on the north and the north end of Blackwells Island on the south. Between these two points the evidence given in the Tide Tables is not so clear. From these as well as from the Current Tables published by the U. S. Coast and Geodetic Survey, it is seen that the rates of propagation of the tidal waves are greater than the velocities of the tidal currents produced by the waves, until Hell Gate is attained. The onward movements of the waves do not cease when these points are reached, since the tidal curves show that their energies had not then become exhausted. Tidal curves taken between Hunt's Point and the north end of Blackwells Island show clearly the superposition of the waves, and that they do meet in, and north of, Hell Gate. Other evidences of this action could be named.*

This question is of more than passing importance to an engineer. If the currents in Hell Gate are purely hydraulic in character, it would follow that an increase in the dimensions of the cross-sections of the connecting channels in Hell Gate would reduce friction and cause increased velocities. If, on the other hand, wave action does exist between the limits named, such action would cause, first of all, a change of "head" between the two points, by permitting a freer propagation of the waves, with a corresponding effect on the velocity of the currents.

An analysis of the tidal wave movements in the East River, more detailed than has yet been made, will be necessary before it is possible to predict with even approximate accuracy how, and to what extent, an increase in the dimensions and curvatures of the three channels at Hell Gate, and of the two channels to the south will change the rate and amount of tidal wave propagation, the surface slopes, and the currents in that vicinity.

Bonnet's theory of the action of a river tidal wave, and his method of analysis of tidal conditions, if followed, would throw great light on the problem of the reduction of the rapid currents in Hell Gate, a problem of primary importance for New York and the nation. A similar necessity exists for the further study of the tidal action in the other tidal waterways of the United States.

Francisco J. Gaston,† M. Am. Soc. C. E. (by letter).—This paper is most interesting and valuable. The whole world is indebted to the U. S. Coast and Geodetic Survey for its authoritative information about tides and currents.

The problem of determining the mean sea level, or mean low tide, is one that often confronts engineers, and they are not always fortunate enough, in many countries, to be able to obtain ready-made information from a reliable authority, such as the U. S. Coast and Geodetic Survey.

* See *Special Publication III*, U. S. Coast and Geodetic Survey, "Tides and Currents in New York Harbor," by H. A. Marmer, p. 77.

† Engr., River and Harbor Impvts., Dept. of Public Works, Havana, Cuba.

In preparing for an extensive final sounding, preliminary to an important dredging project in Isabela de Sagua Harbor on the northern coast of Cuba, the writer was confronted with the task of determining, in the shortest possible time, the plane of mean low tide. The datum, once selected, was to be accepted as final, for all sounding, for contract work, and for final measurements.

As no local information worth having was obtainable, mean low water during a month was found, and a correction introduced for that particular month. This was the zero or datum finally accepted for the work, and it proved to be (by a fortunate coincidence) the almost exact mean low tide for a series of years.

This matter of taking into account the monthly or seasonal variation of the level of the sea to obtain a mean of the whole year, received considerable attention. A record of tides and other meteorological information was started by the writer in 1911 and was continued under his supervision until the end of 1918. The record showed, since its beginning, the relative importance of monthly variation, on Cuban coasts, as compared with the mean range of tides. The mean low tide in January, 1912, was 0.33 m. (1.1 ft.) lower than the mean low tide in September of the same year. The mean range in Isabela de Sagua is 0.48 m. (1.6 ft.), so that the relative importance of the monthly variation is patent.

There is reason to believe that the same monthly variation occurs in Havana Harbor, where the mean range is only 0.28 m. (0.9 ft.). It is possible, therefore, that two independent observers, one in January and the other in September or October, may obtain results for the same tidal plane, which differ by 1 ft., or more; or that one observer may obtain, in a month, a mean high tide lower than the other observer has obtained in another month for a mean low tide. The year 1912 was extreme in that respect, the average of the eight years of observation giving 0.08 m. (0.26 ft.) below the mean of the year, in January, and 0.09 m. (0.30 ft.) above the mean of the year, in September and October.

The information obtained gave rise to a rule for determining the mean sea level, or mean low tide, which was to determine the average during a whole month and to apply to that value a correction, positive or negative, equal to the variation from the zero obtained in the same month at the Port of Havana, or the Port of Isabela de Sagua. If no observations were obtained from those standard ports (as is now unfortunately the case), a correction was to be applied, according to the month in which the observations were taken.

The Department of Public Works, at present (1927) building the Central Highway of the Island, a modern road 700 miles long, has announced that it will establish bench-marks, referred to mean sea level, on each kilometer post.

In the paper by Commander Rude, reference is made to this monthly or seasonal variation and the diagram (Fig. 19), giving the monthly means at Fort Hamilton, N. Y., from 1900 to 1909, inclusive, shows it plainly. The author states: "Sea level as determined by a series of observations extending over only a month may differ as much as 1 ft. or more from that determined by another month". This covers very well the experience obtained at Isabela de Sagua.

The further statement that: "For practical purposes a tidal plane obtained from a month of observations may be considered as fairly well determined", is not in contradiction with the other because it all depends on what is considered sufficient for practical purposes; but if taken separately, it may be misleading. Engineers basing their work on that authoritative source will continue to determine mean sea level or mean low tide from a month of observations and will believe they are "practical", leaving any further observations or corrections to the "theoretical" man.

The conclusion seems to be offered from the text that those monthly variations, although not always unimportant, cannot be determined on account of being due to differences of atmospheric pressure. The atmospheric pressure was determined with sufficient accuracy at Isabela de Sagua, and the diagram showing its mean monthly variation resembles, although in the opposite sense, that of the tidal planes. The highest pressure in January corresponds to the lowest level of the sea in that month and the lowest pressure in September and October corresponds to the highest level of the sea in those months. Further studies could not be made because exceptional months in the mean sea level could not be related to exceptional months in the atmospheric pressure, and thus no correction could be established for the mean sea level depending on the mean barometric pressure during the time of observations.

However, if the mean monthly variation of the sea level, depends on the difference of atmospheric pressure, this, in its turn, on account of its known regularity, must depend on some astronomical cause; and as such it is within the scope of the scientist. It is no doubt included in some of the elementary constituent tides, of yearly and semi-yearly periods, which are summed up in the wonderful tide-predicting machine of the U. S. Coast and Geodetic Survey.

Wind observations were made at the same time, in Isabela de Sagua, and were given considerable attention, both as to intensity and direction. Diagrams were thus obtained showing the average prevailing winds in each month.

This information about the wind is considered very interesting in harbor work. It may even show, in what month or season of the year, in a partly exposed location, it is advisable to proceed or to stop dredging or other harbor work. It also gives information about the best time of the year for soundings, with results that are sometimes contrary to popular belief.

Observations on atmospheric pressure, rain, and temperature were also made simultaneously.* These are subjects which also have their engineering aspects.

F. W. Scheidenhelm,† M. Am. Soc. C. E.—The respect which the speaker has had for the work of the U. S. Coast and Geodetic Survey has not been diminished in the least by this paper. Indeed it has been broadened to include

* The tabulated values and a general graphic of all the information referred to, have been published under the title, "Observaciones Mareográficas y Meteorologicas en el Puerto de Isabela de Sagua" ("Mareographical and Meteorological Observations at the Port of Isabela de Sagua"), in *Revista* de la Sociedad Cubana de Ingenieros, Sección de Obras Públicas, Vol. XI, (1919), September, October, November, and December. An article by the writer, with explanations and comments on the same, entitled "El Estudio de las Mareas y los Vientos en relación con las Obras de Puertos" ("The Study of Tides and Winds in Connection with Harbor Work") was published in *Revista* de la Sociedad Cubana de Ingenieros, Vol. XVII (1925), March–April.

† Cons. Engr. (Mead & Scheidenhelm), New York, N. Y.

the well-nigh human tide-predicting machine devised and designed by the engineers of the Survey.

The speaker is especially interested in the engineering aspects of tides as they affect water-power development. Much has been said and written about the proposed development of tidal power in the Bay of Fundy, and in regard thereto the speaker joins in marveling at the courage, and likewise the optimism, of those who seek to curb and utilize those tides for the generation of hydro-electric power on a mammoth scale. He has in mind, not the generation of power by means of tides, but rather the effect of tides on the more usual type of water-power development along streams.

At St. John, the principal city and seaport of the Province of New Brunswick, Canada, located on the Bay of Fundy, the outstanding natural attraction is the so-called "Reversible Falls" at the mouth of the St. John River. That river drains about 26 000 sq. miles and hence under ordinary circumstances would afford an attractive opportunity for the development of water power at the Falls. However, the foot of the Falls is practically at low tide, and, despite the fact that at times a fall of perhaps 12 ft. is apparent, the tides of the Bay of Fundy of about 20 ft. completely submerge the Falls at high tide. Indeed, the flow is then actually up stream, sometimes to a depth of about 12 ft. over the crest of the falls. For a period of less than an hour, at high slack tide, ships can pass from St. John Harbor over the falls up into the river.

This condition makes it apparent why the Falls by themselves are not suitable for the development of hydro-electric power. However, inasmuch as the development of tidal power in the ordinary sense involves shifting the means of development according to the ebb or flow of the tide, it may not involve too great a flight of the imagination to conceive that at some future time the Reversible Falls at St. John may be called upon to function in the generation of power for a part of each 24-hour period, with corresponding reliance placed upon some other source of power generation during periods of partial and complete submersion of the Falls.

In passing, it may be noted that the tidal fluctuations of the Bay of Fundy take place to the full extent in the Harbor of St. John and give rise to problems affecting harbor construction, the use of docks, and the handling of shipping. These problems have many interesting and difficult phases. The situation may be the better understood if one will visualize the fact that at high tide a vessel alongside a dock rides about 20 ft. higher than at low tide.

The speaker has had occasion to investigate the Provincial development (by the New Brunswick Electric Power Commission) of the power of the Musquash River, which empties into the Bay of Fundy about 15 miles west of the City of St. John. Inasmuch as the power station is located close to sea level, the great tides of the Bay play an important part. They affect the power-station tail-water for about 15 hours of each day. The power project really consists of twin developments, in each of which an intake reservoir is connected by a wood-stave pressure pipe to the power station. The twin developments operate under average effective heads of about 100 ft. and 120 ft., respectively, and the sources of water supply are not interchangeable.

In the usual type of water-power development the head is at a minimum during flood periods. In the case of the Musquash, however, the heads, so far as tail-water is concerned, are at a minimum at high tide. Naturally, it is the spring tides, as described by the author, that are the most serious in this respect. At times, the spring tide at St. John attains at least 28 ft., or about 8 ft. in excess of the relatively high normal tides.

When a spring tide coincides with a depleted condition of an intake reservoir, it follows that there will be reduction of head both at the head-water and at the tail-water. In order to maintain the turbine output at approximately normal capacity, it would be necessary to utilize greater water supply with correspondingly greater velocity of flow through the pipe line. This, in turn, causes greater friction loss and, consequently, further loss in energy.

So far as the reduction due to tides is concerned, conditions may be further aggravated if the wind should happen to be in the proper direction to heap up the tide still more. Indeed, it is not impossible that the combination of the several tidal components may result in increasing all tides, spring as well as normal, in their travel up the Musquash Estuary at the head of which the power station is located. As concerns the Musquash water-power development, it seems fortunate that it is the east and not the west side of the Bay of Fundy that has the 5-ft. higher tides. Another interesting phase of the Musquash situation is that, during the period of tidal records to which the speaker had access, there appeared to be no instance of an extreme spring tide occurring between 4:00 and 6:00 P. M. These are the hours of coincidence of industrial demand for power with the needs of power for early evening lighting during the autumn and winter, and thus they constitute the period of maximum demand on the power station. It may be, therefore, that, during that critical period of the day, the power station may be spared the reduction of its head due to the full extent of the maximum spring tides. As to whether or why maximum spring tides never occur during that period of the day, the speaker has no knowledge, nor did his inquiries meet with any satisfactory answer.

Charles H. Lee,* and Harold F. Gray,† Members, Am. Soc. C. E. (by letter).—The writers have been especially interested in the flow of tidal currents in estuaries and bays. In connection with the question of sewage pollution they have had to determine the rates of discharge and volumetric renewal of water in the tidal canal known as the Oakland Estuary lying between the Cities of Oakland and Alameda, Calif.

Description of Conditions.—Referring to Fig. 45, the estuary is seen to extend as a dredged channel from San Francisco Bay at its northwestern end, between the Southern Pacific (Alameda) and the Western Pacific Railway moles, to San Leandro Bay at its southeastern end. San Leandro Bay is a shallow body of salt water, much of its area being mud flats at low tide. It has a southerly opening into San Francisco Bay between Alameda and Bay Farm Island.

* Cons. Hydr. Engr., San Francisco, Calif.
† San. and Hydr. Engr., Berkeley, Calif.

FIG. 45.—OAKLAND ESTUARY, OAKLAND, CALIF.

The level of water in the Estuary is promptly affected by tide-level changes in San Francisco Bay, and strong currents occur during each ebb and flow period. The filling and emptying of the tidal prism in San Leandro Bay largely results from tidal flow through the estuary. The tidal currents at the San Francisco Bay outlet of San Leandro Bay (at Bay Farm Island Bridge) are seldom strong, and are inward more than 75% of the time. Outward flow occurs at irregular intervals and during four to six hours each day, being controlled by the relative levels of San Francisco and San Leandro Bays at the Bay Farm Island Bridge. These relative levels depend, in turn, on the filling or emptying of San Leandro Bay through the tidal canal of the Oakland Estuary.

At present, about one-half the sewage of the City of Oakland, and most of the sewage of the City of Alameda, discharges into the Oakland Estuary. The problem was to determine the probable future date at which the quantity of sewage discharged therein would be so great as to exceed the safe dilution capacity of the Estuary water.

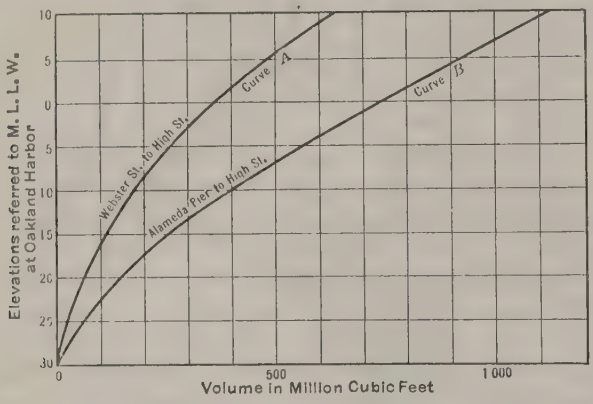

FIG. 46.—CAPACITY-TIDE ELEVATION CURVES, OAKLAND ESTUARY.

The total volume of water in the Estuary for various tide stages between the end of the Alameda Pier and the High Street Bridge, and between the High Street and Webster Street Bridges, was determined by computations from cross-sections furnished by the Corps of Engineers, U. S. Army (First San Francisco District). Curves showing such tide stage-volume relationships are presented in Fig. 46. Tidal discharges were obtained by measurements with current meters at the High Street Bridge for various ranges of tide. Check measurements were made during the first set of observations by simultaneous current-meter gaugings at the Webster Street Bridge. Velocity measurements by means of rod floats (weighted lath) were also made at Bay Farm Island Bridge (where the velocities were too low to be measured by current meters), and tide stages and current directions were observed at all four stations.

Program of Observations.—Careful soundings were first made at the High Street, Webster Street, and Bay Farm Island Bridges to determine the cross-

sections and to designate the current-meter stations for both incoming and outgoing tides. Staff gauges were set at these bridges and illuminated so as to be easily read at night. An automatic water-stage recorder was set at the end of the Alameda Pier.

Preliminary to the actual gaugings, the tide gauges were observed for several days to determine whether there were any marked peculiarities of flow to be considered. Current directions under the bridges were observed by suspending the meter in the water and measuring the angle between the bridge rail and the tail of the meter. At the High Street Bridge the direction of flow was at a marked angle, and this had to be taken into account in the computations.

The results of the first set of measurements indicated that discharge measurements at the High Street Bridge would give all necessary information, and check measurements at the other bridges, therefore, were not made at the times of subsequent observations.

The first set of discharge measurements was made on August 12 and 13, 1927, when a large tidal range was anticipated. The following schedule was observed:

1.—An observer was stationed at Alameda Pier to note the times of change of current direction.
2.—An hydrographer and assistant were stationed at the Webster Street Bridge, with a current meter.
3.—An hydrographer and assistant were stationed at the High Street Bridge, with a current meter.
4.—An observer with two assistants was stationed at the Bay Farm Island Bridge, to measure velocities by means of rod floats (weighted lath).

Continuous tide-gauge observations were made, and discharge measurements were repeated as frequently as possible during the tidal runs. There were numerous interruptions due to openings of the draw-spans at the Webster Street and High Street Bridges. The observations covered a tidal range of 5.0 ft. on the incoming tide from high low water to high high water on the afternoon and evening of August 12, and a tidal range of 8.4 ft. on the outgoing tide from high high water on the evening of August 12 to low low water on the morning of August 13. The results of these discharge measurements were plotted against time, and the total discharge for each tidal run was determined graphically (see Fig. 47(*a*)).

The total discharges as thus measured and computed at the Webster Street and High Street Bridges were then compared with the results computed from the formula,

$$Q_1 = (V_1 - V_2) + Q_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which,

Q_1 = volume passing Webster Street Bridge, or Alameda Pier, according to purpose of calculation;
Q_2 = volume passing High Street Bridge;
V_1 = volume in Estuary between bridges at higher tide stage; and
V_2 = volume in Estuary between bridges at lower tide stage.

For the incoming tide on August 12,

$$Q_2 = 121\,000\,000 \text{ cu. ft. (measured)}$$
$$V_1 - V_2 = 106\,565\,000 \text{ " "}$$

$$Q_1 = 227\,565\,000 \text{ " " (computed)}$$
$$Q_1 = 228\,000\,000 \text{ " " (measured)}$$

For the outgoing tide on August 12-13,

$$Q_2 = 197\,800\,000 \text{ cu. ft. (measured)}$$
$$V_1 - V_2 = 173\,152\,000 \text{ " "}$$

$$Q_1 = 370\,952\,000 \text{ " " (computed)}$$
$$Q_1 = 368\,000\,000 \text{ " " (measured)}$$

As the agreement between the measurements and the computed values at the Webster Street and High Street Bridges were thus reasonably close, subsequent measurements of flow were made at the High Street Bridge only.

The discharge curves for subsequent observations made on September 6 and October 4, 1927, are shown in Fig. 47 (*b*). The tide range on August 12 and 13 was large; that on September 6 was intermediate; and that on October 4 was small.

The total discharges for these tide runs of varying range as obtained from Fig. 47 are shown on Fig. 48. The plotted points indicate a direct relation between tidal range and discharge, as shown by the straight line. At low ranges the tidal flow west at High Street Bridge for the same tidal range is somewhat erratic. This is probably due to hydraulic conditions in San Leandro Bay, which has a flow out into San Francisco Bay only at short and irregular intervals. It is probable that this condition assumes importance only at small tide ranges. In view of its irregular occurrence it has been neglected in this investigation.

The inflow through the Alameda Pier entrance was the only one considered to be of immediate concern, for the reason that dissolved oxygen tests on the ebb flow from San Leandro Bay into the Estuary showed a depletion of about 50% below saturation. The water coming from San Leandro Bay and flowing down the Estuary on the ebb tide is, therefore, so depleted in oxygen that for practical purposes it cannot be considered as "new" water available for sewage dilution. For the calculation of replacement percentages, only the incoming water from San Francisco Bay at the Alameda Pier entrance, which is constantly at or close to oxygen saturation, should be considered.

Having determined the tide stage-discharge relationship for the High Street Bridge, as shown on Fig. 48, and having the tide stage-volume relationship as shown on Fig. 46, it is possible to determine the total tidal flow in the Estuary for any tidal run by means of Equation (1).

The critical period with respect to sewage dilution will occur when the tidal flow is the least, and during that period when the sewage has the greatest total oxygen demand. The latter condition occurs annually in September when the canneries are in operation and the temperatures are generally the

highest. The former condition occurs approximately once a month. For the purpose of this discussion only the condition of minimum tidal flow will be considered.

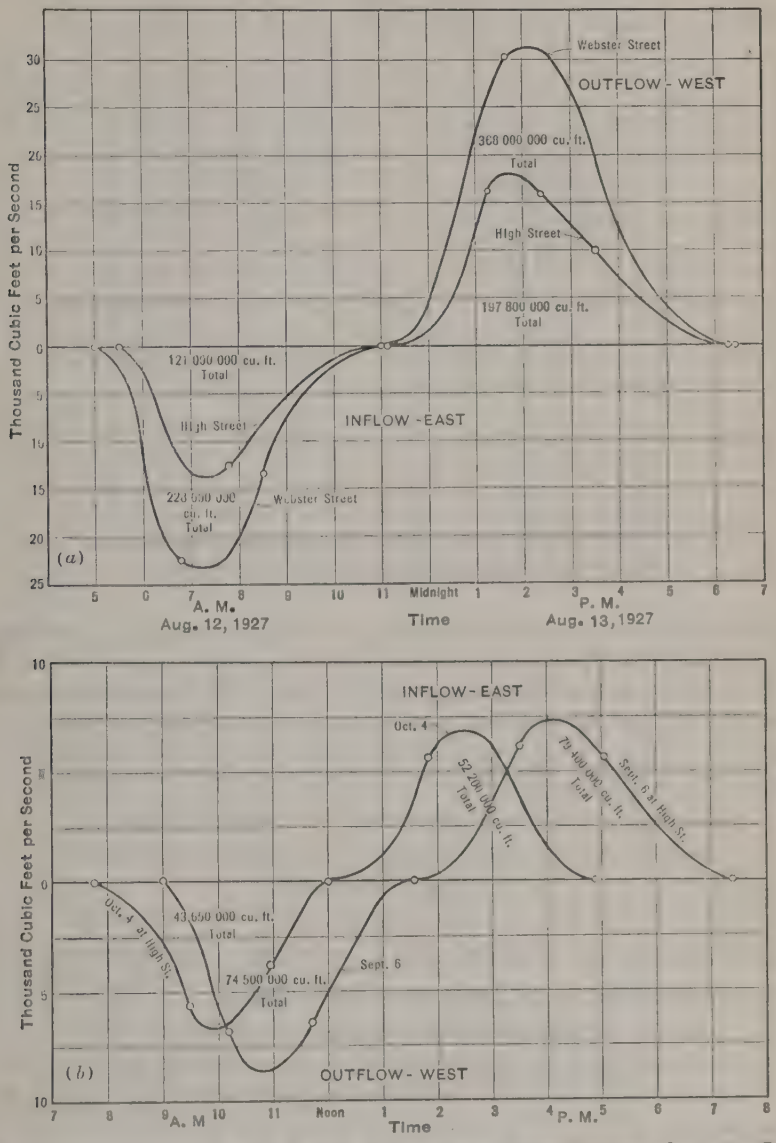

FIG. 47.—TIDAL FLOWS AT HIGH STREET AND WEBSTER STREET BRIDGES, OAKLAND, CALIF.

Excluding from consideration the ebb flow, it is apparent that the minimum inflow into the Estuary will occur when the sum of the ranges of the two incoming tides each day is the least. An examination of the tide tables shows

such a minimum range on September 2 and 3, 1927, as an example. These ranges at the Fort Point standard station for San Francisco Bay are as follows:

High low water to high high water.. 2.9 ft. to 4.9 ft. = 2.0 ft.
Low low water to low high water... 1.5 ft. to 3.8 ft. = 2.3 ft.

Total..... = 4.3 ft.

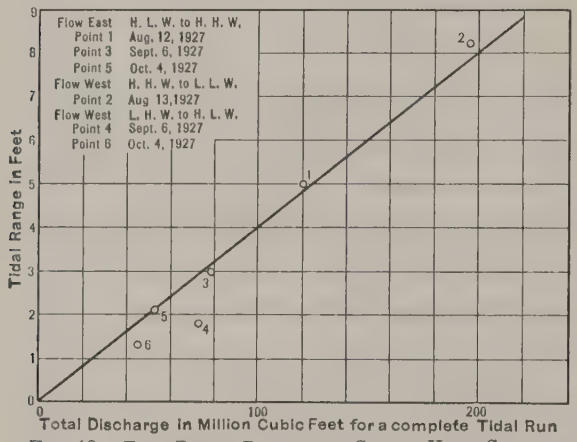

FIG. 48.—TIDE RANGE-DISCHARGE CURVE, HIGH STREET BRIDGE, OAKLAND, CALIF.

The U. S. Coast and Geodetic Survey's factor for tide ranges at Oakland Harbor (Session's Basin) is 1.22, to be applied to the ranges at the Fort Point standard station. Applying this factor to the ranges given, there results 2.4 ft. and 2.8 ft., respectively, or a total of 5.2 ft. Using these values and taking off corresponding discharge and volume quantities from Figs. 46 and 48, for high low water to high high water, 2.4-ft. range,

$$\text{At } (4.9 \times 1.22) = 6.0\text{-ft. stage, } V_1 = 955\,000\,000 \text{ cu. ft.}$$
$$\text{At } (2.9 \times 1.22) = 3.5\text{-ft. stage, } V_2 = 865\,000\,000 \text{ cu. ft.}$$
$$Q_2 = 60\,000\,000 \text{ cu. ft.}$$

Therefore,

$$Q_1 = (955\,000\,000 - 865\,000\,000) + 60\,000\,000 = 150\,000\,000 \text{ cu. ft.}$$

For low low water to low high water, 2.8 ft. range,

$$\text{At } (3.8 \times 1.22) = 4.6\text{-ft. stage, } V_1 = 905\,000\,000 \text{ cu. ft.}$$
$$\text{At } (1.5 \times 1.22) = 1.8\text{-ft. stage, } V_2 = 805\,000\,000 \text{ cu. ft.}$$
$$Q_2 = 70\,000\,000 \text{ cu. ft.}$$

Therefore,

$$Q_1 = (905\,000\,000 - 805\,000\,000) + 70\,000\,000 = 170\,000\,000 \text{ cu. ft.}$$

The total inflow at Alameda Pier will then be the sum of the two values of Q_1, or,

$$150\,000\,000 + 170\,000\,000 = 320\,000\,000 \text{ cu. ft.}$$

The volume of water in the Estuary between Alameda Pier and High Street Bridge at mean sea level is 863 000 000 cu. ft. Therefore, the approximate percentage of new water entering at Alameda Pier is,

$$\frac{320\ 000\ 000}{863\ 000\ 000} = 37$$

If, instead of calculating the percentage on the basis of the average tide stage (mean sea level), it is calculated on the basis of the volume of water in the Estuary at the beginning of each inflow, the percentages would have been 17 and 21, respectively, or a total of 38 of new water. On this basis one would expect a complete change of water in the Estuary every 2½ to 3 days (except at dead ends and in pockets alongshore) under the worst probable conditions.

As all field work was done according to standard practice and under reasonably good working conditions, the actual measurements of discharges and volumes are believed to be within reasonable limits of accuracy (possibly ± 5 per cent). In drawing the graphs of the tidal flows (see Fig. 47), it was necessary to exercise more or less judgment in order to draw curves which would represent the actual flows satisfactorily. However, a reasonable estimate of the volume of tidal flow available for sewage dilution has been obtained. This estimate, combined with information as to the present and probable future total oxygen demand of the sewage coming into the Estuary and San Leandro Bay, the amount of surface re-aeration, and other significant factors, should serve as a fair basis for the estimation of future conditions in this Estuary.

This investigation was a part of the studies being made by the Engineering Commission on Sanitation and Drainage of the City of Oakland, of which Charles D. Marx, Hon. M. Am. Soc. C. E., and the writers are members.

C. R. F. Coutlee,* M. Am. Soc. C. E. (by letter).—A subject related to tides is the founding and connecting of a concrete structure to rock bottom along the sea coast. The tide rises and wets the concrete which was perhaps, poured only an hour before.

It is suggested that the concrete be placed in canvas and deposited at a temperature of 70° Fahr. If the canvas is placed in a bottom dumping box, which is then filled at the mixer and the top of the canvas gathered and tied with wire, there will be little loss of time. This insures a good setting heat protected from rapid loss by the canvas.

Between high and low tide canvas may become an eyesore, but the inside of the form may be sheeted with it and the heat preserved. In cold weather the zone between tides had better be concreted in one operation. It should be poured hot and should contain a 2% solution of calcium chloride as well.

In the north, the tide belt is bared twice daily, and the soaked face is exposed to severe frost. Only 3 000 lb. concrete can withstand this influence and no less strength should be used.

Tidal range is destructive to timber structures because of buoyancy tending to draw the piling, especially when ice is attached. The attack of

* Ottawa, Ont., Canada.

teredo and *limnoria* occurs largely at the tide zone and can only be met with creosote treatment.

It is necessary, in localities with high tides, to design vessel beds in front of wharves so that a boat may rest on an even keel when the tide is out. Often steel vessels of considerable size lie on the soft mud without injury.

G. T. Rude,* M. Am. Soc. C. E. (by letter).—The writer is indebted to the Society for publishing this paper, and to the members of the Society who have contributed useful information and criticism in the discussions. In submitting the paper the writer had in mind a brief, general outline of the fundamentals of the subject of tides and currents for those engineers who have neither the time from their own particular sphere of work, nor the inclination, to digest mathematical treatises on the subject.

Mr. Haupt in his discussion refers to the "resacas" of the Bay of Rio de Janeiro and by letter has very kindly furnished the writer a reference to the subject.† The "resacas" are not a part of the tidal phenomenon, but are storm waves, due to local winds or to distant storms, which enter the Bay. They do not have a vertical rise and fall of "100 ft." in the meaning of the rise and fall of the tide; but these wind-produced waves, on striking against the vertical protective walls along the cities' fronts, are at times thrown 100 ft. into the air. It is quite probable that their force is increased by the topography of the Bay and perhaps, too, by the fact that the period of oscillation in the Bay, depending upon its dimensions, may coincide very closely with the periods of the waves.

Captain Faris and Mr. H. de B. Parsons have emphasized the importance to the engineer of rational datum planes. The writer is in hearty accord that this matter is one of basic importance in the subject of tides and their relation to the engineer. There can be no argument against Mr. Parsons' recommendation in regard to mean sea level as a datum for elevations on topographic maps. This is recognized by the U. S. Coast and Geodetic Survey, as evidenced in the system of levels which that Bureau is spreading over the country for the use of the engineer and for datums for the topographic mapping of the country. For this whole system mean sea level is used as a datum.

The use of high water as the datum for elevations on a nautical chart undoubtedly had its origin in the fact that the high-water line represents the demarcation between land and sea as visible to the mariner at practically all times, being usually marked by débris, or by other objects along the shore, and by discoloration of rocks, etc. As to the land depicted on the chart, the mariner is interested in the outline of the harbor or shore as it appears to the eye, and high water more nearly fills this requirement, for in low, flat country the grass or tree line usually ends very close to the high-water line; in hilly, rolling country, eroded bluff lines coincide very closely with the high-water line for the purposes of the mariner; in rocky country, such as in New England and Alaska, cliff lines are practically the shore line shown on the chart. The mariner, therefore, quite often is able to locate his vessel by

* Commander, U. S. Coast and Geodetic Survey, Washington, D. C.

† *The Engineer*, April 11, 1924, pp. 380–388.

bearings on the visible shore line, tangents to well-defined points, islands, etc., plotting the bearings to the charted high-water line.

For these reasons the high-water line was taken as the shore line and the zero contour from which to reckon elevations on the land bordering the sea and harbors. In general, the mariner has little interest in mean sea level, but is more inclined to estimate the elevations of shore objects in their relation to the visible high-water line.

The writer is glad to have Colonel Brown's discussion, particularly regarding currents in canals. It happens that the straits and canals connecting two differently tided bodies of water, for which the U. S. Coast and Geodetic Survey has had occasion to make predictions, have been of a length and depth in which the hydraulic feature has predominated to the extent that thoroughly satisfactory results have been obtained by considering only the hydraulic gradient, with a constant for the inertia of the mass of water. It is quite probable, as pointed out by Colonel Brown, that, when occasion arises for predicting slacks and velocities for points in a long, shallow canal, this method will not suffice, and an analysis of actual current observations will have to be made.

Colonel Brown had charge of the lowering of the Chesapeake and Delaware Canal to sea level, and any studies he has made of wave propagation in the Canal will be awaited with interest by the profession. Several years ago he furnished the U. S. Coast and Geodetic Survey with records of eighteen months of continuous tide observations at Chesapeake City, Md., the western terminus of the Canal, and at Delaware City, Del., the eastern terminus. Using these data for determining the hydraulic gradient, predictions of the times of slack water were made for Chesapeake City. These times were in very close agreement with the times of observed slack waters obtained over a short period of actual current observations at Chesapeake City during the summer of 1927.

From information received from the office of the U. S. Engineers in Wilmington, Del., it appears that the times of slack waters vary considerably in different parts of the Canal, indicating that these predictions are satisfactory only for the western end of the Canal.

Mr. Godfrey's discussion is, as he states, "a challenge of the universally accepted theory of the tides."

The basic theory of the tides, pertaining to the astronomical forces involved, which has been universally accepted by scientists in the past, has been found to afford a solid foundation for practical work in this subject; and tidal predictions for all parts of the world, made not only by the United States Government, but also by other maritime nations, have agreed remarkably well with actual observations. It is to be understood, of course, that these predictions are based upon both theory and observations.

The manifestations of the astronomical tide-producing forces are complicated by terrestrial conditions which give rise to various secondary theories upon which scientists have not been in entire agreement. The stationary-

wave theory of Harris, discussed briefly by the writer, seems to be in accord with most of the tidal phenomena as observed.

Gen. William Barclay Parsons has referred to an interesting and economically important characteristic of the tide in a short strait connecting two independently tided bodies of water, deduced from his studies of the Cape Cod Canal—the curved instead of straight line of low-water elevations through the canal. These deductions for the Cape Cod Canal likewise hold good in the case of the East River, New York, the same characteristic in the low-water plane existing also in that strait.*

Mr. Thomson refers to the probable results which would be brought about in the tidal régime of Long Island Sound by a new East River from Flushing to Jamaica Bay and a new Harlem River from Hell Gate to the Hudson, 2½ miles long instead of 6¾ miles, if each of the new rivers were 50 ft. deep and of ample width. Since there is no comparable project available, the matter is debatable, and, too, the results would depend somewhat on the conception of "ample width". Two such rivers, 50 ft. deep and of a width comparable with the present rivers, would probably not reduce the difference in the tide levels appreciably at Governors Island and Hell Gate.

Mr. Thomson also brings up the question whether the Cities of New York, Philadelphia, Pa., and Baltimore, Md., have a comparatively small range of tide due to the fact that the bodies of water on which they are located are "at right angles to the direction of Long Island Sound, Bay of Fundy, and the St. Lawrence, and also whether, if all these rivers, bay, and sounds were running parallel to the equator, the tidal ranges would be greatly increased." It is doubtful whether the azimuth of these bodies of water affects to any extent their ranges of tide.

The tidal graphs from observations by Mr. Dunham are very interesting, showing oscillations in Green Bay, Wisconsin, with a range as great as a foot at times and with a distinct tidal period. It is generally assumed that the fluctuations in the levels of the Great Lakes are due to wind and barometric pressure, with a periodic tidal oscillation of possibly a few inches at most, largely masked by meteorological conditions.

Mr. Bennett brings out the need for self-recording current meters for observations in waters such as Santa Monica Bay, California. To be fair to instrument designers and manufacturers it should be borne in mind that, while a degree of performance similar to that required has been attained in the modern curve-tracing tide gauges, the work required of the tide gauge and also its installation are much simpler than that required of the current meter. In fact, the difficulties of holding the current meter on station without considerable cost is a much more troublesome matter than the development of the meter itself, particularly in water of considerable depth on an open coast, such as the Pacific Coast of the United States.

Self-recording current meters have been developed. One of these, which makes a photographic record of both the velocity and the direction of the cur-

* *Special Publication No. 111*, U. S. Coast and Geodetic Survey, "Tides and Currents in New York Harbor," pp. 73-74.

rent, is described by the writer.* Another self-recording current meter, which records, electrically, the velocity and the direction of the current,† was developed on the *Maud* while that ship was drifting in the Arctic.

The photographic-recording meter (Pettersson's) is already on the market,‡ and it is understood that the electrically-recording meter (Sverdrup) is being further developed.

Mr. Gelineau calls attention to the requirement of location of the high-water line forming the boundary between State-owned and privately-owned property in the sale or lease of riparian lands flowed by tide water. In this connection the engineer can be of considerable assistance to legislative bodies in the wording of proposed laws covering such cases; that is, to have the law state definitely the high water or other tidal plane in the meaning of the law, so that a proper interpretation can be made, which will be recognized by the Courts in deciding cases of litigation. As an example, the writer recalls a case in which the term, "ordinary high water", was used. That might be taken as meaning "mean high water". This interpretation, if accepted by the Courts, might apply to the Atlantic Coast of the United States, but again that definition would not hold good on the Pacific Coast. Due to the diurnal inequality in the tides on that coast the law should be even more specific as to whether "mean high water" or "mean higher high water" is meant, since these are two comparatively widely separated tidal planes. Mean high water is the mean of all the high waters, and mean higher high water, the mean of all higher high waters.

General Black refers to the use of the terms, "progressive" and "stationary", in connection with the classification of tidal waves. The writer agrees with him that non-uniformity in the nomenclature of a particular subject is likely to be misleading. It was for this reason that the writer was careful to employ the nomenclature used by the majority of tidal students and writers on the subject of tides, both in the United States and abroad.

General Black has made a strong point in favor of a study by engineers as to what changes would ensue in the tidal régime of a body of water from certain engineering projects as, for example, in the deepening and widening of the East River. Such studies, however, would have to be predicated on the nature and extent of the proposed projects. In the case of the East River it is doubtful whether any engineering project within reason, except locks, would have any considerable effect on the velocity of the currents. The removal of rocky shoals in Hell Gate and of jutting points in the immediate vicinity would probably have the effect of eliminating, to some extent, the swirls and eddies in the currents which constitute a much greater menace to navigation than an equally high current velocity in a straight channel.

General Black is of the opinion that the characteristics of the tidal movement in the East River, New York, are due to the interference of two tide

* See pp. 662–667. Also, "A Recording Current Meter for Deep Sea Work," by Dr. Hans Pettersson, *Quarterly Journal*, Royal Meteorological Soc., Vol. XLI, No. 173, January, 1915.

‡ Those purchased by the U. S. Coast and Geodetic Survey were obtained from Stockholm, Sweden.

waves, one entering from New York Bay and the other from Long Island Sound, and he refers to data for the East River in the U. S. Coast and Geodetic Survey Tide and Current Tables as evidence in support of this opinion. The predictions of slack waters in the East River contained in the Current Tables, however, furnish the strongest evidence that the movement of the water in that strait is without question primarily hydraulic. The predictions, made two years in advance, are based entirely on hydraulic movement, and thoroughly satisfactory results are obtained. The velocities of the current, also predicted in a similar manner, have been compared with observed velocities with like results. Beginning with the Current Tables for the calendar year 1930, the predicted velocities of the currents in the East River, based on hydraulic movement, will be published, in addition to the times of slack-water.

In further support of the idea of the combined action of two tidal waves in the East River, General Black makes the statement (page 698): "Other evidences of this action could be named", with a footnote reference to *Special Publication No. 111*, U. S. Coast and Geodetic Survey, "Tides and Currents in New York Harbor", by H. A. Marmer, page 77. The writer is unable to find any evidences in the reference (page 77) of combined action of two tidal waves in the East River. On the other hand, the text (pages 77-78) of the publication to which reference is made and the diagram of slope line both specifically bring out evidences of hydraulic movement, as follows:

"It is obvious that in the East River the tidal movement is conditioned by the fact that it is open to the tides of Upper Bay and also to the tides of Long Island Sound. It has therefore been customary to ascribe the peculiar characteristics of the tidal movement in East River to the interference of two tide waves—the one entering from Upper Bay and the other from Long Island Sound.

"However, the mechanism of the tidal movement in East River can best be understood by regarding the phenomena from the hydraulic point of view; that is, we may regard the changing height of the water in East River as brought about by the fact that part of the time the level of the water in Upper Bay is higher than in Long Island Sound, and part of the time it is lower. In other words, we may regard East River as a channel through which the water flows from the body having temporarily the higher level to the one having the lower level. The height of the water at any point in East River is therefore due to the relative elevations of the water at the two ends.

"If we plot the simultaneous heights of the level of the water at the two ends of East River, the lines joining these simultaneous heights will represent the slope of the water surface in the river and thus the height of the water at those times. These slope lines will then permit the time and range of the tide throughout the river to be determined, since the time and height of the water at any place will be represented by the highest point in the slope lines passing that place, while the time and height of the low water will be indicated by the lowest points in the slope lines."

Then follows a page of comparisons (page 78), showing that actual observations of the tides in the East River agree very closely with times and heights as read from the slope line diagram, and ending with the following paragraph:

"It is obvious that the simple hydraulic considerations upon which Fig. 25 [*Special Publication No. 111*] is based can give only a first approximation to

the tidal conditions existing in the East River. The slope lines are drawn as if the channel from Governors Island to Willets Point ran straight for the stretch of 14 miles with unvarying width and depth. No account has been taken of the varying depths in the waterway, of the differences in width, changes in direction, nor of the effect of the water coming through Harlem River. These factors must obviously bring about modifications; but, notwithstanding this, it is seen that the principal tidal phenomena are easily derived by considering the movement of the water in East River as hydraulic. In the chapter [*Special Publication No. 111*] devoted to the currents in the East River it will be seen that the characteristics of the current give further proof of the correctness of the view that the tidal movement in the East River is primarily hydraulic in character."

In ordinary tidal rivers, such as the Hudson River, the observed current velocities may be corrected to mean values by a factor, which is the ratio of the mean range of tide divided by the range for the period of observations.* In the case of the East River, however, and in similar straits connecting two differently tided bodies of water, such as Seymour Narrows, British Columbia, and Deception Pass, Washington, this reduction factor to mean values is not the ratio of the mean range of tide divided by the range at the time of observations, but the square root of this ratio. This fact furnishes further evidence of primarily hydraulic motion in the East River, since in hydraulic motion the velocity varies as the square root of the head.

General Black refers to *Special Publication No. 111*, U. S. Coast and Geodetic Survey, "Tides and Currents in New York Harbor". Attention should perhaps be called to the others of a series of such publications, one of which the Coast and Geodetic Survey is issuing each year, covering the tides and currents in the principal waterways of the country.† Besides those already issued, the publication covering Boston Harbor is now (1927) in press and the manuscript of a publication covering Portsmouth Harbor is being prepared. Each of these publications is being issued following a comprehensive current and tide survey of the harbor in addition to the observations made in past years. As an example, the publication for New York Harbor discusses the data from 149 tide stations, of which 63 are in the East River; and 322 current stations, of which 93 are in the East River. This publication discusses in considerable detail the tide and current conditions as they exist in that harbor at present. The data can be used for predicting the results on the tidal regime by engineers interested in a specific project of harbor improvement. Any analysis, discussions, or predictions of results on the tides and currents in a harbor based on one or more probable projects of harbor improvement is beyond the purpose and scope of such publications. The data are furnished for tide and current conditions as they are at present; and the field is open to engineers interested in any specific project for further analysis based on that particular project.

* *Special Publication No. 111*, U. S. Coast and Geodetic Survey, "Tides and Currents in New York Harbor," by H. A. Marmer, p. 141.

† *Special Publication No. 116*, "Tides and Currents, San Francisco Bay"; *Special Publication No. 123*, "Tides and Currents, Delaware Bay and River"; and *Special Publication No. 127*, "Tides and Currents, Southeastern Alaska".

Mr. Gaston states:

"The conclusion seems to be offered from the text that those monthly variations [in tidal planes], although not always unimportant, cannot be determined on account of being due to differences of atmospheric pressure."

The writer did not intentionally mean to convey the idea that these variations are limited to differences in atmospheric pressures only. They may be due, in addition, to other meteorological conditions, such as fresh-water runoff, prevailing winds, etc. It is possible, too, that variations in atmospheric pressures over wider areas than those shown by local pressure observations may play a part in bringing about these variations in the tidal planes.

The writer is glad to have the references of the mareographical and meteorological observations at the Port of Isabela de Sagua furnished by Mr. Gaston. These data will be extremely valuable in any studies of the variation in mean sea level.

Mr. Scheidenhelm refers to the fact that, during the period covered by the tidal records to which he had access in connection with the Musquash water-power development, there was no occurrence of an extreme spring tide between 4:00 and 6:00 P. M. This is due to the fact that in the vicinity of the Musquash River the high-water lunitidal interval, that is, the time elapsing between the moon's passage across the local meridian and the occurrence of local high water, happens to be about 11 hours. Spring tides occur at the times of new and full moon, at which times the moon crosses the meridian at noon and midnight. Therefore, since the high-water lunitidal interval for this vicinity is about 11 hours, high water occurs at that place at about 11:00 A. M. and 11:00 P. M., during the time of spring tides. In fact, during this time, low water occurs in the vicinity of Musquash Bay between 4:00 and 6:00 P. M.

Messrs. Lee and Gray have submitted an interesting discussion on their work in determining the rates of discharge and volumetric renewal of water in the Oakland Estuary, California, in connection with the question of sewage pollution in that tidal canal. The U. S. Coast and Geodetic Survey is now obtaining a series of current observations in this estuary, the data from which will be incorporated in the Current Tables issued by this Bureau for the use of the mariner.

Paper No. 1669

PREPARING THE GROUNDWORK FOR A CITY: THE REGRADING OF SEATTLE, WASHINGTON*

By Arthur H. Dimock,† M. Am. Soc. C. E.

With Discussion by Charles Evan Fowler, M. Am. Soc. C. E.

Historical

In the fall of 1851 a little band of pioneers landed on a point of land between Elliott Bay and Puget Sound. With the optimism of the adventurer they promptly christened their new settlement "New York". They spent the winter crowded into one small log cabin and having for neighbors nearly a thousand Indians. Their time was chiefly occupied in exploration. Before determining their future course, and not being in possession of the charts made by Captain Wilkes in 1841, they made a hydrographic survey of Elliott Bay, their instruments consisting of a clothes-line and two horse-shoes. When the shoes failed to reach the bottom, they knew they had ample depth for ships. In the spring of 1852, the majority of these pioneers removed to the east side of Elliott Bay. One of the reasons impelling their removal was that the steeper slope of the shores on that side made possible much shorter wharves than the long flat slopes of "New York". One of their number, Carson D. Boren, built the first cabin in Seattle near the intersection of Second Avenue and Cherry Street, where the Hoge Building now stands. By 1853 they had constructed a saw-mill near the foot of Yesler Way and laid out and platted the new town site.

There were other pioneers on Puget Sound in those days and these used to wag sapient heads and remark "Alki New York", "Alki" being Chinook for "by and by", or "a long time ahead". Finally, "New York" was dropped, and to this day the place retains the name of Alki. For several years, however, "New York" and Seattle were rival towns.

* Presented at the meeting of the City Planning Division, Seattle, Wash., July 15, 1926.
† Cons. Engr., Seattle, Wash.

In 1855 Governor Isaac I. Stevens, who had charge of the explorations for a Northern Pacific railroad which were being made by Captain George B. McClellan, and others, for the United States War Department, of which Jefferson Davis was then Secretary, recommended the selection of Seattle as the Western terminus because of its "unequalled harbor". This report gave a great impetus to the new settlement and raised the expectations of the pioneers to the highest pitch.

Topography

The general topography of the new city and vicinity is shown on Fig. 1. Taking First Avenue and Yesler Way as the center in those early days, there lay to the south about 1 500 acres of tide flats, bounded on the east and west by steep slopes and intersected by the Duwamish River. (See Fig. 1.) The flat low-lying valley of this river, about 1 mile in width, extends southeasterly for about 8 miles, where it opens into far wider valley lands reaching to Tacoma, Wash. North of the central point are steep slopes coming directly down to the water-front, flattening in the vicinity of Pike Street to form a considerable level area about 100 ft. above high tide. Immediately north of Pike Street, and a little to the westward, lay Denny Hill, with a maximum elevation of about 240. To the east of Denny Hill was a valley extending to Lake Union, also bounded on the east by steep slopes.

About 1 mile from Pike Street and less than 2 miles from Yesler Way is the south end of Lake Union, a body of water of about 800 acres, 1 mile in length due north and south, and ½ mile in width, lying 8 ft. above high tide. It is bounded on the east and west by steep hills, but has level land at its southern end. It possessed an outlet to Puget Sound through Salmon Bay and was separated from Lake Washington by a narrow ridge. From the earliest times the pioneers dreamed of connecting these lakes with the Sound by a ship canal, which has since been accomplished. Between Elliott Bay and Lake Washington, about 20 miles long and 2 to 3 miles wide, was a series of hills and valleys. North of Lake Union was an extensive, rolling plateau.

Such, in brief, was the general character of the site selected by these pioneers for the city of their dreams. It possessed many elements corresponding to their vision. First, was the sheltered harbor with ample depth of water, which had caught the eye of McClellan, and the bays and lakes, which, when connected, were to form an internal system of water communication. Then, there were the tide lands which, when filled, were to form a manufacturing district with easy access to rail and water. The level lands in the neighborhood of Pike and Pine Streets, when extended by proper grading operations, were to become the retail business section and between the manufacturing and retail areas, on the slopes of the hillside, was ample room for the buildings of the office and financial districts. On the hills, surrounded by sea and lake and encircling snow-clad mountains, were home sites of rare beauty. The instincts of the pioneer led them aright. Although not without its difficulties, the situation of Seattle is unique among the cities of the world.

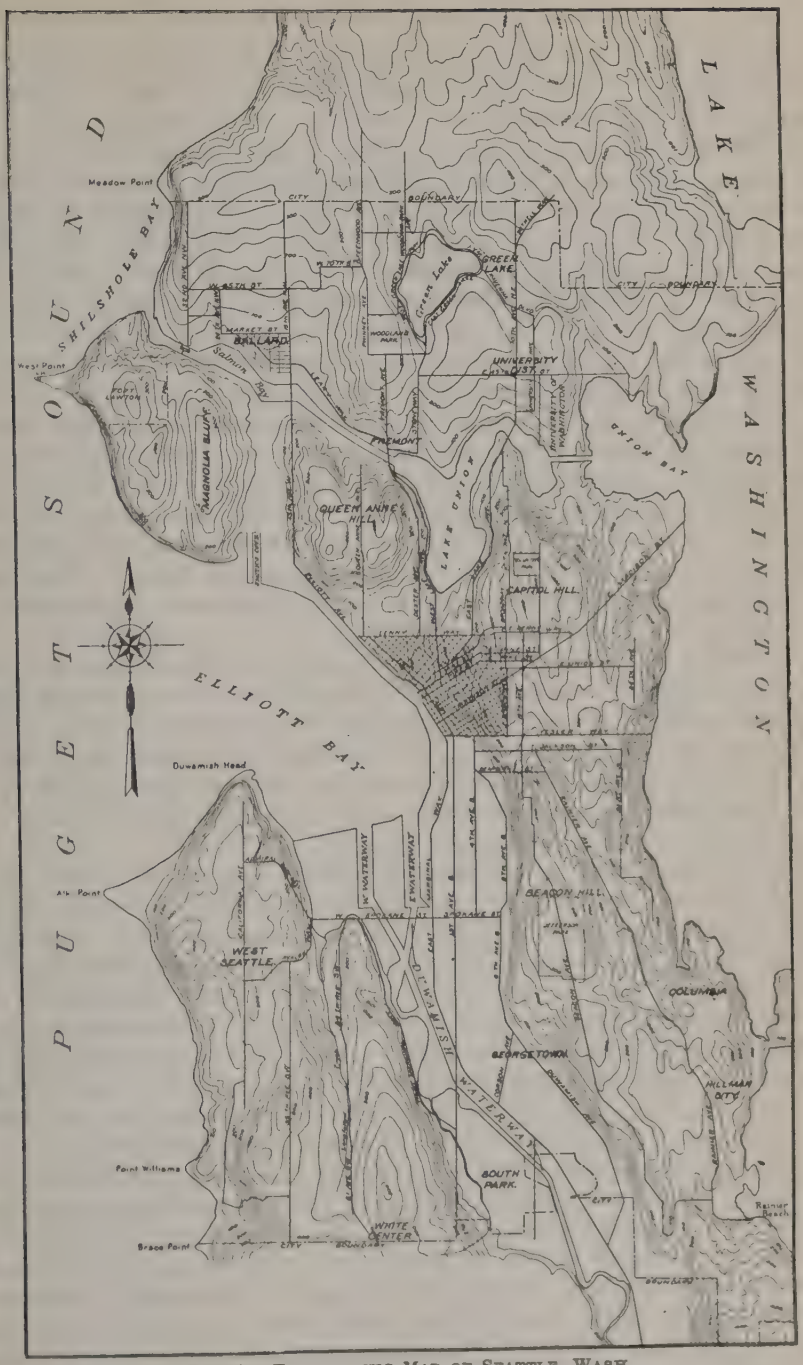

FIG. 1.—TOPOGRAPHIC MAP OF SEATTLE, WASH.

Physical Obstacles to Growth of City

The original business area was along First Avenue between Jackson and Cherry Streets. With no possibility in early days of growth southward because of the tide flats, the city was compelled to grow northward until to-day one of the large department stores is about a mile from the original center. Lying across this natural line of development was Denny Hill, a great obstacle in the path of progress. The removal of the major portion of this hill is known as the "Denny Hill Regrade". Referring to Fig. 1, there will be seen lying east of the ridge rising from Elliott Bay, the Rainier Valley, extending from Pike Street and Broadway to Rainier Beach, a distance of seven miles. The lowest point in this ridge was at Jackson Street and Tenth Avenue South where it had an elevation of 210 ft. The easiest grade over this hill from the water-front to the Rainier Valley was about 15 per cent. Here, then, was a second obstacle to progress, the removal of which was accomplished by the Jackson Street and Dearborn Street regrades. Moreover the streets parallel with the water-front from Yesler Way to Pike Street, with the exception of Second Avenue, had gradients more excessive than was convenient or permissible. The earlier grading of these streets was necessarily limited, by reason of costs, to the least possible amount of work. Here, then, was another problem, a third obstacle to growth, which led to the regrading of Third, Fourth, and Fifth Avenues.

In 1889 a large section of the business area was destroyed by fire. An unusually far-sighted and energetic Mayor and City Council seized the opportunity to widen First and Second Avenues from 66 to 84 and 90 ft., respectively, and to raise the grades of the lower part of the city. A period of rapid growth followed the fire ending in the bad year, 1893. In 1897 gold was discovered in Alaska, and another era of rapid growth began, which was checked by the panic of 1907.

It was during this period, however, that the obstacles which have been described were removed. The rapid rise in the value of real estate caused the optimism and furnished the incentive to the undertaking of great enterprises. Seattle was fortunate in this juncture in having as City Engineer R. H. Thomson, M. Am. Soc. C. E., a man who clearly comprehended the necessities of the situation and had the courage and skill to take advantage of this favorable opportunity to carry into execution the practical plans and measures necessary to secure elbow room for the growing city. In initiating and carrying through the project for the removal of Denny Hill, the strong support of Mr. James A. Moore, a real estate operator, was invaluable.

The work of regrading began in a small way by cutting down First Avenue north of Pike Street. This street ran over a shoulder of Denny Hill which jutted out toward the water-front. This was followed by similar work on Second Avenue north from Pike Street. It was unfortunate that financial limitations and some local politics combined to prevent the securing of the most desirable grades on this street. By the time it became possible to proceed with the work on Third, Fourth, and Fifth Avenues, commonly known as the Denny Hill regrade, a considerable number of new buildings had been erected along

Second Avenue. This made it practically necessary to conform the grades of the new work to that of Second Avenue and led to the creation of a hump at Second Avenue and Virginia Street, which subsequent efforts have failed to remove.

Street Grades.—Under modern conditions, however, the necessity for easy gradients has diminished. These gradients were determined formerly by considering the load a team of horses could pull, and those pavements were selected which afforded the best footing. The motor vehicle has made old theories seem very ancient indeed. It is still true that easy grades are better than steep ones, but the limits have been greatly widened. There is one street in Seattle which was paved with asphalt on a maximum grade of 12%, on the theory that it would never be used anyway; but it has become the main access to the First Hill District. It requires a sprinkling of sand under certain weather conditions, but the capitalized cost of this expense would go a very small way toward paying the cost of securing a better gradient. The ease and comfort of the lowly pedestrian is a more potent factor than motor traffic in limiting the growth of a business district and in determining limiting gradients. Traffic now will avoid detours and seek the steep short-cut wherever possible. In order to obtain a 5% gradient on one of the parkways, a series of hair-pin turns, reminiscent of stage coach days on mountain roads, was used. To-day, these turns are a source of inconvenience and even danger. A more direct route with a 12% gradient would be preferable.

The writer has recommended the use of escalators on the steep cross streets of the business district of Seattle. The practical effect of these escalators would be equivalent to the flattening out of these grades to pedestrians. Some day, owners of the property on these steep streets will awaken to the value of this mechanical means of overcoming the disadvantages of their situation. When the first street is properly equipped with this means of easy access, owners on the remaining streets will hasten to follow the lead.

The rates of grade on the different regrade projects are shown on Figs. 2, 3, and 4. The maximum grade in the Denny Hill District is 5% on the north and south streets and 6.7% on the east and west streets. In the Jackson Street District the grade on Jackson Street itself is 5%, with somewhat steeper grades on the less important streets. Dearborn Street possesses a 3% maximum, but no advantage seems to accrue to it because of this better rate. On the streets in the office district the maximum rates are as follows: First Avenue, 7%; Second Avenue, 5%; Third Avenue 3.7%; Fourth Avenue, 4.7%; and Fifth Avenue, 6 per cent.

The maximum depth of cuts on the Denny Hill project was 110 ft., on the Jackson Street project, 84 ft., and on Dearborn Street, 108 ft. The quantities of earth removed were, respectively, 5 400 000 cu. yd., 3 400 000 cu. yd., and 1 600 000 cu. yd.

Material Encountered.—Fortunately, these hills were composed of sand, gravel, clay, and hardpan. They were the product of glaciers which, in the Pleistocene Age, covered the site of Seattle to a depth of several thousand feet. Geologists state that there were two such ice sheets, each originating in the

Cordilleran center and coming down from the north. They were separated in time by a considerable inter-glacial period. Little of the deposits of the first sheet are exposed, but the handiwork of the second constitutes the foreground of much of the scenery of Puget Sound. The glacier extended to a point about 70 miles south of Seattle. It dammed the natural outlet of the Sound through the Straits of Juan de Fuca. When it began to recede and melt, the water, denied its normal outlet through the Straits, formed a lake or lakes into which flowed many of the rivers of the Sound Basin. The outlet for this water was over a low divide to the south and down the Chehalis River to the Pacific Ocean.

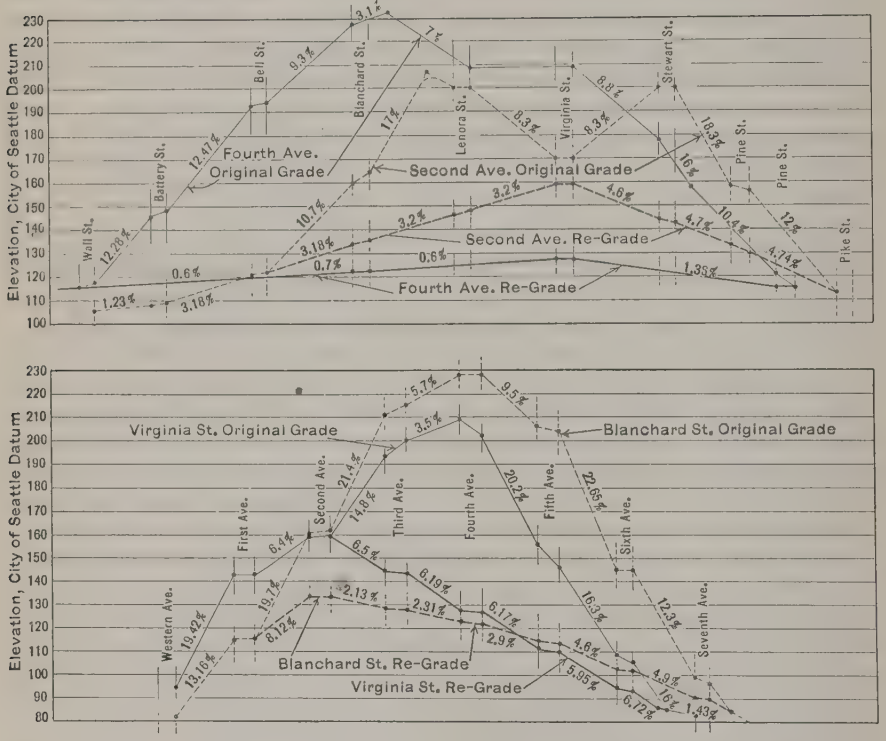

FIG. 2.—PROFILES OF DENNY HILL REGRADE.

The outwash from the glacier formed extensive gravel plains south of Tacoma which now yield a large part of the sand and gravel required for building and engineering construction in Seattle, Tacoma, and other Puget Sound cities. As only the very best and hardest of the rocks survived the action of the glacial mill, the quality of this material is exceptionally high. The retreating glacier also deposited a layer of material called Vashon Till by geologists and commonly known as hardpan. Its thickness varies from 2 or 3 to 20 ft., or more. Beneath are sand and gravel and extensive deposits of a hard blue clay, laid down in the glacial lakes from materials accumulated by

the first glacier. It constitutes the foundation of much of the construction work. Rock occurs only in a very few places in the city and not at all in the business district. This, then, was the material to be moved, and as the cost of handling the large volume of excavation by orthodox methods would have been prohibitive, a new and cheaper method had to be discovered.

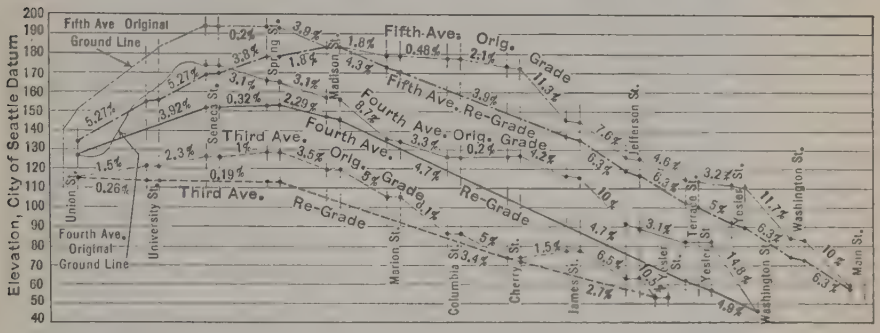

Fig. 3.—Profiles of Third, Fourth, and Fifth Avenue Regrades.

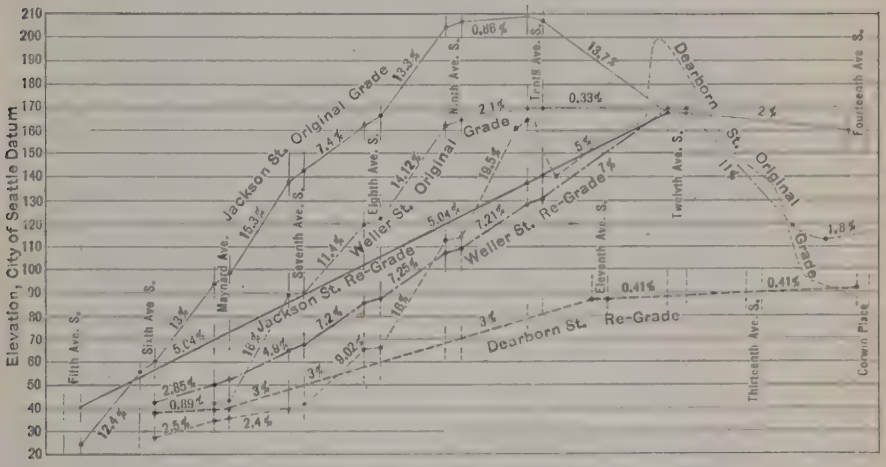

Fig. 4.—Profiles of Jackson and Dearborn Street Regrades.

Application of Hydraulicking.—Mr. William H. Lewis, a lawyer more interested in engineering and constructive work than in law, possessed property interests in the Rainier Valley. This property, although close in, was separated from the business section by the ridge on Jackson Street previously described. The removal of this ridge at a cost within the ability of the property owners to pay became to him a topic of absorbing interest. His attention was called by W. C. Morse, M. Am. Soc. C. E., and by Mr. James Hopkirk, to the successful use of the method of hydraulic sluicing in extensive gold-mining operations at various points on the Pacific Coast. The method, however, had never been applied to the problem of moving large volumes of clay

and hardpan on a city grading job. Many said it could not be done. Bankers refused their support, but Mr. Lewis, by his energy and enthusiasm, overcame all difficulties, worked out the problem, secured the approval of the property owners and of the City Council, and finally organized a company which obtained the contract and successfully completed the Jackson Street and Dearborn Street projects.

The older form of giant was adapted to the new work by equipping it with a ball-and-socket joint to enable it to swing both horizontally and vertically as conditions required. Detachable nozzles varying in diameter from 2½ to 3½ in. were also provided. The water had a pressure at the nozzle of 75 to 100 lb. With this equipment much of the material could be removed by the water alone; but the harder materials required loosening by blasting with low-grade powders. It was soon learned by experience where preliminary shattering of the material increased the efficiency of the water sufficiently to offset the cost of the blasting. Figs. 5, 6, and 7 show the magnitude of the hydraulicking operations on the Denny Hill regrade.

The material when broken by jet and powder was washed down to sluice-boxes provided with fan-shaped approaches and openings screened by bars or "grizzlies" to keep out roots and material too large for the pipes. A man stationed at the "grizzly" kept it from clogging and broke up the larger chunks of clay or hardpan. Part of the material was conveyed in open sluice-boxes, lined with wooden blocks, similar to paving blocks. Set on end these blocks withstood the wear better than any other material, and when worn out were easily and cheaply replaced.

In many places, however, open sluice-boxes were not suitable as the material had to be conveyed under pressure. In such cases wood-stave pipe, like the hydraulic giants, also a Western product, was used almost exclusively in this earlier work, although of later years steel pipe has come into use. The diameter of such pipe varies, of course, but is usually from 18 to 24 in. As this plain wood pipe wore out with great rapidity, a special pipe, Fig. 8, was designed by Mr. Hopkirk, which made provision for an invert lining of replaceable wooden blocks. These blocks greatly lengthened the life of the pipe.

Water Supply.—The water supply was derived from several sources. On the Jackson Street and Dearborn Street work surplus water from the Cedar River water supply system of the city was turned into an abandoned reservoir with a capacity of about 4 000 000 gal., situated about 1 mile from the work. From the reservoir this water was fed to the giants through steel and wood stave pipe. From 6 000 000 to 10 000 000 gal. per day were thus supplied at a charge of $15 per 1 000 000 gal. This, however, was not sufficient. A pumping plant was constructed on Elliott Bay, with a capacity of 12 000 000 gal. per day, consisting of four 10-in., 5-stage pumps direct-connected to two 650-h.p. motors. As the tide has a range of 16 ft., the pumps were set somewhat below extreme high tide, and provision was made for a water-tight floor and wall. The discharge was made through 24-in. wood stave pipe having staves 1⅝ in. thick and bound with No. 1 wire spaced ⅞ in.

FIG. 5.—VIEW OF OLD DENNY HOTEL, SEATTLE, WASH., AND VICINITY.

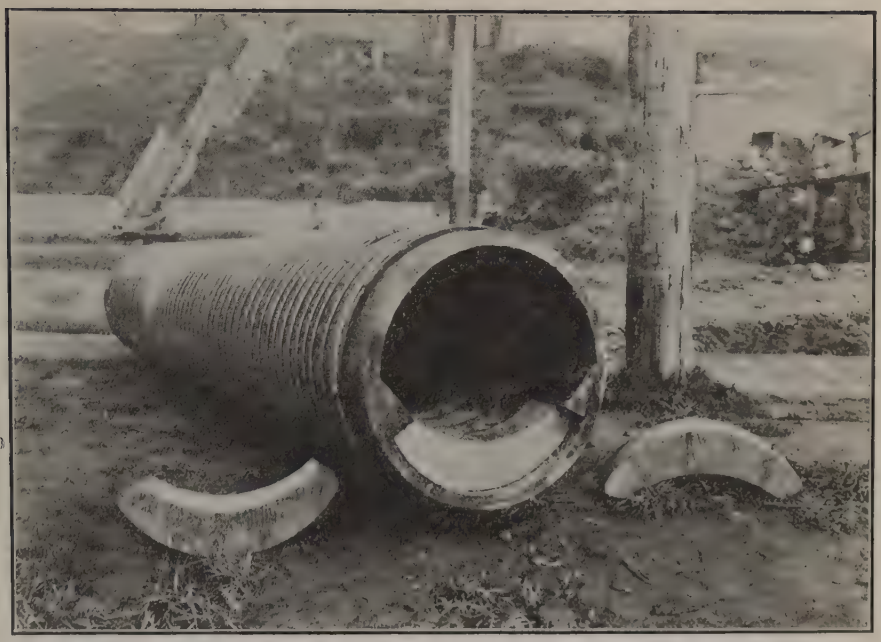

FIG. 8.—SECTION OF NEW SPOIL PIPE, REGRADING OPERATIONS, SEATTLE, WASH.

FIG. 9.—JACKSON STREET REGRADE, SEATTLE, WASH., SHOWING FOUR GIANTS OPERATING IN CLAY OVERLAID BY HARDPAN OR GLACIAL TILL.

On the Denny Hill work, city water was not available. The supply was from two sources. On the water-front a 4-stage pump with a 850-h.p. motor delivered 5 000 000 gal. per day. A second plant of three units was constructed on Lake Union about 1 mile from the work. Two units consisted of two 10-in., 4-stage turbines each, with a 650-h.p. motor. The other unit was a 15-in., 4-stage pump, with a 650-h.p. motor. The total capacity was 12 000 000 gal. per day. Here, also, wood stave pipe conveyed the water to the giants.

The quantity of spoil carried by the water varied within wide limits, depending on the gradients of the discharge pipes and the character of the material. On Jackson Street the average was 6.75% of the volume of water. With a water supply of 20 000 000 gal. per day, this would mean 10 000 cu. yd. of material moved. A large allowance, however, on such work must be made for changing pipe lines, moving giants, clogging of discharge pipes, and all the innumerable petty delays incident to such work. On Jackson Street the quantity moved averaged about 4 000 cu. yd. per calendar day.

Disposal of Spoil.—In the Jackson Street regrade all the material was used to fill in the adjacent tide lands. The grades of some of this area were raised about 40 ft. In this, as in the Denny Hill project, provision was made in the specifications for the removal of earth from private property at the same price as that paid by the City, the contractor being required to accept a lien on the property payable in ten annual installments, as in the case of the assessment for the street work. This provision applied also to the fills. The result was a substantially unanimous acceptance of this provision by the property owners, there being, however, a few exceptions.

In the Denny Hill District a large part of the spoil was wasted in the deep water of Elliott Bay about ½ mile from the work. A part, however, was used to fill in the valley lying east of Denny Hill. Grades in this valley were raised as much as 25 ft., resulting not only in a fine area for growth of business which is now coming into its own, but also in providing access by easy grades to the Broadway-Pike Street area, which has since developed into the principal motor-vehicle district. This by-product of the removal of the Denny Hill is proving to be even more valuable as affording scope for growth than the original project itself, as the largest development of Seattle is in a general northeastward direction and this valley lies almost directly along the axis of this movement. Another reason is that the Denny Hill District has been hampered in attaining the most complete benefit from its heroic work because the streets were originally laid out parallel with the salt-water front. This was perfectly natural for the pioneers to do, as they could not, at that time, visualize a removal of this hill, and they failed to grasp the northeastward trend which business later would take. Consequently, they extended this platting as determined by the direction of the salt-water shore-line up and over Denny Hill and even across a part of the valley. The result was that these streets diverge about 45° from their proper direction. A few streets paralleling the shore line and the remainder paralleling the section lines would have been almost ideal in its conformity to present necessities, for the

valley lies almost due north and south. This failure to perceive the future development, therefore, has given rise to several perplexing and difficult street rectification problems which are vexing the City Planning Commission and the City Council.

A part of the excavation was carried on by steam shovel and dump cars. Much material was conveyed in this way to sluice-boxes, whence it was washed down to the Bay. Other parts were used to fill in the valley streets as outlined. In the Jackson Street District the low ground was brought up to basement level by hydraulicking (Fig. 9), and the street fills brought up to grade by the shear-board method, shown on Fig. 10, the slopes being on private property. This method, which was specially devised to meet the conditions of this work, consisted of driving stakes against which were placed a couple of 1-in. boards. These stakes were braced to the step below. The steps were, say, 1½ ft. high and 2 ft. wide. The earth was then sluiced in nearly to the top of the boards when another step was made, and so on to the top. The steps varied somewhat in height and width, depending on conditions. Much of the lumber used in these steps could be used over again, and it proved to be a cheap and efficient method of building up the fills. In a few cases wooden pile bulkheads were constructed.

On Third, Fourth, and Fifth Avenues, between Yesler Way and Pike Street, in the central business district, all excavation was carried on by steam shovel and cars. This area, because of the character of the adjoining buildings, did not permit the use of the sluicing method. Crossing this district were two cable street-car lines, affording access to important residence districts. When the excavation of adjoining areas had proceeded sufficiently, these cable roads were blocked up on timber cribwork. After the excavations had been completed, they were lowered by degrees during the night. In this way traffic was maintained almost continuously. Electric street-car traffic on the north and south streets was shifted from one street to another and handled by various other expedients. The carrying on of this work in these streets greatly inconvenienced the stores and business houses. Although every possible aid was extended to the owners by the City authorities, nevertheless, there must have been considerable loss in many cases. This was a part of the price paid for the reshaping of these streets. In the Denny Hill and Jackson Street Districts, however, the cuts were so great that the buildings were wrecked, thus leaving the area entirely free for the sluicing operations. The most conspicuous example of this razing of buildings was the Denny Hotel, a brick structure of six or seven stories.

The total quantity of earth removed on this regrading work was approximately 14 000 000 cu. yd. A part of Denny Hill was not included in the original work, but provision is now (1926) being made for the full completion of this project. A great deal of such work has been done since by the hydraulic method, but it has not possessed the magnitude and spectacular features in depth of cut and volume of material moved, of the Denny Hill, Jackson Street, and Dearborn Street projects.

FIG. 10.—VIEW SHOWING SHEAR-BOARD METHOD OF CONSTRUCTING EMBANKMENTS.

FIG. 11.—VIEW SHOWING COMPACTED GRAVEL USED IN PORTLAND, ORE., FOR CONSTRUCTION OF HIGH EMBANKMENTS BY HYDRAULIC PROCESS.

Building Embankments by Hydraulic Process

An interesting development of the art of hydraulic sluicing is the construction of embankments which are entirely free from subsequent settlement. Fills have been made in Portland, Ore., 40 to 50 ft. deep, on which houses were built shortly after the fills were finished. These houses showed no more effects from settlement than those built on original ground. The University of Washington Stadium was built by the same method. The construction of the concrete work followed immediately on the completion of the fill, and no cracking due to settlement has occurred.

For the successful use of this method, suitable material must be available. Earth containing a large percentage of clay cannot be used successfully. The process reverses the theory of hydraulic construction of dams which retains the fines in a central pool, and allows these fines to run off. The water must be kept moving at the correct velocity to prevent deposition of the fines while it drops the coarser material. Fig. 11 is a view of compacted gravel banks, used in Portland, Ore., for the construction of high embankments. Such embankments drain very rapidly and form extremely compact and solid fills. The process is somewhat similar to the construction of the slopes of the hydraulic-fill dam.

It will be noted that the dreams of the original pioneer settlers for a great city, which they visualized, perhaps, somewhat hazily and indistinctly, required for their initial realization the development of pioneer engineering methods. Hydraulic sluicing, the hydraulic giant, wood-stave water pipe, wood-stave pipe lined with blocks for carrying spoil, and the shear-board method of building up embankments, are all the product of Western conditions.

DISCUSSION

CHARLES EVAN FOWLER,* M. AM. SOC. C. E. (by letter).—The regrading of Seattle, as carried out largely under R. H. Thomson, M. Am. Soc. C. E., and the author, approached in magnitude of the material to be handled, the digging of the Panama Canal, and in some respects the difficulties were much greater. The first extensive regrading was done by steam shovels on Denny Hill near the old Washington Hotel, the material being hauled in dump cars, down the principal business streets, to the tide flats for making fill. The writer operated two steam shovels in this general district, one at the Washington Hotel, and one on the old University grounds on Fourth Avenue. The material was sold to the Great Northern Railway for tide-flat filling.

The steam shovels were served by horse-drawn, 2½-yd. dump wagons, from 24 to 30 for each shovel, and the dirt was hauled about ½ mile to the north end of the Great Northern Railway Tunnel, where it was chuted into railway dump cars about 30 ft. below, and hauled in trains to the final place of deposit, south of the Great Northern Station. The selling price was 7 cents per cu. yd., which, added to the excavation price, made the total receipts about 20 cents per cu. yd., or a very profitable figure for the pre-war period.

The dumping grounds were just south of the territory and comprised several hundred of the 1 200 acres of the Seattle tide flats, which were brought to grade at 2 ft. above extreme high tide. This filling was done by the writer with two 20-in. hydraulic dredges, and the 12 000 000 cu. yd. so placed, formed an essential part of the regrade work of Seattle, making usable the land from the foot of Queen Anne Hill to the southern end of Elliott Bay. The portion of the tide flats near the Jackson Street regrade was filled with the dirt sluiced down in doing this work. This, together with the material removed from the Denny Hill regrade, constitutes the greatest sluicing operation ever carried out, and it redounds to the credit of those who did the work, as well as to the City of Seattle, the possibilities of which were dependent on the great works described.

Not less notable in the making of the city that had the courage to regrade its hills, fill in its tide flats, and build its port, was the creation of the Park System. This work was planned and begun while the writer was a member and, part of the time, President of the Park Board. Parkways, now about 60 miles in length, connect the city parks proper and represent a form of regrading of the hills of the city so as to make the beautiful drives which wind about these hills and through much of the primeval forest preserved for the pleasure of future generations. This system is certainly a wonderful creation of man and is the result of allowing full play to the imagination and creative energy of the engineer. Hundreds of thousands will thank the imagination and tireless energy of Mr. Thomson who for more than a score of years was City Engineer and the creator of the future of the city.

Paper No. 1670

RE-ARRANGEMENT OF A BUSINESS DISTRICT: CHANGES IN RECENT YEARS IN PITTSBURGH, PENNSYLVANIA*

By Nathan Schein,† M. Am. Soc. C. E.

With Discussion by Messrs. Edwin K. Morse and Francis J. Mulvihill.

Incorporated as a city since 1816, and situated at the confluence of the Allegheny and Monongahela Rivers, uniting to form the Ohio, Pittsburgh, Pa., is one of the greatest industrial, financial, and distributing centers. The city proper, which has an area of 46.93 sq. miles, is divided by the rivers into three principal sections. The largest and most populous section known as "Peninsular Pittsburgh", or the "Old" City, occupies the territory between the Monongahela and Allegheny Rivers, and includes the down-town or business district. The territory south of the Ohio and Monongahela Rivers is known as the South Side, and that north of the Ohio and Allegheny Rivers, formerly the City of Allegheny, as the North Side.

The city ranks eighth in population, but the area included within a 10-mile radius and including that known as the Pittsburgh District, ranks fifth among the metropolitan districts of the United States. The down-town, or the business, section is substantially that part of the city known as the Point District, and is bounded by the two rivers and by Grant Street on the east.

The street plan in this district consists of a low-level section in which three main streets, Duquesne Way, Penn Avenue, and Liberty Avenue, are laid out parallel to the Allegheny River, with intersecting streets at right angles. To the east of Liberty Avenue, the streets and avenues are parallel to the Monongahela River, with Market, Wood, Smithfield, and Grant Streets intersecting at right angles.

The basic problem in this section is that of means of transportation, especially the problem of the street plan. Prior to 1904, this district consisted

* Presented at the meeting of the City Planning Division, Seattle, Wash., July 15, 1926.
† Div. Engr., Dept. of Public Works, Pittsburgh, Pa.

of narrow streets and ways or alleys. There was no street or avenue wider than 60 ft. except Liberty Avenue of 80 ft. (referred to subsequently), and most of them were 40 ft. wide; all the alleys or ways were 20 ft. wide.

FIG. 1.—LOW-LEVEL DISTRICT, PITTSBURGH, PA., ALONG THE ALLEGHENY RIVER, WHICH WAS RAISED ABOVE FLOOD LEVEL. HUMP DISTRICT, ABOVE SMITHFIELD STREET, WHICH WAS REDUCED IN GRADE.

In 1904, the City realized the need of more street area in the down-town section and widened Diamond Street to 50 ft. from Smithfield Street to East Diamond Street, and, at the same time, Oliver Avenue was widened to 44 ft. from Smithfield Street to Liberty Avenue. In 1905, the Pennsylvania Railroad Company removed its tracks from Liberty Avenue which then became the first street of this city with a free roadway of 48 ft. between curbs. These were the only improvements that had been made in the re-arrangement of the streets in this district and the problem of transportation began to be seriously felt.

The various civic and trade organizations as well as the Department of Public Works began to study this problem. In 1910, Mr. Frederick Law Olmsted, in a report entitled "Pittsburgh, Main Thoroughfares and Down-Town District", made recommendations for the general improvement of the city, and called attention to the importance of proper and adequate city planning. This study resulted in the creation of the City Planning Department in 1911, which gives the City the power to bring about proper planning and provided a body for its administration.

In 1911, a broad and comprehensive program of street improvements was started. These projects included the improvement of main thoroughfares, particularly those leading from the business district to outlying sections; opening of new highways; elimination of grade crossings; raising of low-level areas; reduction of grades; and widening of business thoroughfares. The two methods of city planning carried out were the reduction of grade in the "Hump" District and the raising of the low-level districts above flood stage. The location of these districts is shown in Fig. 1.

Reduction of Grade in the Hump District

The improvement of streets in what is known as the "Hump" District, completed in 1913, involved the lowering of grades in an area of about 40 acres in the down-town business district, the opening of a new thoroughfare, and the widening of a number of streets. The necessity for this work arose from the fact that the grades of Fifth, Oliver, and Sixth Avenues, over which the greater part of the east-going traffic passes, were very steep. The traffic congestion on Fifth and Sixth Avenues, and the necessity for providing an outlet for Grant (now Bigelow) Boulevard, demanded the opening of an additional parallel route which was accomplished by widening Oliver Avenue. Other street widenings for the accommodation of through traffic and to meet local requirements were also made.

Twice before the grade of Fifth Avenue had been reduced, and as the last improvement had been long agitated and discussed, it was necessary to dispose of the question for all time, so as to permit property owners to develop the district with assurance of permanence of conditions.

The greater part of the area in question lies between Sixth and Fourth Avenues, and between Smithfield and Ross Streets, including Sixth, Oliver, and Fifth Avenues, and Diamond Street running east and west, and Cherry Way, Smithfield, Grant, and Ross Streets running north and south. The improvement was carried eastward as far as the intersection of Sixth and Fifth Avenues, and northward so as to afford a connection with Grant Boulevard, involving in this district Webster and Wylie Avenues, Strawberry Way, and the extension of Grant Boulevard. Oliver Avenue, Cherry Way, Diamond Street, and Fifth Avenue between Grant Street and Sixth Avenue were widened. The maximum cut of 16 ft. was at the intersection of Fifth and Wylie Avenues. The cut at Fifth Avenue and Grant Street was 14 ft., and this improvement is sometimes referred to as the 14-ft. "Hump Cut". As a result of the improvement, the grade of Fifth Avenue was reduced from 7.6 to 4.87% between Grant and Smithfield Streets, and the grades of the other streets in the district were reduced in proportion. Fig. 2 shows the new and old grades of Fifth Avenue between Smithfield and Grant Streets.

The city bore the physical cost of the work, including the grading, reconstructing the entire sewerage system, relaying of water lines, constructing new pavements and sidewalks, tearing down buildings where the street lines had been changed, and similar work. Public service corporations at their own expense relaid street railway tracks, electric conduits, and gas lines. At the same time these companies generally enlarged their facilities. The property

owners attended to the shoring, underpinning, and protection of their buildings, and all the resulting reconstruction, alteration, and demolition work. Many of the older buildings were torn down, but a considerable number were lowered or additional stories provided below the former ground floor.

The city secured waivers of damage from nearly 80% of the property owners affected in so far as these related to the reduction of grade. The property owners, therefore, to a great extent defrayed the cost of the alteration and adjustment of their properties. The city, however, recompensed property owners for the net damages incurred due to widening of streets, this amount being materially reduced owing to the benefits accruing.

The total cost of the improvement amounted to $2 364 673, itemized as follows:

Cost of physical work—grading, regrading, paving, repaving, etc., Fifth Avenue, Diamond Street, and adjacent streets	$732 019	
Cost of physical work—lowering water lines	30 981	
Cost of alterations in Fire and Police Wiring System	13 771	
Cost of alterations to Public Safety Building	1 421	
Cost of repaving Sixth Avenue	2 772	$780 964
Damage awards on account of above improvements		499 059
Damage awards on account of widening:		
Fifth Avenue	$259 830	
Cherry Way	202 157	
Oliver Avenue	308 253	
Strawberry Way	130 403	
Grant Boulevard	315 404	1 216 047
Engineering and incidental expense		34 533
Total cost		$2 530 603
Benefits assessed by viewers:		
Widening Fifth Avenue	$595	
" Cherry Way	48 460	
" Oliver Avenue	92 875	
" Strawberry Way	14 000	
" Grant Boulevard	10 000	165 930
Net cost to City		$2 364 673

In addition, the expense borne by the Public Service Corporations and by property owners undoubtedly reached a very high figure.

The principal items of work and the unit prices were as follows:

Excavation, 153 900 cu. yd.	@ $3.00
Block stone pavement, 13 800 sq. yd.	@ 3.75
Créosoted wood block pavement, 11 000 sq. yd.	@ 4.00
Vitrified brick pavement, 4 100 sq. yd.	@ 3.00
Protected concrete curb, 17 200 lin. ft.	@ 1.00
Concrete sidewalks, 149 700 sq. ft.	@ 0.20
Lumber in temporary structures 27.3 M. ft. B. M.	@ 80.00

FIG. 2.—HUMP DISTRICT, PITTSBURGH, PA., VIEW OF FIFTH AVENUE, SHOWING NEW AND OLD GRADES.

FIG. 3.—HUMP DISTRICT, PITTSBURGH, PA., FIFTH AVENUE FROM SMITHFIELD STREET TO GRANT STREET.

FIG. 4.—VIEW SHOWING FLOOD OF MARCH 28, 1913, PITTSBURGH, PA., AT 30.4-FOOT STAGE, DUQUESNE WAY AND SEVENTH STREET, WEST.

FIG. 5.—PITTSBURGH, PA., VIEW OF SECOND AVENUE WEST FROM GRANT STREET.

Work was begun April 5, 1912, and finished in November, 1913. The work was arranged so as to permit of the maintenance of traffic; work on Fifth, Oliver, and Webster Avenues was first completed, through traffic being carried on Sixth Avenue and Diamond Street. Pedestrian traffic was maintained by the erection of temporary boardwalks supported on trestles, and the public utilities were supplied by lines laid generally on the surface of the ground, as shown on Fig. 3.

Since the completion of the improvement, many costly structures have been erected within this area, among which are the William Penn Hotel, City-County Building, Union Arcade, Bell Telephone Company, Philadelphia Company, Harry Davis Theater, *Gazette-Times* Building, and others. The taxable valuation of properties in this district has greatly increased due in large measure to the erection of buildings on sites formerly vacant, or occupied by small structures. The increase in the taxation receipts for the district, assignable in a large measure to this improvement, has covered the cost and expenses borne by the City. In 1914, the Second Ward in which this district lies had an assessed valuation, for taxable purposes, of $183 398 440 and, in 1924, it was $221 804 410, a gain of about 21 per cent.

Raising of Flood District

One of the problems with which the City of Pittsburgh has had to contend, and which has been remedied to a great extent, has been the periodic flooding of the low-level business, residential, and industrial territory along the rivers, causing serious and extensive damage to property, unsanitary conditions, and the suspension of business and traffic. River control and flood prevention have been extensively studied and reported on by the Flood Commission of Pittsburgh. This Commission, in ascertaining the extent of flood damages to the city, in a careful examination of three floods which occurred within a year, from March 15, 1907, to March 30, 1908, found direct losses within the city to be as follows:

Damage to buildings, equipment, and machinery...	$782 400
Damage to materials.....	1 698 900
Loss to employers by supension of business.....	1 974 200
Loss to employees due to shutdown.....	1 308 300
Expense of cleaning up.....	547 400
Charities dispensed and funds for prevention of disease	27 800
Fires uncontrolled through inaccessibility or lack of water pressure.....	175 000
Total	$6 514 000

It was found that the loss ranges as follows:

For the flood of 27.3 ft.....	$414 700
" " " " 30.7 ".....	839 800
" " " " 35.5 ".....	5 259 500

The general condition of streets in the down-town, low-level district in 1913, during a flood stage of 30.4 ft., is shown on Fig. 4; and the enormous damage to property for floods of greater height can be easily surmised.

Since 1908, there have been fifteen floods recorded over the 25-ft. stage, and twenty-six times the Ohio River has passed the danger line of 22 ft.

The lower part of the down-town business section comprising an area of 60 acres, was raised to an elevation of 35 ft. and more, in order to avert this periodic flooding of streets. This re-grading of the low-level business district was started on April 28, and completed on December 1, 1915. The cost of the work, exclusive of the cost to the various utility corporations, was $162 000. The net damage to property owners along the improvement amounted to $165 000. The work was arranged to permit the maintenance of traffic and business. The property owners attended to the alteration and raising of their buildings to the new grades.

Having attended to the regrading of its business area, immediately following the World War, the City began again to pay attention to the congestion of traffic in the down-town section. On July 8, 1919, a $20 000 000 bond issue was approved, and, as a result, the down-town section was materially re-arranged and the city in general improved. New avenues of traffic were provided; dangerous grade intersections eliminated; the waterworks systems extended and improved; new highway bridges were constructed and some present bridges reconstructed; and provisions made for the improvement of parks and recreation facilities; extensions to the drainage system; and improvements for public health, welfare, safety, and charity services. Last, but not least, a sum of $6 000 000 was favorably voted for a start of subway construction in the down-town section.

The streets in the down-town section were materially re-arranged. Second Avenue from Grant Street to Liberty Avenue, was widened from 40 ft. to 80 ft., with a roadway width of 56 ft., sufficient for six lines of traffic, as shown on Fig. 5. Ferry Street from Water Street to Liberty Avenue, was widened from 40 to 70 ft. Diamond Street from Smithfield Street to Grant Street was widened from 25 to 54.5 ft., and Diamond Street from Ferry Street to Market Place was widened from 50 to 70 ft.

The widenings in the down-town section were very costly. The physical work in widening Second Avenue cost $177 733, and the net damages assessed against the City amounted to $1 851 460, making a net total cost to the City of $2 029 193.

The cost of the physical work on Ferry Street was $62 997, and the net damages assessed against the City were $666 480, making a total cost to the City of $729 479. The cost of the physical work on Diamond Street between Smithfield Street and Grant Street, only one block long, was $14 517, and the net damages assessed against the City were $391 795, making a total cost to the City of $406 312. On account of the valuation of property in the congested business section, it is quite evident that the cost of future widenings of streets therein will be prohibitive.

The cost in 1920 per square foot of net assessment against the City for widening Second Avenue was $45, for Ferry Street, $30, and for Diamond Street, $82 per sq. ft. The more important widenings of streets in the down-

town business section are shown on Fig. 6. Diamond Street, from Liberty Avenue to Ross Street, was widened in sections at three different times, and, as a result, there is now a zigzag alignment of street.

FIG. 6.—MAIN STREETS WHICH WERE WIDENED IN DOWN-TOWN BUSINESS SECTION OF PITTSBURGH, PA. DIAMOND STREET WHICH WAS WIDENED AT THREE DIFFERENT TIMES, IS NOW A ZIGZAG THOROUGHFARE AS TO ALIGNMENT.

More than any other single improvement, the new Boulevard of the Allies, caused the greatest re-arrangement of the street plan in this district. The Boulevard starts at Grant Street and Second Avenue, and extends eastward along the hillside to Bluff Street, by an elevated structure of easy grade. This Boulevard is a main thoroughfare to the down-town section from the east. It is one of the through routes of the city and has been chosen as a part of the Lincoln Highway. Its location high on the hillside overlooking the Monongahela River, as shown on Fig. 7, furnishes a picturesque driveway of a character distinctive of the rugged topography of the city. This thoroughfare which cost $2 600 000, was named Boulevard of the Allies as a memorial to the World War, and bronze tablets on columns at the entrance, as shown on Fig. 8, serve in commemoration of that event.

The item of a down-town subway at an estimated cost of $6 000 000 was the largest and the most important improvement proposed affecting the welfare and development of practically the entire community, especially as it opened up again the entire question of transit facilities for the City of Pittsburgh. The proposition itself was not even then new, and had been

considered by both the City and by private interests. As early as 1906, the subway project was under consideration by the City Council, when the Pittsburgh Subway Company was seeking a franchise for the building of subways to furnish rapid transit. In 1910, the entire traction problem was studied by Bion J. Arnold, M. Am. Soc. C. E., who submitted an exhaustive report to the Mayor and Council of the City, in which reference was made to a down-town terminal. In 1913, an ordinance was passed by Council but vetoed by the Mayor granting the right of building a subway to the Pittsburgh Subway Company.

In 1914, the Rapid Transit Committee of the Chamber of Commerce made a report on this problem, and in 1916, a Committee of the Engineers' Society of Western Pennsylvania reported on a down-town subway loop. In 1917 and 1918 E. K. Morse, M. Am. Soc. C. E., as Transit Commissioner of the City of Pittsburgh, recommended the construction of certain rapid transit lines. However, work on the construction of a down-town subway has not been begun. A Department of Transit has been established in the City Government, that has the power and the facilities to make studies, investigations, and construct transit lines in the city. This Department is equipped with a technical staff, and is headed by a Commission of six members, with George S. Davison, Past-President Am. Soc. C. E., as the Chairman. Since 1924 this Department has been and is now (1926) studying the rapid transit question for the whole community, under the supervision of D. L. Turner, M. Am. Soc. C. E., as Consulting Engineer, and Winters Haydock, M. Am. Soc. C. E., as Chief Engineer. The original sum of $6 000 000 has been found to be inadequate for the construction of a down-town subway.

The ever-increasing congestion in the down-town section is partly being taken care of by parking restrictions, the establishment of one-way thoroughfares, and the re-routing of street cars. Most of the streets in this district are one-way thoroughfares, and the street cars are making use of short loops in the business district.

The City of Pittsburgh will again resume improvements to its public works, for in May, 1926, the people voted favorably for a bond issue of $19 902 000 to be expended for improvements to the various facilities and activities of the city. A summary of the proposed improvements is as follows:

For maintenance of service of existing facilities of water supply, bridges, sewerage, and streets.....	$7 950 000
For equipment and buildings for Fire and Police Departments to provide adequate protection.....	600 000
For the care of the City's poor, insane, and sick.....	2 750 000
For adding to the inadequate facilities of playgrounds.	750 000
For street improvements in widening and improvement of existing main thoroughfares to remedy traffic congestion and provide necessary arterial streets....	7 852 000
Total	$19 902 000

FIG. 7.—BOULEVARD OF THE ALLIES, PITTSBURGH, PA., VIADUCT NO. 1, VIEW EAST OF EAST END FROM ROE BUILDING.

FIG. 8.—BOULEVARD OF THE ALLIES, WEST ENTRANCE, VIEW EAST, PITTSBURGH, PA.

Under this new bond issue Grant Street from Water Street to Seventh Avenue, will be widened 20 ft. on the easterly side, making an 80-ft. street. The total estimated cost of this improvement is $1 620 000, of which the physical work will cost about $90 000.

The damage estimated to be assessed against the City for this 20-ft. strip of property is $1 530 000, or $100 per sq. ft. of ground taken. Grant Street may be said to be the key street to the down-town section of the city.

The problem of transportation in the down-town section has brought forth the study of the development of the wharves of the city. A sum of $50 000 has been appropriated by Council for the payment of:

"Costs and expenses of making surveys, investigations, estimates, and plans for the improvement for public uses and purposes of the river-fronts of the Allegheny, Monongahela, and Ohio Rivers within the City of Pittsburgh, for providing adequate and improved facilities and terminals for all forms of river traffic and for such changes and improvements in the street, sewerage and drainage systems of the City, and of properties affected thereby, as may be necessary to carry out the foregoing improvements and for such other changes, improvements, and measures as may be deemed necessary therefor or desirable in connection therewith."

This study is under way in both the Department of Public Works and the Department of City Planning, and it is expected that, as a result, the City will be again asked to vote on the bond issue to make possible the improvement of the wharves in the down-town section.

Citizens Committee on City Planning

In 1918, the Citizens Committee on City Plan, an unofficial body of private citizens, was organized with the object of producing a "Pittsburgh Plan". This Committee has no political connection and no partisan purposes. It planned to give to the city, an orderly, scientific, and comprehensive program of city building. It contributed an exhaustive report in six parts: Part 1, published in 1920, dealt with the study of Pittsburgh playgrounds; Part 2, published in 1921, dealt with the Major Street Plan of Pittsburgh; Part 3, published in 1923, dealt with the transit question; Part 4, published in 1923, dealt with the Pittsburgh parks; Part 5, published in October, 1923, dealt with the railroads of the Pittsburgh District; and Part 6, published also in October, 1923, dealt with the problem of water transportation.

The City Planning Commission, with Morris Knowles, M. Am. Soc. C. E., as its Chairman, supplemented the report of the Major Street Plan as proposed by the Citizens Committee on City Plan, with a report on the Inter-District Traffic Circuit, issued in March, 1926. This report deals with the planning and estimate of the cost of the re-arrangement of the business district, and includes those thoroughfares, bridges, and other improvements that are, individually, integral parts of a so-called "Triangle By-Pass System", improvements of parts of tributary major radial streets, and modifications of minor streets immediately related to and affected by the changes proposed. The aggregate cost of these improvements will be more than $50 000 000.

In conclusion, it may be stated that the re-arrangement of a business district, such as that of the "Golden Triangle in Pittsburgh", is a basic problem of means of transportation, especially of the street plan.

The street plan requires careful consideration not only by the municipal authorities, but also by the various civic and trade organizations, citizens committees, and planning bodies, and includes problems of river and rail transportation, flooding of rivers, terminals, rapid transit, adjustment of grades, regulation of traffic, and zoning laws.

DISCUSSION

EDWIN K. MORSE,* M. AM. SOC. C. E. (by letter).—When it is realized that the area of the central business district of Pittsburgh is only 218 acres; that Chicago contains 600 acres within "the Loop"; Philadelphia, 1 400 acres; Boston, 1 900 acres; and New York City, to 42d Street, 4 000 acres, the comparison impresses one with the intensity of the Pittsburgh business man's activity, because in no equal area in the civilized world is the same volume of business so successfully transacted. The Flood Commission of Pittsburgh has presented comprehensive plans for wharf and river improvements as prepared by its Board of Engineers in April, 1925, which, if approved by the U. S. Army Engineers and carried out by the City, will add more toward maintaining Pittsburgh's supremacy than any other local construction.

By deepening the channels of the Allegheny and Monongahela Rivers to a uniform depth of 16 ft., and straightening their shore lines, it will reclaim about 57 acres of what is now a sloping wharf of little value to a small shipping interest, costing practically nothing to the City.

The plans contemplate modern slips for river and rail transportation. They specify walls around the city and along the North Side to a level above the highest known flood. The surface and basements of more than 40% of the 218 acres in the central business district were damaged during the disastrous flood of March 15, 1907.

The contemplated construction would bring about the rebuilding of all the flooded districts in the city, and in ten years would completely repay the City by increased taxation of the section benefited. The 57 acres would be turned over to the Planning Commission of the City of Pittsburgh for comprehensive study. A boulevard, 80 to 100 ft. wide and more than 2 miles long, with no streets crossing it, could then be built along the banks of the Allegheny and Monongahela Rivers. Parking space for thousands of automobiles would be provided in a location convenient to the business sections, and when the time comes, a free right of way for a double-deck street, involving no consequential damages, would be awaiting posterity.

The average yearly loss to Pittsburgh, caused by floods, is estimated at $2 000 000. This money loss could be greatly reduced if the Flood Commission's plans were adopted. If that Commission's plans for the improvement of the Allegheny, Monongahela, and Ohio Rivers, within the city limits, had been fulfilled as recommended, the level of the disastrous flood of March 15, 1907, would have been reduced at least 10 ft. and, instead of nearly $6 000 000, the City would have lost less than the present annual cost of $2 000 000. With provision for intercepting sewers, back-fill, re-grading of streets, and paving complete, the engineers of the Flood Commission estimate the cost of building the walls around the city and along the North Side at $6 000 000.

The Mayor and Council of Pittsburgh have authorized the Department of Public Works to report on the plans submitted by the Commission and submit plans for river terminals. In connection with this study, the City has just

* Pittsburgh, Pa.

completed soundings in the Allegheny and Monongahela Rivers within municipal limits.

The U. S. Government expects to complete the locks and dams on the Ohio River from Pittsburgh to Cairo, Ill., a distance of 967 miles. That will provide an all-year river transportation. Pittsburgh, strategically located for river and rail transportation, has no river terminals. The City's study contemplates making Pittsburgh the greatest inland river terminal in the United States except New Orleans, La., which is ocean and river combined. The City will have to condemn whole sections of improved property along the riverfront so as to provide adequate terminals for slips handling river tonnage and rail and river shipments. In addition to the moderately equipped docks and slips, locations are being considered for large basins in which to store floating crafts and arrange transshipment of barges between down-river and up-river ports.

The mills, factories, mines, railroads, etc., that direct traffic to the rivers, have been modernized to the limit. Nothing has been done by the City to modernize the rivers and provide river terminals. Within recent years, the big steel industries have built river steamboats and steel barges that are now sending thousands of tons of structural steel and steel products down the Ohio and the Mississippi Rivers as far as New Orleans. The Inland Waterways Corporation is operating successfully on the Mississippi and Warriors Rivers. It is hoped and believed that Pittsburgh will build modern river terminals, thereby profiting by the great tonnage received and dispatched.

Francis J. Mulvihill,* Assoc. M. Am. Soc. C. E. (by letter).—The paper by Mr. Schein is an important and direct contribution to the literature of city planning accomplishment. Because there are so few histories and progress reports of this art, the recorded experience at Pittsburgh, Pa., may suggest and stimulate additional response from "about five hundred cities and town"† in the United States engaged in city planning. The whole movement needs such accounts of accomplishment. The theory is fairly well established, but, in addition to knowing "how to do", "doing it" is important; so that practical demonstration lends impetus and acceleration to wise planning. Demonstration, too, will prove and serve to answer the question, "City planning is of what use?" The experience recorded by the author concerning the basic problem of transportation and circulation dependent on (*a*) the street plan of the Pittsburgh Business District; (*b*) the engineering data of costs and materials; and (*c*) the overcoming of physical obstacles by demonstration of engineering skill, all suggest some consideration or comment. That which follows is not critical, but is offered for the purpose of emphasis and expansion. The paper suggests relevant considerations: First, city planning procedure and accomplishment in Pittsburgh; and, second, the business district of Pittsburgh in the future.

City Planning Procedure and Accomplishment.—In general, the procedure followed and the accomplishment acquired are good. There are perhaps a

* Landscape Archt.; Town and City Planner, Germantown, Philadelphia, Pa.

† "Annual Survey of City and Regional Planning in the United States, 1926," by Theodore Kimball Hubbard, Annual Survey Number, *City Planning* (quarterly), April, 1927.

half dozen municipalities in the United States where substantial progress is being made, both in preliminary studies and actual accomplishment. Mistakes and inadequate planning cause great financial loss, entailing millions; but the annual budget of approximately $100 000 for the Department of City Planning of Pittsburgh is ungrudgingly provided by an appropriation ordinance of the City Council. No other city grants as much. In a sense it is just an insurance premium to prevent great loss. What is done now in public works is better done than it was a few years ago, and the budget amount is likely to increase. An historic background is a requisite for determining the rate of progress. Pittsburgh, like other cities, grew haphazardly and by chance from an unhappy aggregate of accidents in a series. Problems developed, consequently, and when they became serious, it was expedient to solve them. Prior to 1904 there was no comprehensive planning in Pittsburgh. Mr. Olmsted's report entitled "Pittsburgh, Main Thoroughfares and Down-Town District", in 1910, was among the first on city planning as it is understood to-day. It was only the year before, in Washington, D. C., that a meeting, the forerunner of the existing National Conference on City Planning, was held. The comprehensive Olmsted report stressed the importance of proper and adequate city planning. In 1911, the Pennsylvania Legislature passed the Enabling Act and the Department of City Planning of the City of Pittsburgh was created. The subsequent street improvements incorporated, almost in detail, the general Olmsted recommendations and the Department of City Planning established "follow-up". General studies were made by the City Planning Department for the relief of traffic congestion. In 1918, Diamond and Ferry Streets and Second Avenue were widened, and the Boulevard of the Allies was constructed. The Department of Public Works has much to do with projects of the character stated, because it is responsible for the engineering design and construction.

The supporting interest of the Citizens Committee on the City Plan is of so much value to the entire movement in Pittsburgh, that to treat its work and labors adequately would require the space devoted to the paper and more. Its report and study on playgrounds is indeed a classic of this element of city planning.

Since the paper was prepared, Grant Street has been widened from 60 ft. to 80 ft. With this widening completed, buildings of a height and architectural type new to Pittsburgh are being constructed and projected.

The Business District of Pittsburgh in the Future.—The distress of cities may be caused by difficulty in: First, making its life fit the mould of yesterday; and, second, trying to visualize to-morrow in the light of to-day's conditions. It is dangerous to attempt prophecy without the gift of vision. The Enabling Act of 1911, already mentioned, does not elaborate the functions of the Department of City Planning as does the recent Pennsylvania Act (1927). Until the present Act there was no authority at law that permitted the adoption of a thorough, studied, comprehensive, development, general design, or master city plan for the present and future guidance of Pittsburgh. The De-

partment of City Planning is, therefore, at work on the master thoroughfare and general design plans.

The author has mentioned changes that were accomplished a few years ago, and possibly there will be changes in the future. About the beginning of 1928 the Allegheny County projects of the Liberty Tunnels and Liberty Bridge will be open to traffic. These are a part of the Inter-District Traffic Circuit. The Department of City Planning has completed the preliminary design study of another link in the Circuit, the Crosstown Thoroughfare. This study has been approved by the City Planning Commission. The widening of Grant Street has permitted a re-routing of trolley cars in a loop system. Every day, judging from congestion, the down-town streets look like Saturday afternoon, and the time is coming when they will look like the week before Christmas. Two-way streets will become one-way streets. Merchants are overcoming the fear of loss and the notion that all trolleys must pass their doors. Unlimited parking of automobiles has been replaced with limited parking or with none at all.

Streets cannot continue to be widened because of the cost. The people are realizing that the area in down-town streets is ample, but the best use of them is not practiced at present. The cost of delays to the owners of trucks, buses, taxicabs and automobiles, conservatively estimated, now is $25 000 daily. These owners will avoid the delays and effect the saving. A railroad will abandon or salvage its equipment along Duquesne Way and in "the Point"; sell its land in these locations; acquire a site and provide better modern facilities elsewhere, without any financial loss, from the proceeds of the old plant. The Point, now backward, will have a new life and business will expand into that area. The flood will be controlled and the rivers' fronts improved. The down-town traffic circuit will be operating, gyratory, one-way, along Duquesne Way, Water, Grant, and Eleventh Streets. Within the circuit there will be no vehicles, unless in an emergency, during the day. Trolleys will be in a subway loop and off the street surface. Buses and cruising taxicabs will have stations and terminals off the streets. Streets for deliveries, collection, and merchandising services will then be used at night. Vehicles will be absent from the streets down town, not because they cannot get there or are prohibited, but because of the economic loss to the owners if they attempt it. The streets will again be free to the people when every day is Christmas in Pittsburgh.

Paper No. 1671

THE PLANNING OF THE INDUSTRIAL CITY OF LONGVIEW, WASHINGTON*

By S. Herbert Hare,† Esq.

With Discussion by Messrs. B. L. Lambuth, Brookes Baker, and S. Herbert Hare.

"City Planning", a term applied to the orderly physical development of a community, would in most cases be more properly classed as "City Re-Planning".

The opportunity of planning a complete new city of any great extent on undeveloped land seldom presents itself. The planning of Longview, Wash., was perhaps the largest project of this kind since the planning of the National Capitol by L'Enfant under President Washington, and involved some pioneering in the field of city planning.

History of the Development

A very brief historical account of the project is as follows: The Long-Bell Lumber Company, in looking forward to a continuation of its operations after its Southern timber supply was exhausted, purchased a large tract of timber land in Lewis and Cowlitz Counties, Washington, about 15 miles north of the Columbia River. In looking about for a mill site for the manufacture of this timber, a location on the Columbia River at the mouth of the Cowlitz was finally decided upon, and options were taken on land to cover the mill site and other lands in the valley. As the operations of the Company were to be very extensive and the number of people to be employed necessitated a great increase in the population of the district, the development of a town site adjoining the mills was discussed early in 1922. The purpose was not so much to secure the profits which might result from increased land values produced by the Company's operations, as to prevent exploitation of the land in the district and a haphazard growth of unrelated development in the vicinity of

* Presented at the meeting of the City Planning Division, Seattle, Wash., July 15, 1926.
† Landscape Archt. and City Planner (Hare & Hare), Kansas City, Mo.

the mills. It was decided, therefore, that an industrial city should be built which would serve not only the Long-Bell interests but other industries as well. It was not to be a "company town" or a "one-industry town", and it was to be sold as there was demand.

In February, 1922, officials of the Company visited the site and sought advice on the feasibility of developing a town. This visit was followed later in 1922 by conferences, after which various industrial cities were investigated for information about developments similar to the one proposed, including land values, store counts, rail and transportation facilities, and many other subjects. In the meantime, a topographical survey of the lands involved was being made under the direction of Wesley Vandercook, Chief Engineer of the Long-Bell Lumber Company.

In June, 1922, after a thorough inspection of the property, the Company exercised options on approximately 14 000 acres of land, the area which has since been included in the plan for the city. At this time the writer made studies for both a skeleton plan of the entire area and for the detailed development of the interior section. In connection with these studies he had the general advice of the late George E. Kessler, Landscape Architect, and B. L. Lambuth, Realtor.

Upon arriving at a general scheme further studies were developed. These plans were made at different scales; the general plan at a scale of 1 000 ft. to 1 in.; plans for sections of the city at a scale of 400 ft. to 1 in.; and detail plans, each covering an area of 1 500 by 2 000 ft., at a scale of 40 ft. to 1 in. The detail plans, which showed lot lines, curbs, walks, easements, building and outbuilding lines, and other features, with controlling dimensions, were sent to Mr. Vandercook, in whose department calculations were made, streets and lots staked out, construction work supervised, and utilities planned.

After the initial planning was completed, special advice on commercial water-front treatment and railway problems was secured. As the building of the city progressed scores of detail plans were prepared for park areas, school sites, hospital property, and other public and semi-public developments. The first lot in Longview was sold in February, 1923, and the city was incorporated in February, 1924.

The Topography of the Site

The town site is principally a rich, flat valley bounded on the north by hills, on the south and southwest by the Columbia River, and on the east by the Cowlitz River. It includes more than 7 miles of deep-water frontage on the Columbia River, available for ocean-going vessels, and about 5 miles of frontage on the Cowlitz River suitable for barge service. On the north, the land included in the town site reaches into the hills at some points for a distance of about 1 mile and rises to an elevation of about 400 ft. The valley ranges from a little above tide level at the western end to Elevation 20 or higher at the point chosen for the center of the city. The land in the valley was included in seven separate diking districts which were merged into one large district, the intermediate dikes were removed, and a new and higher dike was built along the river-front.

FIG. 1.—SKELETON MAP OF STREET SYSTEM, LONGVIEW, WASHINGTON.

The outstanding topographical feature of the valley is a small mountain rising from the valley floor near the western end. This mountain is more than 2 miles long and nearly 1 mile wide, reaching an elevation of 560 ft. at its peak. In some places it is very precipitous, covered with heavy tree growth, and in others more rolling on the upper levels with cleared farms. It is probable that the greater part of this interesting topographical feature, known as Mt. Solo, will be preserved as a large public park.

Another topographical feature which influenced the plan was a slough or old bed of the Cowlitz River which formed a loop about the place chosen for the center of the city. About 1½ miles of this has been preserved as a crescent-shaped parkway.

Adjoining the town site on the east is Kelso, Wash., which is situated on both sides of the Cowlitz River, and which had a population of 2 500 at the time operations at Longview were begun. Across the Columbia River on the south is the smaller town of Ranier, Ore.

The Plan

The plan of the city (Fig. 1) shows a system of main thoroughfares, or major streets, designed to carry the bulk of the through traffic, with secondary and minor streets to serve local needs. The main thoroughfares in some cases form radials, leading traffic to and from the center, but with ample by-passes both near and farther away from the center to prevent traffic being forced to the center. At the center of the radials is a 6-acre park known as Jefferson Square about which the public buildings will be grouped (Fig. 2). Fifteenth Avenue, which with Oregon Way, forms the main thoroughfare from the Columbia River to the business center, was purposely planned to be one block from Jefferson Square so that business frontage on this street would be continuous on both sides. Thus, although Jefferson Square is the focal point of the diagonal streets, it will not be the center of business activity. This business center is, however, as readily accessible by streets leading from the diagonals as the focal point itself.

The individual areas formed by the main thoroughfares and diagonals are subdivided for the most part in a rectangular or grid-iron manner with some irregular arrangements where the topography or the form of the areas dictated. The arrangement is, therefore, for the most part a systematic one so that streets can be easily named and numbered. The plan has been compared in a general way to that of Washington, D. C., perhaps because of the diagonals. It is, however, much more simple and there is an important difference in the treatment of the diagonals in relation to the rectangular streets. In Washington, the diagonals were superimposed upon a rectangular or grid-iron arrangement with no considerations given to the confusing angles which the intersections produced. At Longview, the rectangular arrangement is in a series of separate units, with connecting streets articulated across the diagonals, usually at right angles.

In order to clear the wholesale or light industrial district to the southeast of the business center from the confusion which would be caused by a

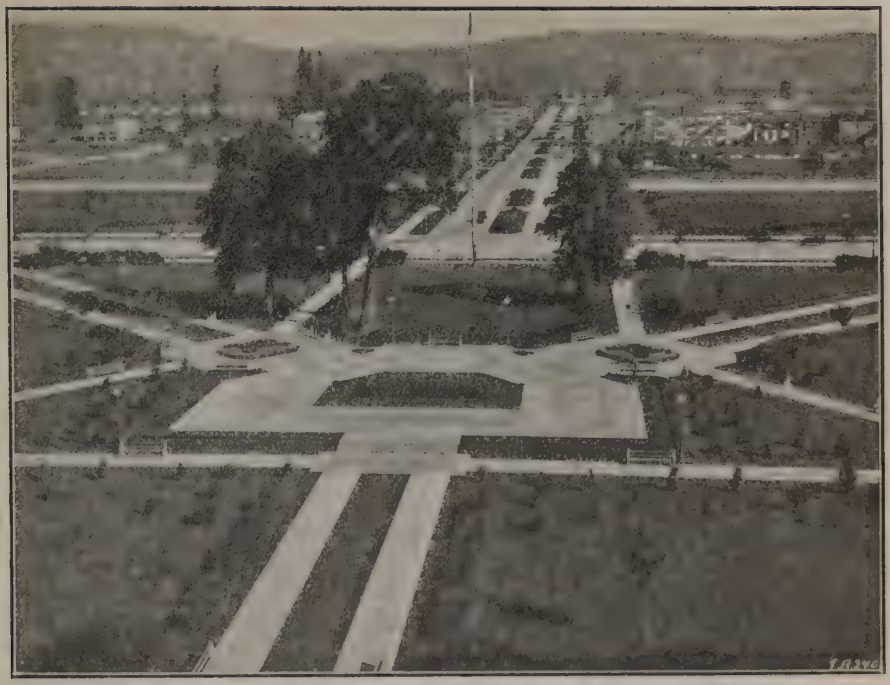

FIG. 2.—VIEW OF LONGVIEW, WASH., EAST FROM MONTICELLO HOTEL.

FIG. 3.—VIEW DURING DREDGING OPERATIONS ON LAKE SACAJAWEA PARKWAY, LONGVIEW, WASH. SMALLER HOUSE DISTRICT IN FOREGROUND.

diagonal, the diagonal in this direction was offset along the line of Fifteenth Avenue to a point where it could be used for an approach from the Pacific Highway across the Cowlitz River from the southeast. The location of this diagonal also offered an unusual opportunity for convenient railroad leads into the industrial districts, with only one track across the thoroughfare and with obtuse angles on the curves in the industrial tracts. The city is served directly by the Longview, Portland, and Northern Railroad, a common carrier, 30 miles long, which connects with the transcontinental lines just across the Cowlitz River.

After careful consideration a lot depth of 120 ft. was adopted as the standard for the regular portions of the city, as this depth was considered most suitable for the various uses. Alleys were provided quite generally, even in the residence districts, partly owing to a local custom in the use of slab wood for fuel. These alleys will probably not be provided in future high-class residence districts, and the districts which are being developed in the hills are irregular and carefully adjusted to the topography. A width of 20 ft. was adopted for the alleys, providing for two lines of traffic and pole lines.

In the street system, the main thoroughfares are 100 and 120 ft. wide, secondary thoroughfares and main business streets, 80 ft. wide, and other streets, 50 to 60 ft. wide. Roadways on the streets vary from 24 to 25 ft. on the minor streets to 60 ft. on the major streets. In some cases esplanades are used which may be removed when traffic demands. Block lengths are from 300 to 500 ft. in the business district and 600 to 1 100 ft. in the residence districts, the longer blocks being usually in the direction of traffic.

The distribution of schools has been given careful study and 5 acres or more have been reserved for grade school sites, with an area of 30 acres for a Junior and Senior High School, the latter to have an athletic field. Church sites, a golf club, cemetery site, and other community needs have been provided for as the complete plan developed.

In addition to the 6-acre park at the civic center, other local parks and playgrounds have been reserved at convenient intervals. It is contemplated to retain some of the more precipitous slopes in the north hills for park lands, as well as the land on Mt. Solo previously mentioned, and some of the frontage on the Cowlitz River.

The development of a part of the slough surrounding the central section of the city (Fig. 3) promises to be one of the most interesting parkways in the country. The area reserved, containing 100 acres, is from 500 to 800 ft. in width, bordered by boulevards, and is 1½ miles long. To secure material for filling in the vicinity nearly 2 000 000 cu. yd. of sand was pumped by hydraulic dredge from this parkway, forming a series of connected lakes carefully designed to simulate natural bodies of water. Four thoroughfares will cross these lakes on bridges. Complete detailed grading plans were prepared for this development, not only showing the grading by sections, but accurately indicating by contours of finished grades the naturalistic rolling ground forms desired. This parkway has been named Lake Sacajawea, after the woman Indian guide of the Lewis and Clark Expedition.

Zoning

Zoning was one of the interesting problems of the planning of the city. The uses to which various properties were to be put was necessarily determined in the planning of the street system, and this street arrangement will tend to stabilize those uses and prevent shifting values. Early in the planning, a zoning map was prepared showing areas to be used for residences, apartments, business, and light and heavy industries. As there was no municipal corporation at that time to enact a zoning ordinance and no State enabling act to authorize such an ordinance, the zoning regulations were put into effect by private restrictions. These restrictions are partly in the deeds, but are mostly filed with the plat. They follow the most modern practice and are self-perpetuating, thorough, and complete, but in no way drastic, protecting the investment of the small home owner as well as that of the more wealthy one.

One of the difficult problems in connection with zoning was the necessity of starting development in a series of more or less disconnected centers rather than in one center. This at first produced a scattered appearance and extra cost of paving and utilities, but the wisdom of the procedure is already apparent as the population is growing, and the scattered centers are gradually being joined into a homogeneous whole without conversion of property from one use to another. The plan provides for a population of 50 000 and by converting suburban acreage into city lots a much larger population could be housed on the town site. The installation of utilities and the problems of diking and drainage have been intricate.

Throughout the planning it was constantly kept in mind that this city was to be a thoroughly practical, general industrial city, one in which convenience and economy, although of primary importance, were to be combined with the highest type of beauty—that beauty which is designed into a development as an organic part rather than added to it as an ornament. The people of Longview will work amid pleasant and convenient surroundings and will enjoy some of the amenities of life.

DISCUSSION

B. L. Lambuth,* Esq.—Virtually all outstanding real estate development is a product of the joint effort of skilled men drawn from many professions. The modern tendency is for the realtor, the town planner, and the civil engineer to work together toward a desired end. One of the greatest sources of interest and pleasure in connection with the Longview development was the harmonious relations between a considerable group of specialized experts, including, in addition to those mentioned, architects, lawyers, transportation men, title experts, advertising men, and others.

An interesting feature of the operations at Longview to those interested in this type of development is the fact that in theory at least it has been possible to avoid a tremendous aggregate annual loss and wastage arising as a result of the necessary reconstruction at the center of American cities which accompanies growth by a process of accretion at the circumference. The founders of the city had adopted what has been designated by Mr. J. C. Nichols, of Kansas City, Mo., as a "skeletal" plan of development, whereby the entire city site is completely planned and zoned and the actual development of each district is started in a small way in its proper relationship to a finished whole. By this means it is expected that large economies will be effected. Although on the one hand some extra cost is necessarily involved in tying the various districts of the city together by suitable street improvements and public utilities, yet, on the other hand, the great bulk of the property is carried until required for development as vacant agricultural acreage with correspondingly low overhead carrying charges, such as interest and taxes. Furthermore, the plan adopted offers the advantage of permitting one of the several districts of a city to be prepared for development in relatively small parcels as actually needed for immediate use from time to time; but the principal advantage of the "skeletal" plan is that business, housing, institutional, and, in fact, all building development, is in its proper relationship to a finished whole. Therefore, the usual necessity of tearing down and reconstructing building—improvements which ordinarily accompany growth of a city from nothing to 40 000 or 50 000 population—is quite largely obviated.

Another interesting feature of the Longview plan is the association of suburban agricultural and garden tracts with the other districts of the city, and as a part of the general scheme. This is on the principle that one of the very important and very substantial elements of urban population is the family seeking a small tract of land as a means of providing over-time employment and a home that is partly self-sustaining.

A large number of people visit Longview each year. Apparently, the first three outstanding impressions of the more thoughtful and better trained of these visitors are, first, that they are viewing a city in the making; second, that the city was planned before construction was begun; and, third, that beauty and spaciousness of design and execution have been attained.

* Mgr., Real Estate Dept., The Longview Co., Longview, Wash.

Brookes Baker,* Esq. (by letter).—The plans for Longview, Wash., appear to cover the requirements for a well-balanced community so completely that little remains to be said. As the designer states, the planning of an entire new community, with an assured future, occurs so infrequently that there are no precedents by which to judge. Most engineers who have been connected with matters pertaining to land developments have at times staked out new town sites in unsettled territory, this work being generally the mere execution, on the ground, of the promoter's desire to secure the greatest possible number of lots out of a given number of acres, without any regard for the future welfare of the purchasers of the lots. All who have done this will join in congratulating the designers of Longview on the happy solution of their problem.

The placing of the central park one block removed from the business district is a most excellent solution of the need for a park which is of the business district, but not in it. The diagonal streets are indeed convenient; the plan of adjusting the cross-streets to right angular intersections retains the most convenient rectangular spacing on the main streets, where values are greatest, and puts the angular and point lots in the less desirable locations.

The long parkway, occupying the old slough bed, with its many pools set in their banks of green, some shaded by magnificent trees, some spanned by attractive bridges, and all skirted by pleasant drives, affords an excellent example of the adaptation of an offensive waste into an object of beauty, which will contribute throughout the years to the pleasure, comfort, and refinement of the growing community.

S. Herbert Hare,† Esq. (by letter).—In the discussion by Mr. Lambuth, the important point of co-operation is again emphasized; not only the co-operation of the engineer, the city planner, the landscape architect, the architect, and others, but that of the realtor, who can render a valuable service in connection with the development of such a plan as was produced for Longview, Wash. The real estate operator who is to have the responsibility for marketing the land, if he has a broad understanding of the problem and of the aims of the city planner, should very properly have a voice in the physical arrangement and development of this land.

Mr. Lambuth has referred to the building of Longview in various nuclei as a "skeletal" plan of development and has pointed out the saving which results from such a program. The success of such a plan, of course, depends somewhat on the prophetic vision of the planner, engineer, and real estate operator in judging the market and rate of growth, and weighing the somewhat greater initial expense involved in such a procedure against the immense losses which result from converting the uses of property early in the life of constructions. The results at Longview have undoubtedly justified the decision.

The provision for suburban garden tracts to which Mr. Lambuth refers was, of course, a part of the carefully considered general plan for the city,

* Civ. Engr., Fort Worth, Tex.

† Landscape Archt. and City Planner (Hare & Hare), Kansas City, Mo.

wherein provision was made, in its proper place, for every class of property which a city would normally require.

Mr. Baker refers to the Lake Sacajawea development by saying that it "affords an excellent example of the adaptation of an offensive waste into an object of beauty". Almost every city, new or old, has land which is a menace under private ownership but which, with proper development, would be a great asset under public ownership. It has been interesting to note, in the many interviews that have been given at various times by visitors to Longview, that the majority have seemed to appreciate, but accept as a matter of fact, the convenience, order, and systematic arrangement of the city, but few have failed to make special comment regarding the beauty of the city and particularly the park developments. This seems to indicate a growing demand for, and interest in, beauty in civic development.

NOTES ON ARCHED GRAVITY DAMS*

By B. F. Jakobsen,† M. Am. Soc. C. E.

With Discussion by Messrs. George R. Rich, A. Floris, Lars R. Jorgensen, P. Wilhelm Werner, Paul Bauman, William Cain, F. W. Hanna, E. W. Kramer, A. J. Wiley, W. P. Creager, Edward Godfrey, C. A. P. Turner, and B. F. Jakobsen.

Synopsis

Formulas are developed for a gravity dam having a triangular section and a vertical up-stream face that is curved in plan to a radius, R_u. It is shown that the radius of curvature influences the stresses considerably and that it is never safe to neglect the curvature as has been customary in the past. The middle-third theorem, therefore, does not hold for arched dams.

Introduction

The customary investigation of gravity dams is based on the assumption that the horizontal sections, such as $F\ G$ in Fig. 1, remain plane and that the modulus of elasticity remains constant, so that the stress, s_b, produced by a bending moment, M, is,

$$s_b = \frac{M}{I}\, y \qquad (1)$$

in which, I is the moment of inertia of the horizontal section, $F\ G$, about its center of gravity, and y is the distance from this center of gravity to the point in which the bending stress is s_b.

It is also customary to neglect the curvature of a gravity dam and assume that the horizontal section is a rectangle, as shown in Fig. 1, while actually

* Published in August, 1927, *Proceedings*.

† Cons. Engr. (La Rue & Jakobsen), Los Angeles, Calif.

it is trapezoidal, as shown in Fig. 2. It is the purpose of this paper to show that it is not safe to neglect the curvature and that this may lead to, and has led to, dams with tension in the up-stream face. Such a dam is not in fact a gravity dam, since it will not stand by gravity, but requires tension in the up-stream face.

Let B be the base width (Figs. 1 and 2) and H the height of a triangular section with a vertical up-stream face and let w be the weight of a cubic foot of concrete; then if uplift is assumed as negligible and if the water level stands even with the crest of the dam, the section determined by,*

$$B = H\sqrt{\frac{62.5}{w}} \qquad (2)$$

will have zero stress at the heel when the reservoir is full, provided the dam is straight. If the dam is arched there will be tension in the up-stream face, on the assumption that the cantilever carries the entire load and, in general, this assumption will be the correct one and always on the safe side.

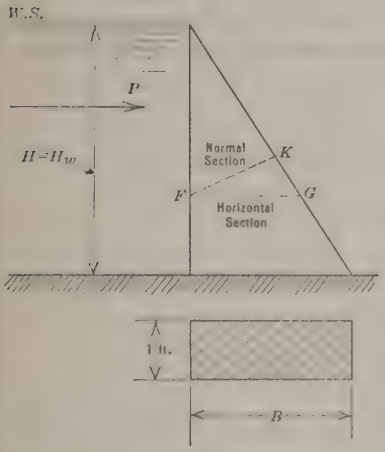

Fig. 1.

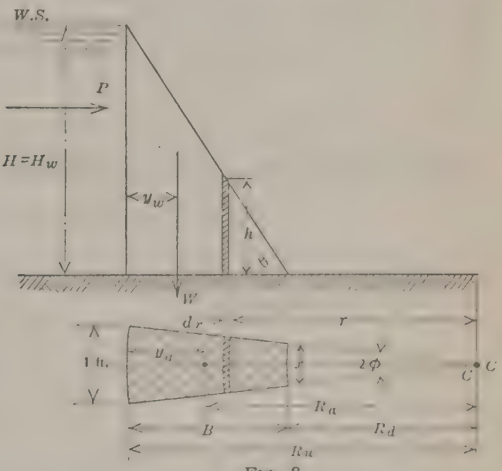

Fig. 2.

In deriving the ordinary bending formulas, it is assumed that normal sections remain plane when the shear deformations are neglected; but a horizontal section, such as $F\ G$ in Fig. 1, is not a normal section, as is $F\ K$. The writer has dealt elsewhere† with this question and the approximation introduced by substituting an oblique section for a normal section, but in order to avoid mathematical complications, the assumption that horizontal sections remain plane will be maintained. It is very essential, however, that the designing engineer bears in mind that the theory is not exact; then he will not be tempted to reduce the section to the theoretical minimum.

* See, for example, the writer's discussion in *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 93.

† "Stresses in Multiple-Arch Dams." *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 289; see, also, Professor Cain's discussion on p. 316. Also, Professor Résal's paper, "Formes et dimensions des grands barrages en maçonnerie," *Annales des Ponts et Chaussées*, II, 1919.

In this paper a triangular vertical section with a vertical up-stream face will be considered. It is customary to give the up-stream face a slight batter in order that there may be no tension in the down-stream face when the reservoir is empty. There can be no objection to such a batter. On the other hand, it is much more important to make sure that tension does not exist in the up-stream face when the reservoir is full, because if this results in a horizontal crack, the tension is thereby increased. Conversely, if there is tension in the down-stream face with reservoir empty, and a crack results, the tension is thereby reduced; the crack in the down-stream face is, therefore, self-limiting and is not likely to be more than a mere surface crack, while a crack produced by tension in the up-stream face is dangerous. Two fairly large dams have failed from tension in the up-stream face several years after they were built.*

Formulas for Stresses

Consider in Fig. 2 a volume 1 ft. wide at the up-stream face and limited by two vertical radial planes, instead of by two vertical parallel planes. Let R_u be the radius of the up-stream face; B, the base width of the section; R_d, the radius of the down-stream face; and $2\,\phi$, the central angle of the sector. Then,

$$2\,\phi = \frac{1}{R_u}$$

and the width of the down-stream face is,

$$x = 2\,\phi\,R_d = 2\,\phi\,(R_u - B) = 1 - \frac{B}{R_u} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The distance, R_a, from the center, C, to the center of gravity of the base is given by Merriman:†

$$R_a = \frac{2}{3}\,\frac{R_u^3 - R_d^3}{R_u^2 - R_d^2}\,\frac{\sin\,\phi}{\phi} = \frac{2}{3}\,\frac{\sin\,\phi}{\phi}\,\frac{R_u^2 + R_u R_d + R_d^2}{R_u + R_d}$$

$$= \frac{2}{3}\,\frac{\sin\,\phi}{\phi}\,\frac{(R_u + R_d)^2 - R_u R_d}{R_u + R_d} = \frac{2}{3}\,\frac{\sin\,\phi}{\phi}\left(2\,R_m - \frac{\left(R_m + \frac{B}{2}\right)\left(R_m - \frac{B}{2}\right)}{2\,R_m}\right)$$

$$= \left(R_m + \frac{B^2}{12\,R_m}\right)\frac{\sin\,\phi}{\phi}$$

in which, $R_m = R_u - \frac{B}{2}$, is the mean radius.

The distance from the up-stream face to the center of gravity of the base is then,

$$y_a = R_u - \left(R_m + \frac{B^2}{12\,R_m}\right)\frac{\sin\,\phi}{\phi} = \left(\frac{B}{2} - \frac{B^2}{12\,R_m}\right)\frac{\sin\,\phi}{\phi} + R_u\left(1 - \frac{\sin\,\phi}{\phi}\right)$$

The last term is always very small, because ϕ is small; for $R_u = 100$ ft., it becomes 0.0004 ft.; for $R_u = 500$ ft., it is 0.0000835 ft. Since y_a is approxi-

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII, Session 1907–08, Part II, p. 73. The two dams are the Habra Dam in Algiers and the Bouzey Dam in France.

† American Civil Engineers Handbook, Fourth Edition, 1920, Section 12, Article 23, p. 1471.

mately equal to $\frac{B}{2}$, the last term is negligible and $\frac{\sin \phi}{\phi}$ is always practically equal to 1, so that, very nearly,

$$y_a = \left(\frac{B}{2} - \frac{B^2}{12\,R_m}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

For a straight dam, $\frac{B^2}{12\,R_m}$ vanishes, so that $y_a = \frac{B}{2}$ as it should.

The volume of the dam sector limited by the two vertical radial planes (Fig. 2) is found by multiplying the area of the triangle, or $0.5\,B\,H$, by the length of the path described by the center of gravity of the triangle, as it revolves about the center, C. The length of this path is,

$$2\,\phi\left(R_u - \frac{B}{3}\right) = 1 - \frac{B}{3\,R_u} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

If w is the weight per cubic foot of concrete and all dimensions are in feet, the weight of the dam sector is,

$$W = \frac{w}{2}\,B\,H\left(1 - \frac{B}{3\,R_u}\right) \text{ lb} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

For a straight dam, $\frac{B}{R_u}$ vanishes and Equation (6) remains correct.

The position of the center of gravity of the volume is found by determining the moment of the volume about C and then dividing by W. The moment about C of the part of a cylindrical surface indicated in Fig. 2, is,

$$\text{Moment} = w\,h\,dr \times 2\,r\,\phi \times r\,\frac{\sin \phi}{\phi}$$

since the center of gravity of this thin cylindrical surface is given by $r\,\frac{\sin \phi}{\phi}$. The moment about C of the whole volume is, then,

$$M_c = \int_{R_u - B}^{R_u} 2\,r\,w\,\phi\,h\,dr\,r\,\frac{\sin \phi}{\phi} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

From Fig. 2,

$$\frac{h}{H} = \frac{r - R_d}{R_u - R_d}$$

or,

$$r = \frac{B}{H}\,h + R_d$$

Introducing this into Equation (7),

$$M_c = 2\,w \sin \phi \int_0^H \left(\frac{B}{H}\,h + R_d\right)^2 \frac{B}{H}\,h\,dh$$

$$= w\,H\,B \sin \phi \left(R_d^2 + \frac{4}{3}\,B\,R_d + \frac{B^2}{2}\right)$$

The length of the path of the center of gravity of the triangle in Fig. 2, is, from Equation (5),

$$2\,\phi\left(R_u - \frac{B}{3}\right) = 2\,\phi\left(R_d + \frac{2}{3}\,B\right)$$

so that the weight of the volume of the dam is,

$$W = w\ \phi\ B\ H \left(R_d + \frac{2}{3}\ B\right)$$

and since,

$$\left(R_d + \frac{2}{3}\ B\right)^2 = R_d^2 + \frac{4}{3}\ B\ R_d + \frac{4}{9}\ B^2$$

the distance from C to the center of gravity of the volume of dam, is,

$$r_w = \frac{M_c}{W} = \left(R_d + \frac{2}{3}\ B + \frac{B^2}{18\left(R_d + \frac{2}{3}\ B\right)}\right)\frac{\sin\phi}{\phi} \quad \ldots\ldots (8)$$

Designate by y_w the distance from the up-stream face to the center of gravity of the volume, then, $y_w = R_u - r_w$, and since $\frac{\sin\phi}{\phi}$ is practically unity,

$$y_w = \frac{B}{3} - \frac{B^2}{18\ R_u\left(1 - \frac{B}{3\ R_u}\right)} \quad \ldots\ldots\ldots\ldots\ldots (9)$$

The moment of inertia of the trapezoidal base in Fig. 2 with reference to its own center of gravity is,*

$$I = \frac{B^3}{36}\left(\frac{x^2 + 4\ x + 1}{x + 1}\right) \quad \ldots\ldots\ldots\ldots\ldots (10)$$

in which, x is given by Equation (3), as,

$$x = 1 - \frac{B}{R_u}$$

By direct integration is found,

$$I = \frac{\phi}{4}\ (R_u^4 - R_d^4) - \frac{\phi}{2}\ (R_u^2 - R_d^2)\ R_d^2$$

The expression given in Equation (10) is much more convenient. If the water level is H_w ft. above the base, the horizontal water pressure is $31.25\ H_w^2$ and the moment about the base is,

$$M_P = -\frac{62.5}{6}\ H_w^3 \quad \ldots\ldots\ldots\ldots\ldots (11)$$

The weight acting in the center of gravity of the volume may be considered as producing a vertical downward thrust equal to W and applied in the center of gravity of the base, and a moment,

$$M_w = W\ (y_a - y_w)$$

This moment acts in a direction opposite to the M_P produced by the water pressure; the resulting moment is, therefore,

$$M = -\frac{62.5}{6}\ H_w^3 + W\ (y_a - y_w) \quad \ldots\ldots\ldots\ldots\ldots (12)$$

From Equations (4) and (9),

$$y_a - y_w = \frac{B}{6} - \frac{B^2}{36\ R_m\left(1 - \frac{B}{3\ R_u}\right)} \quad \ldots\ldots\ldots\ldots\ldots (13)$$

* See, Goodman, "Mechanics Applied to Engineering" (1912), p. 86.

The vertical stresses at the up-stream and down-stream faces, respectively, are then,

$$\left.\begin{aligned} s_u &= \frac{W}{A} + \frac{M}{I}\, y_a \\ s_d &= \frac{W}{A} - \frac{M}{I}\,(B - y_a) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (14)$$

in which, A, the area of the base, is,

$$A = B\left(1 - \frac{B}{2\,R_u}\right) = B\,\frac{1+x}{2} \quad \ldots\ldots\ldots\ldots (15)$$

In Equation (14) compression is positive and *vice versa*. The maximum compression, $s_{max.}$, occurs at the down-stream face and is parallel to that face*:

in which,

$$\left.\begin{aligned} s_{max.} &= \frac{s_d}{\sin^2\theta} \\ \tan\theta &= \frac{H}{B} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (16)$$

Influence of Uplift

Assume that uplift is a maximum at the heel, decreasing linearly to zero at the toe. If the maximum uplift pressure is $62.5\ k\ H$ lb. per sq. ft., the coefficient, k, measures the percentage, so that for $k = 1$† the maximum possible uplift is considered and for $k = 0$, there will be no uplift. The total uplift acting on the trapezoidal base is, by Equation (6),

$$U = \frac{62.5}{2}\, k\, B\, H\left(1 - \frac{B}{3\,R_u}\right) \text{ lb.} \quad \ldots\ldots\ldots\ldots (17)$$

Its point of application is given by Equation (9), since the uplift may be considered as due to a triangular mass of water acting on the base. It follows that provision for uplift may be made by substituting, in Equations (12) and (13), $W - U$ for W, or simpler still, by reducing w accordingly. If, for example, $w = 150$ lb. per cu. ft. and full uplift is to be assumed, the new value is,

$$w' = 150 - 62.5 = 87.5 \text{ lb. per cu. ft.}$$

If w' is substituted in Equation (2) for w, this equation gives B direct. If, for example, $w = 150$, Equation (2) gives $B = 0.645\ H$; if $w' = 87.5$, that is, full triangular uplift, then $B = 0.845\ H$. Equation (2) is correct only for a straight triangular dam having water level with the crest.

The foregoing formulas are correct for any radius of curvature and, therefore, also for a straight dam for which the radius of curvature is infinitely great.

* "Stresses in Masonry Dams," by William Cain, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXIV (1909), p. 208.

† $k = 1$ is a limiting condition, which may be approached but cannot be reached, since the weight of the concrete exceeds the uplift and, therefore, some part of the base must have contact with the foundation.

Example

When the radius of curvature has a finite value, the relation between the height and the required base width cannot be reduced to a simple formula, such as Equation (2), which applies only to a straight dam. In order to ascertain the influence of curvature it is more convenient to consider an actual case—to compute the stresses on the assumption that the dam is straight and then to re-compute them for an arched dam having the same section. Consider, therefore, a horizontal section of the Exchequer Dam of the Merced Irrigation District, Merced, Calif.* At Elevation 437.5, the dimensions are, $H = H_w = 272.5$ ft.; $B = 171.4$ ft.; $R_u = 674.7$ ft.; and $R_m = 589$ ft. The actual section is not triangular with a vertical up-stream face, but has a definite top width, and the up-stream face is battered, so that at the elevation considered it lies 1.97 ft. up stream from the crest. The dimension, B, used in the calculations is the actual total base width; it has merely been shifted 1.97 ft. down stream. The approximation involved in substituting the ideal triangular section for the actual section is a very close one.

If the dam were straight the value of w, giving zero stress at the heel with the reservoir full, may be obtained from Equation (2), since the dimensions are known. This gives $w = 160$ lb. per cu. ft.—an unusually high value for designing a gravity dam; but if w is assumed as less, a straight dam of the section given would show tension in the up-stream face. Assuming, now, $w = 160$, $y_a = 81.54$ ft.; $W = 3\,418\,000$ lb.; $y_w = 54.49$ ft.; $I = 364\,000$ ft.^{4}; $x = 0.746$ ft.; and from Equation (12),

$$M = -210\,800\,000 + 578\,000\,w = -118\,400\,000 \text{ ft-lb.}$$

The area of the base is $A = 149.5$ sq. ft., and the vertical stresses at the heel and toe, respectively, are, $s_u = -25.9$ lb. per sq. in. (tension) and $s_d = 362.0$ lb. per sq. in., and the maximum stress is $\frac{362}{0.847^2} = 504$ lb. per sq. in. If the dam had been straight, the stresses would have been $s_u = 0$, and $s_d = 303$ lb. per sq. in. If $w = 152.0$ is assumed, the actual section ($R_u = 674.7$ ft.) gives $s_u = -40.5$ lb. per sq. in (tension).

Consider that there is 50% uplift at the heel and none at the toe, and a linear decrease; also, assume $w = 152$, so that,

$$w' = 152 - 31.25 = 120.75 \text{ lb. per cu. ft.}$$

Then, for $H = H_w = 272.5$ and a straight dam, from Equation (2), $B = 196$ ft. If, as before, $R_u = 674.7$ ft., $H = 272.5$ ft., but $B = 196$ ft., so that $R_m = 576.7$ ft., then the values will be $x = 0.7095$ ft.; $W = 2\,912\,400$ lb. (this is actually the weight less the uplift, since w' and not w was used); $M = -121\,607\,000$, since $y_a - y_w = 30.618$ ft.; the area, $A = 167.53$ sq. ft.; $y_a = 92.45$ ft.; $I = 531\,160$; and the stress in the up-stream face with reservoir full is, $s_u = -26.3$ lb. per sq. in. (tension).

* A section of this dam is given in *Western Construction News*, January 25, 1926, p. 25.

General Remarks

From this example evidently it is never safe to neglect the curvature; the higher the dam and the smaller the radius, the larger is the error committed when the dam is computed as straight.

It is also evident that an arched gravity dam will receive some support from the arch and, in most cases, probably sufficient support to prevent actual failure. As gravity dams are usually constructed, however, the arch cannot act until the cantilever has been broken, and in that case uplift would be present. The writer has discussed this phase in his paper entitled "Stresses in Thick Arches of Dams",* and also made mention of the shrinkage cracks in the Mulholland Dam, which proves that the dam is not acting as an arch dam. In a properly designed gravity dam the shrinkage cracks are of little consequence; but when tension is present in the up-stream face the dam should be computed as an arch dam, since it does not appear safe to rely on tension in the concrete, especially across construction joints.

In the writer's opinion the most important condition to impose on a gravity design is that there must be no tension in the up-stream face when the water surface is at the maximum height; it is also well to bear in mind that the assumption of no uplift is the least conservative that can be made, and while no doubt occasionally it is safe, especially when proper drainage is provided, there is always the possibility, not to say certainty, that the drainage will fail at least partly. For reservoir full, the stress at the toe is of importance only for very high dams, but the stress at the heel is by far the most important.

The writer is fully aware of the uncertainties involved in determining the stresses near the foundation of a gravity dam. This uncertainty arises partly from the unknown distribution of the shear near the base.† This phase of the subject has been purposely excluded, because it was desired to show the influence of curvature when the ordinary assumptions were maintained. As Professor Résal points out, a straight gravity dam may also act as an arch dam, since, in general, secondary horizontal arches may be found for any straight gravity dam. The extent of arch action will depend on the width of the site and on the method of construction; whether the dam was pressure grouted after the concrete had cured and the chemical heat had been dissipated; whether it was closed as late as possible; or, finally, whether no attempt at all was made to secure arch action in case the uplift for any reason should prove to be in excess of the assumption.

* *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 475.

† Professor Cain calls attention to this uncertainty in the opening sentence of his paper previously referred to and Professor Résal in the paper referred to deals at some length with this subject.

DISCUSSION

GEORGE R. RICH,* ASSOC. M. AM. SOC. C. E. (by letter).—Curving a gravity dam up stream does not add to the stability of the structure unless the vertical contraction joints between sections are pressure-grouted to insure contact after the heat due to chemical action has been dissipated and the resulting shrinkage has occurred. The writer believes that the volume changes of the entire mass caused by seasonal variations in temperature are of small magnitude compared to those produced by the heat liberated during the chemical process of setting. Temperature measurements on sections of the Wilson Dam show that several months may be required for the dissipation of the chemical heat.†

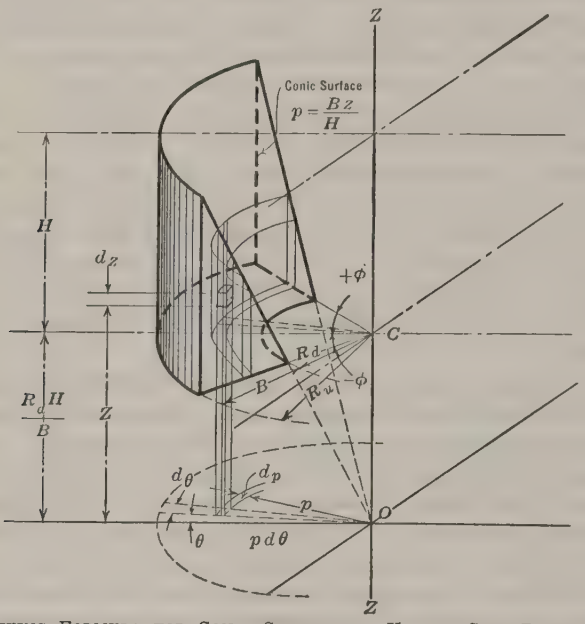

FIG. 3.—DERIVING FORMULA FOR CONIC SURFACE BY USE OF SEMI-POLAR CYLINDRICAL CO-ORDINATES.

Gravity dams of any appreciable length are ordinarily constructed in sections, with vertical contraction joints having shear keys and sealing strips, but without recourse to pressure grouting of the vertical joints. After the aforementioned initial shrinkage has occurred, there will be an opening between adjacent sections and before there could be sufficient deflection to give the contact prerequisite to action of the horizontal arch elements, the vertical cantilever elements would have to fail in tension near the heel of the dam. From this point action toward ultimate damage is progressive, owing to the effect of uplift pressure entering the tension cracks.

* Hydr. Designer, Stone & Webster, Inc., Boston, Mass.

† "Control of Mixture and Testing of Wilson Dam Concrete," by John W. Hall, *Proceedings*, Am. Concrete Inst., Vol. XXII, 1926.

The author demonstrates conclusively that the conventional method of calculating curved gravity sections does not furnish an accurate indication of the existence of heel tension with reservoir full. This analysis, excluding the uncertainty of shear distribution at the foundation as a defense of the usual method of calculation, is a step toward more rational determination of stresses in hydraulic structures.

His derivation of the fundamental formulas has the advantages of clearness and simplicity. The writer's independent check of Equations (7) and (8) by direct successive integration, using semi-polar cylindrical co-ordinates instead of the usual three-dimensional system, may be of some academic interest.

Let p = the radius vector, θ = the variable angle, and z, the height axis. (See Fig. 3.) Taking the origin of co-ordinates at the apex of the conic surface that includes the down-stream face of the dam, the equation of the conic surface is,

$$p = \frac{B\,z}{H}$$

from which the moment of the concrete about C (Equation (7)):

$$M_c = \int_{R_d}^{R_u} \int_{-\phi}^{\phi} \int_{\frac{R_d\,H}{B}}^{\frac{p\,H}{B}} w\,p^2 \cos\theta\,d\,p\,d\,\theta\,d\,z$$

$$= \frac{w \sin\phi\,H}{2\,B}(R_u^4 - R_d^4) - \frac{2\,w \sin\phi\,H\,R_d}{3\,B}(R_u^3 - R_d^3)$$

Simplifying and substituting $R_u = B + R_d$, there results:

$$M_c = w \sin\phi\,H\,B\left(R_d^2 + \frac{4\,B\,R_d}{3} + \frac{B^2}{2}\right)$$

The weight of the concrete,

$$W = \int_{R_d}^{R_u} \int_{-\phi}^{\phi} \int_{\frac{R_d\,H}{B}}^{\frac{p\,H}{B}} w\,p\,d\,p\,d\,\theta\,d\,z$$

$$= \frac{2\,\phi\,H\,w}{3\,B}(R_u^3 - R_d^3) - \frac{\phi\,H\,R\,d\,w}{B}(R_u^2 - R_d^2)$$

Simplifying and substituting $R_u = B + R_d$,

$$W = w\,\phi\,B\,H\left(R_d + \frac{2\,B}{3}\right)$$

A. Floris,* Esq. (by letter).—The author has derived formulas for the calculation of the trapezoidal stresses in curved gravity dams of a triangular profile.

The influence of the curvature on the shape of the horizontal sections is commonly considered by careful designers. The Italian professors, G. Ganassini and A. Danusso,† in checking the design of the gravity base of the Gleno

* Los Angeles, Calif.

† "Relazione peritale sopra la cause che hanno determinato la rovina della diga de pian di Gleno in Val di Scalve, crollata la mattina del 1° dicembre, 1923," *Annali* dei Lavori Publici, Anno LXII, Fasc. 5, Maggio, 1924, pp. 427–428.

Dam, after its failure, used similar expressions for the calculation of the trapezoidal stresses. The derivation of these formulas is given here in some detail.

Making (see Fig. 4):

$$d = a\,\lambda \quad \text{and} \quad b = a + \mu\,d = a\,(1 + \mu\,\lambda)$$

the area of the section will be,

$$A = \frac{d}{2}\,(a + b) = \frac{a\,d}{2}\,(2 + \mu\,\lambda) \qquad (18)$$

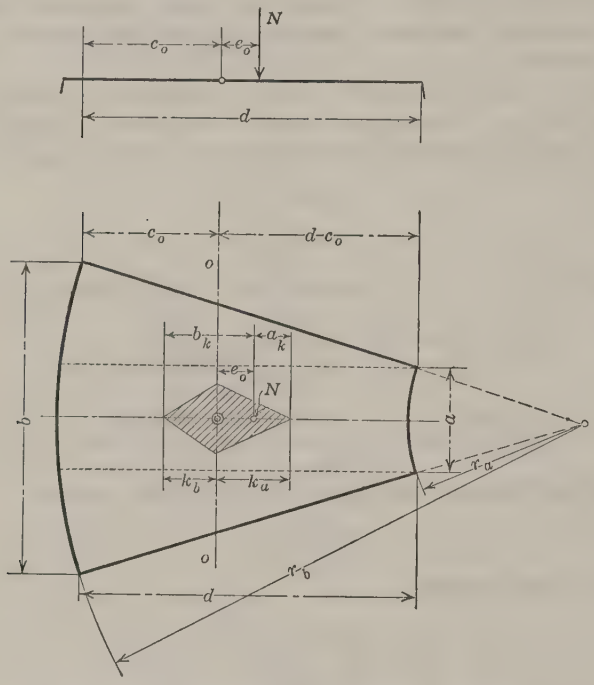

FIG. 4.—CALCULATION OF TRAPEZOIDAL STRESSES.

The distance of the center of gravity of this area from the up-stream face is,

$$c_0 = \frac{d}{3}\,\frac{2\,a + b}{a + b} = \frac{d}{3}\,\frac{3 + \mu\,\lambda}{2 + \mu\,\lambda}$$

and the moment of inertia of the section with respect to the axis, o - o, has the value,

$$I = \frac{a\,d^3}{36}\left[3 + \mu\,\lambda + \frac{(1 + \mu\,\lambda)^2 - 1}{(2 + \mu\,\lambda)^2}\right] \qquad (19)$$

which is derived as follows: Using the well-known formula:

$$I_c = I_0 + A\,c^2 \qquad (20)$$

there is obtained for the two triangles and the rectangle, respectively, into which the total area, A, may be divided, the values,

$$I_t = \frac{a\,d^3}{36}\,\mu\,\lambda$$

and,

$$I_r = \frac{a\,d^3}{12}$$

and for their sum the value,

$$I_0 = \frac{a\,d^3}{36}\,(3 + \mu\,\lambda) \qquad (21)$$

The distances of the centers of gravity of the partial areas from the center of gravity of the total area are given by,

$$c_t = \frac{d}{3}\,\frac{3 + \mu\,\lambda}{2 + \mu\,\lambda} - \frac{d}{3} = \frac{d}{3}\,\frac{1}{2 + \mu\,\lambda}$$

and,

$$c_r = \frac{d}{2} - \frac{d}{3}\,\frac{3 + \mu\,\lambda}{2 + \mu\,\lambda} = -\frac{d}{6}\,\frac{\mu\,\lambda}{2 + \mu\,\lambda}$$

while their corresponding areas are,

$$A_t = \frac{a\,d}{2}\,\mu\,\lambda \quad \text{and} \quad A_r = a\,d \qquad (22)$$

so that there is,

$$A_c{}^2 = \frac{a\,d^3}{36}\left[\frac{2\,\mu\,\lambda}{(2 + \mu\,\lambda)^2} + \frac{\mu^2\,\lambda^2}{(2 + \mu\,\lambda)^2}\right] = \frac{a\,d^3}{36}\,\frac{(1 + \mu\,\lambda)^2 - 1}{(2 + \mu\,\lambda)^2} \qquad (23)$$

The sum of the values of Equations (22) gives Equation (18), while the addition of Equations (21) and (23), according to Equation (20), results in Equation (19).

The stresses at the down-stream and up-stream faces are given, respectively, by,

$$\left.\begin{aligned} \sigma_a &= \frac{N}{A} + \frac{N\,e_0}{I}\,(d - c_0) \\ \sigma_b &= \frac{N}{A} - \frac{N\,e_0}{I}\,c_0 \end{aligned}\right\} \qquad (24)$$

Because, as the author correctly states, the middle-third theorem does not hold for curved dams, it may be appropriate to introduce the core theory (German, "kern") in the stress analysis of such structures. This gives a simple means of knowing whether or not tension does occur, because by excluding tension the resultant of all the forces must fall within the core.

The two points of the core on the line of symmetry of the section are given by the core radii:*

$$k_b = \frac{I}{A\,(d - c_0)} \quad \text{and} \quad k_a = \frac{I}{A\,c_0} \qquad (25)$$

Solving for I and putting these values into Equation (24),

$$\left.\begin{aligned} \sigma_a &= \frac{N}{A}\,\frac{k_b + e_0}{k_b} = +\frac{N}{A}\,\frac{b_k}{k_b} = +\sigma_0\,\frac{b_k}{k_b} \\ \sigma_b &= \frac{N}{A}\,\frac{k_a - e_0}{k_a} = \pm\frac{N}{A}\,\frac{a_k}{k_a} = \pm\sigma_0\,\frac{a_k}{k_a} \end{aligned}\right\} \qquad (26)$$

If $e_0 = k_a$, then $\sigma_b = 0$, while when $e_0 > k_a$, there is tension at the up-stream face and σ_b is negative.

* "Die graphische Statik der Baukonstruktionen," H. Mueller-Breslau, Erster Band, 4 Auflage, 1905, p. 78; see, also, "Strength of Materials," by George F. Swain, Past-President, Am. Soc. C. E., N. Y., 1924, pp. 168-175.

Equations (25) and (26) are general expressions and valid for any section, provided the proper values for A and I are introduced.

In case the dam is straight in alignment, the horizontal section is a rectangle, and $b = a$. Consequently,

$$A = b\,d$$

$$I = \frac{b\,d^3}{12}$$

and,

$$c_0 = d - c_0 = \frac{d}{2}$$

and Equations (25) become,

$$k_b = k_a = \frac{d}{6} \qquad (27)$$

It will be seen, therefore, that the middle-third theorem is merely a special case of the more general core theorem. With the values of Equation (27), Equations (26) take the form,

$$\sigma_a = + 6\,\sigma_0\,\frac{b_k}{d} \text{ and } \sigma_b = \pm 6\,\sigma_0\,\frac{a_k}{d}$$

in which, if $e_0 > \frac{d}{6}$, σ_b becomes negative.

As far as uplift in gravity dams is concerned the following statements are perhaps of interest.*

Under the assumption of an uplift pressure distributed linearly over the entire base or a joint it can be shown† that the pressure diagram is identical with its stress diagram. From this follows as a corollary‡ that in a triangular, rectangular, or trapezoidal distribution of the uplift, the stresses at the heel are equal in all three cases, provided the intensity of the uplift at this point is assumed to be equal.

It can be concluded therefrom also that the stresses due to uplift are of no importance at any point except at the heel and that in a triangular distribution of the uplift the stress at the toe is independent of this pressure.

The author's Equation (2) for rectangular sections was given by many writers, years ago.§

The question whether inclined or horizontal sections should be considered in the calculation of the trapezoidal stresses has been the subject of much discussion in recent years. Professor J. Résal,‖ using elementary methods, devotes nine pages in order to show the necessity of investigating inclined

‖ "Formes et dimensions des grands barrages en maçonnerie," *Annales des Ponts et Chaussées*, 1919, II, Mars-Avril, pp. 165–221.

sections. His main reason was that the horizontal sections are not perpendicular to the bisectrix of the angle, formed by the up-stream and down-stream faces at the crest of the dam. Professor Résal concludes therefrom that the usual bending formulas for prismatic bars are no more valid for beams of triangular shape. In order to correct this discrepancy, he suggested the assumption of the bisectrix as the neutral axis, taking the sections under consideration normal to it.

Dr. Gebauer* also recommends the investigation of these normal sections because, as he claims, tension may occur at the up-stream face of the dam, while stress investigations for horizontal sections fail to detect this. He states, further, that the stresses, thus computed, for gravity dams might be 35% higher than those found by considering horizontal sections.

The use of inclined sections can only be justified, if the dam is analyzed according to the old theory, in which the determination of the trapezoidal stresses alone was considered to be sufficient. However, if the principal stresses are calculated, the use of inclined sections is not necessary. Assuming "plane strain" and the validity of the law of the trapezoid, Dr. Kelen† has shown that for triangular profiles the same principal stresses are obtained regardless of whether horizontal or inclined sections are used. Inasmuch as the stress computations are much simpler for horizontal sections, most designers will prefer this method of procedure.

LARS R. JORGENSEN,‡ M. AM. SOC. C. E. (by letter).—This is not the first time that the author has called attention to the fallacy of arching a gravity dam in plan expecting an increase in stability of the structure therefrom at all seasons. Mr. Jakobsen has shown that a gravity dam should be straight in plan for maximum safety, with a minimum expenditure of material.

If a gravity dam possess a factor of safety of two under the worst conditions of uplift, ice pressure, etc., it has been regarded as a sufficiently stable structure, and probably the future will not change anything in this respect.

Fig. 5 which was prepared for comparing the cross-sections of the highest gravity dams, shows that there is a wide difference in the various profiles. The Kensico Dam, constructed by the Board of Water Supply of New York, N. Y., apparently is the most conservative, and the Exchequer Dam, built by the Merced Irrigation District, California, the least conservative, of all high gravity dams thus far constructed. Between these two extremes is the O'Shaughnessy Dam at Hetch Hetchy, Calif., and the Camarassa Dam, in Spain. These two dams are actually a little more conservative than their relative location on the diagram would indicate, because ice pressure is negligible for both. The two sections nearly coincide and could well be termed standard gravity sections as they represent the middle between the most and the least conservative in high dams. The safety of gravity dams having sections similar to or greater than the two named cannot be questioned, but not all projects can stand the expense of such heavy sections and, consequently,

‡ Cons. Engr., Constant Angle Arch Dam Co., San Francisco, Calif.

the safety is reduced somewhat to suit the purse of less fortunate projects. It is a fact that in many places where slim gravity sections have been built much safer arch dams could have been substituted for less money.

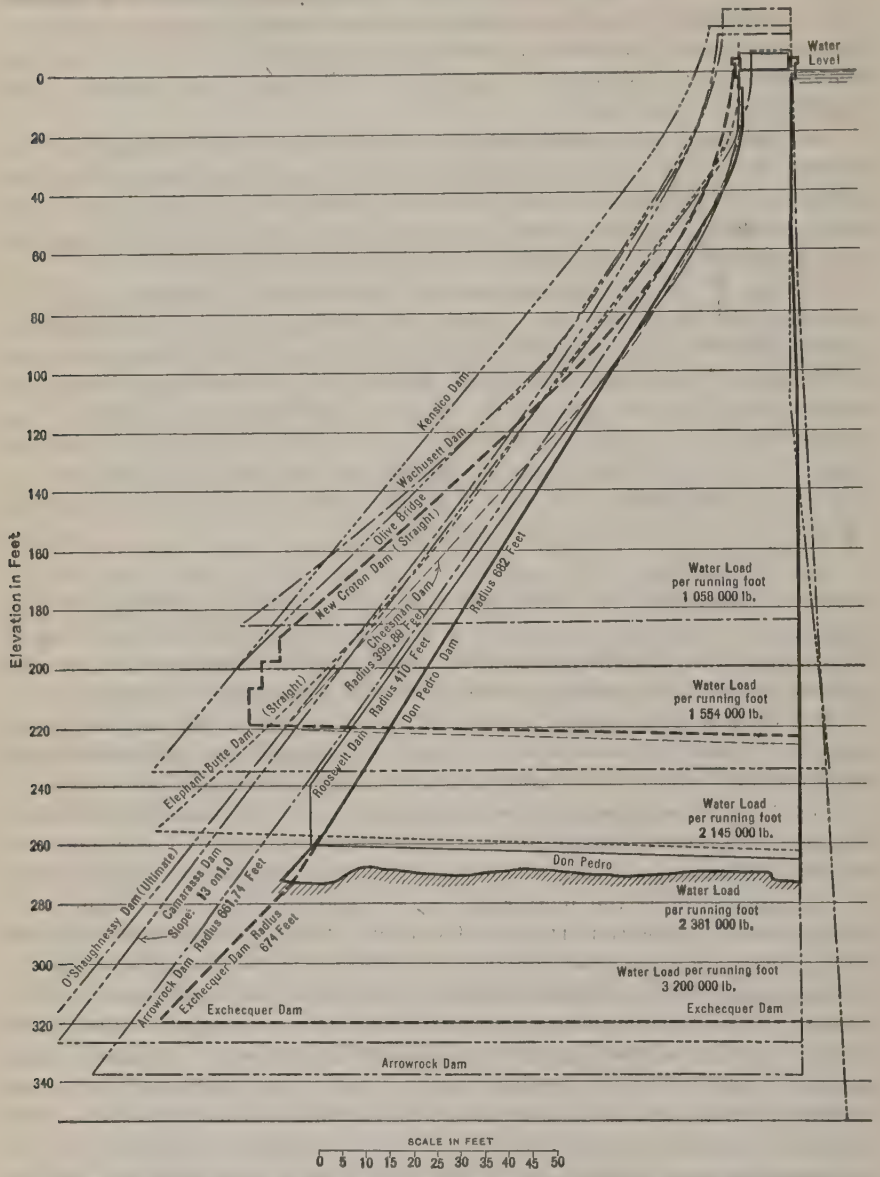

FIG. 5.—MAXIMUM CROSS-SECTIONS OF VARIOUS GRAVITY DAMS SUPERIMPOSED FOR COMPARISON.

In the past the Engineering Profession has been very much divided as to the relative merits of gravity and arch dams; this is still true although to a much less extent. At times, this controversy has resembled a political issue.

The general tendency of the profession to-day is a more favorable attitude toward the arch type in places where arch dams will fit. The problem is now better understood. The merits of strength and economy inherent in an arch dam cannot be overlooked any longer by even the most enthusiastic of gravity dam supporters.

The author's reference to the Exchequer Dam is of interest to the writer who, at one time, was connected with that project and, therefore, is well acquainted with it. An arch dam on this site would have been cheaper and safer than the one built. At that time, the State (California) authorities' distrust in arch dams prevented the construction of the one shown in Fig. 6. This design was made by A. C. Hoff, Chief Designing Engineer of the Constant Angle Arch Dam Company, and the structure was nearly 20 ft. high when the so-called gravity arch dam, described by the author, was substituted. The arch dam (Fig. 6) required 310 000 cu. yd. of concrete as compared with 370 000 cu. yd. for the gravity dam, calculated to the same estimated rock contours. The excavation proved to be more than the estimated amount, but that would not have greatly disturbed the ratio of saving in material. Therefore, a more expensive dam was substituted for a cheaper one.

The design (Fig. 6) was made so that the stresses in the arch dam, using the Cain method of calculation and assuming the entire load to be carried by the arch down to and including Elevation 500, were about 500 lb. per sq. in., compression, and less than 100 lb., tension, which is considered conservative. At and below Elevation 475 the arch does not carry all the load. Shear and various other actions take the principal part on account of the arch being short and thick, and close to the bottom. If, for instance, all the load on the dam below Elevation 475 was transmitted to the foundation through shear action along the rock contact, the average shear would be 45 lb. per sq. in. As the punching shear cannot be transmitted without calling into play arch and cantilever action, a division of load takes place. Although it is hopeless to attempt to calculate the exact distribution, it is easily seen that the part of the load falling on the arch is only small and, therefore, will not cause dangerous tension anywhere in the faces. Horizontal tension along any of the faces of an arch is not dangerous if paired with a compression of moderate value along the opposite face, and is never as dangerous as horizontal tension in the up-stream face of a gravity dam. Furthermore, any apparent tension along the up-stream face will always be greatly relieved or entirely compensated by the swelling effect of the water on the concrete.

The arch at, and below, Elevation 475 will carry the full water load, but apparent tension of more than 100 lb. per sq. in. would develop, and, at present, this tension is regarded as the upper limit. Using the simple cylinder formula as a check, the average stress at Elevation 475 would be 235 lb. per sq. in., assuming all the load to be carried by the arch. Although the stresses are not uniformly distributed for normal load, they are practically thus distributed at the point of failure, which point, therefore, evidently will not be reached until the load has been increased more than ten times the normal at Elevation 475.

Vertical cantilever action in the ordinary sense has not been counted on to support any load inasmuch as under the most unfavorable condition of water-soaking effect (a maximum water-soaking along the up-stream face decreasing gradually to nothing along the down-stream face), the cantilever bends in a down-stream direction without developing any resistance against the water pressure, and, therefore, it cannot carry any load. It is hardly possible to conceive that the water-soaking effect stops at the up-stream face, the remainder of the dam body being dry. Capillary action is always present to some extent.

Allowing for some faulty filling of the contraction joints, and for any conceivable disadvantageous action of the load, this dam can be relied on to possess a minimum factor of safety of five, and this is as much as is economically desirable.

The gravity dam which was actually built has a cross-section, as shown in Fig. 5, and is arched in plan. The arching of a gravity dam may look good, but otherwise it is a detriment to the stability of the cantilever as shown by the author. Unless the up-stream radius is much shorter than 674.7 ft., or the contraction joints are grouted properly, there will be no arch action to aid the cantilever with reservoir full during, and right after, cold weather. During this time the contraction joints have opened at the rate of approximately ¼ in. per 50 ft. length of crest and the voussoirs, therefore, have no contact.

One must not forget that, in arching a dam, the area on which the load acts becomes larger than that for a straight dam having the same amount of material and, at the same time, the center of gravity of the whole mass moves in a down-stream direction, both these items being detrimental to the stability of a dam acting by gravity.

A straight gravity dam of the same total mass as a curved one would have a greater cross-section; the distance between the center of gravity and the down-stream toe would also be greater. As the safety factor is in direct proportion to the product of weight and distance from the turning point, it is plain that it is uneconomical to arch a gravity dam in plan without having the contraction joints properly closed in order to obtain arch action.

Before arch action can take place with the voussoirs separated by a contraction crack, the middle of the dam must first slide bodily in a down-stream direction, but after such a slide it would be very difficult to make the structure water-tight. The Exchequer Dam, at the middle, should deflect slightly more than 1 in. down stream when fully loaded at the crest. This corresponds to a shortening of 0.852 in. at the crest of the dam.

Ordinarily, at the end of a cold period, the length of a dam decreases ¼ in. in 50 ft. The contraction joints open ¼ in., if spaced 50 ft. apart, cracks appear, or else tension is set up. During March and April, the crest of the Exchequer Dam, therefore, would have spaces between the voussoirs of approximately 4 in. with reservoir empty (the crest is more than 800 ft. long).

The cantilever deflection due to full load only shortened the crest 0.852 in., and there is, therefore, a space of approximately 3 in. to be closed with

FIG. 6.—DESIGN OF EXCHEQUER DAM AND SPILLWAY.

reservoir full before contact between the voussoirs is possible, and only after closing can arch action begin. This dam, therefore, must stand by virtue of its weight, and due to the vertical tension along the up-stream face, the margin of safety is uncertain and cannot be very great.

It is not very conservative, to say the least, to allow any vertical tension along the up-stream face of a gravity dam. This is altogether different from having a certain amount of horizontal tension in an arch dam. If vertical tension causes a crack in a gravity structure, the dam is a failure; in an arch, a crack from horizontal tension would merely cause a change in the value of the compression. This is the main reason that horizontal tension in one or the other faces of an arch should not be paired with a high compression in the opposite face, as mentioned.

The Exchequer Dam sustains a higher unbalanced water pressure than any other dam, and it possesses the slimmest cross-section thus far attempted for high dams. It will not fail for it has a factor of safety greater than one if it withstands the tension in the up-stream face. If not, arch action will come into play after a slide of some part of the structure in a down-stream direction. This, however, would be a failure, although not a calamity.

This dam, however, was successful in competition with the arch dam shown in Fig. 6, although the arch required 60 000 yd. less material for its construction. A full discussion on the subject is very desirable as much antagonism still seems to exist against arch dams and too much faith seems to be placed in almost any structure called a gravity dam.

P. Wilhelm Werner,* Assoc. M. Am. Soc. C. E. (by letter).—The author is evidently considering curved gravity dams with convex up-stream face. In this connection, however, it is interesting to compare the so-called arched gravity dam with a curved gravity dam presenting the rather unusual aspect

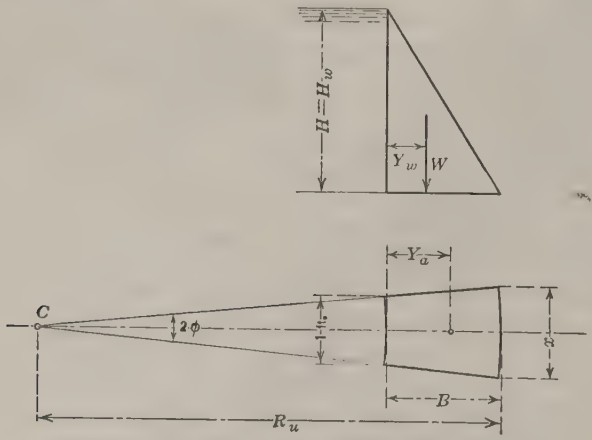

Fig. 7.—Dam with Convex Down-Stream Face.

of a convex down-stream face (Fig. 7). This type possesses some real advantages, in regard to stability, etc., that makes it worth while to consider in any actual case.

* Designing Engr., Stockholm, Sweden.

Using, as far as applicable, the same nomenclature and the same approximations for the computations as the author, the following set of formulas is developed:

$$y_a = \frac{B}{2} \; \frac{R_u - \frac{B}{3}}{R_u - \frac{B}{2}}$$

$$y_w = \frac{B}{3} \; \frac{R_u - \frac{B}{2}}{R_u - \frac{2}{3} B}$$

$$x = \frac{R_u}{R_u - B}$$

$$I = \frac{B^3}{36} \; \frac{1 + 4x + x^2}{1 + x}$$

$$A = \frac{B}{2} (1 + x)$$

$$W = \frac{B}{2} \; \frac{R_u - \frac{2}{3} B}{R_u - B} H w$$

$$M = -\frac{62.5}{6} H_w^3 + W (y_a - y_w)$$

Assume that the Exchequer Dam was designed with convex down-stream face, but of equal volume; so that, $H = H_w = 272.5$ ft.; $B = 171.4$ ft.; $R_u = 731.84$ ft.; $w = 160$ lb. per cu. ft.; with no uplift. This gives, $y_a = 89.5$ ft.; $y_w = 59.8$ ft.; $x = 1.305$ ft.; $I = 482\,000$ ft.^{4}; $A = 197.3$ sq. ft.; $W = 4\,120\,000$ lb.; and $M = -88\,800\,000$ ft-lb. Thus, from the author's Equation (14), the vertical stresses at the heel and toe, respectively, are 30.6 and 250 lb. per sq. in., both compression.

It is especially interesting to investigate the extent to which the base width of this dam can be reduced in order to obtain zero stress at the heel with reservoir full. If $B = 164$ ft., and the other dimensions are as given previously, the values are: $y_a = 85.5$ ft.; $y_w = 57.0$ ft.; $x = 1.29$ ft.; $I = 418\,000$ ft.^{4}; $A = 187.5$ sq. ft.; $W = 3\,920\,000$ lb.; and $M = -99\,100\,000$ ft-lb. Thus, from Equation (14), the vertical stress at the heel is 4.1 lb. per sq. in., compression; that is, practically zero.

Assuming that this section applies between two points, say, 200 ft. apart, the actual length of the dam would be about 201 ft. The volume then equals,

$$0.5 \times 272.5 \times 164 \times 201 = 4\,500\,000 \text{ cu. ft.}$$

The volume of a straight dam (base width = 171.4 ft.) between the same points would be,

$$0.5 \times 272.5 \times 171.4 \times 200 = 4\,670\,000 \text{ cu. ft.}$$

It is seen that the curved dam with the convex down-stream face proves to be nearly 4% cheaper than a straight dam designed according to the same gov-

erning rule. It should be noted that the assumed curvature may, or may not, be the most favorable one. It seems certain, however, that this involves a mathematical problem of finding the least cost in each actual case.

The layout of a dam in plan is, of course, to a great extent, governed by other influencing factors than stability. The geological formation at the dam site, the desirability of increasing the discharging length of the crest, and making the flood water converge better into the natural river channel below, are such factors. Aside from these points, however, under certain conditions, some economy may evidently result in giving the dam a slightly convex downstream face. The writer believes that the preference generally given to the arched gravity dam, is largely due to the additional support which the dam is assumed to receive from the arch. As arched gravity dams are usually constructed, however, this conception seems to be more or less illusory, although the arch action may prevent actual failure, if and when the cantilever has been broken. The writer is of the opinion that if it can be ascertained beyond doubt that the dam receives some support from the arch under working conditions, this should be taken into consideration in the design in order to obtain an economic structure. In case arch action cannot be absolutely ascertained, however, it seems more consistent with a proper economic design to impose upon the dam some other condition that is more easily and clearly realized.

Paul Bauman,* M. Am. Soc. C. E. (by letter).—Valuable equations have been derived by the author, which in a large measure supply the need for simple and yet accurate formulas for the determination of cantilever stresses in arch dams. Certain general conclusions have been advanced, however, which involve more or less error. A measure of the advantage or disadvantage of building a gravity dam, curved in plan, can only be determined after careful study of the topographic conditions.

A gravity dam is necessarily a very massive structure, and, due to the manner in which it is invariably built, the analysis of a thin vertical slice is insufficient. Consideration must be given to the effect of arch action and even of wedge action where the dam is built in narrow canyons. In principle, one might say that the wider the valley the less advantage there would be in a curved dam, assuming always equal foundation conditions along either a straight or curved location.

The possibilities of design of any massive dam lie between the limiting conditions of a straight cantilever dam of infinite length and a true arch dam. Under these ideal, limiting conditions there is either cantilever action or arch action only. In all practical cases, however, there will always be secondary cantilever action or secondary arch action, the amount in each case depending mainly on the ratio between the height and length, and the thickness and curvature, respectively.

It is the writer's opinion that there is insufficient justification for ignoring the effect of arch action in the case of a curved gravity dam, such as the

* Designing Engr., Quinton, Code & Hill, Los Angeles, Calif.

Exchequer Dam. Without question the actual arch action will not be in strict accordance with the computed arch action, but much less error will be involved in considering arch action than in eliminating it from consideration.

The author probably makes the assumption that, because of shrinkage in the concrete, contraction joints open and thus prevent any arch action. Compensating this shrinkage are other factors, such as plasticity and the swelling of the concrete due to absorption of moisture. Concrete has been known to flow even several years after the dam has been completed. Furthermore, contraction joints are not mathematic surfaces, and, as long as sufficient area is in contact to permit transmission of arch thrust without crushing, such arch action will be developed.

The writer has made an analysis of the stresses which, in his opinion, must closely approximate the actual stresses in the Exchequer Dam. The results of this analysis show the effect of arch support, and the conclusion is that no tensile stresses exist at the up-stream face, as claimed by the author, and that appreciable compressive stresses do occur instead, especially in the lower portions of the dam.

The radial cross-section of the dam was taken from *Western Construction News* of January 25, 1926, and the length of the up-stream face from Sheet No. 9 of the Merced Irrigation District, dated June, 1924. The water surface was assumed to be at the top of the dam at Elevation 710.0, and the up-stream radius, or R_u, constant at 675.0 ft. The notation used in this analysis is the same as that used by the author with the following additions:

t = radial thickness of dam.
h = head of water above horizontal sections.
L_u = length of extrados.
S = horizontal shear.
S'_A = deflection of arch slice = $C \frac{p\, r^2}{E\, t}$ (due to full load).*
δ_A = deflection of arch slice due to partial load.
δ'_B, δ'_S = deflection of cantilever due to bending and shear, respectively, due to full load.
δ_B, δ_S = deflection of cantilever due to bending and shear, respectively, due to partial load.
S_u = section modulus of up-stream face.
S_d = section modulus of down-stream face.
K_u = distance from center of gravity of horizontal section to down-stream limit of "kern".†
K_d = distance from center of gravity of horizontal section to up-stream limit of "kern".†
H_0 = polar distance of force polygons.
E = modulus of elasticity of concrete = 2 500 000 lb. per sq. in.

* "The Circular Arch Under Normal Loads," by William Cain, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 233.

† The "kern" of a section lies within the line as described by the point of application the neutral axis of which is a tangent on the section.

For the determination of δ'_B and δ_B, Mohr's method was used,* whereas for the determination of δ'_S, the least work method was used, as follows:

$$\delta'_S = \int_0^H \frac{S' S}{G A} d x$$

in which, $G = \frac{5}{13} E$ and $S' = -P = -1$ (Fig. 8). Therefore,

$$\delta'_S = -\frac{1}{G} \int_0^H \frac{S \, d x}{A} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

$$S = \frac{62.5 \, (H - x)^2}{2}; \; A = \frac{B}{H} (H - x)$$

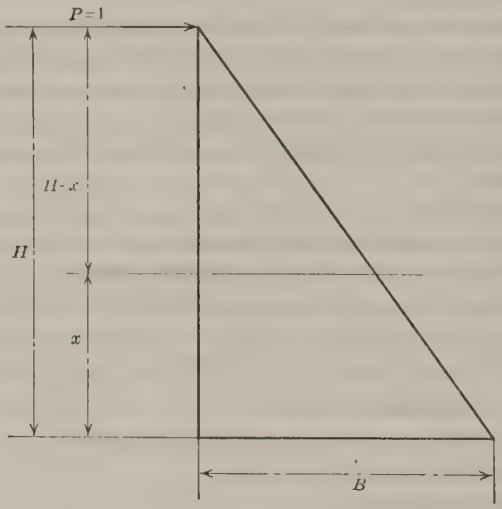

FIG. 8.

Introducing these values in Equation (28),

$$\delta'_S = -\frac{31.25 \, H}{G \, B} \int_0^H (H - x) \, d x = -\frac{31.25 \, H}{G \, B} \left[H x - \frac{x^2}{2} \right]_0^H$$

$$+ c \, (= 0) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

For the determination of δ_S (partial load) the $\frac{S}{A}$-area, Fig. 9 (*e*) was graphically integrated and multiplied by $\frac{1}{G}$; that is, Equation (28) was used in its form:

$$\delta_S = -\frac{1}{G} \sum_0^H \frac{S}{A}$$

In Table 1 various quantities, determined by the author's formulas, are shown. The vertical weights, W (based on a triangular section), their lever arms, $(y_a - Y_w)$, the distance, Y_a, from the up-stream face to the center of

* Beam action is greater than arch action.

† Water load for $w = 160$

‡ Water load for $w = 143$.

gravity, and the effective moments, M, are listed in Columns (5), (6), (7), and (11).

In Columns (12) to (24), Table 1, the areas, A, moments of inertia, I, section moduli, S_u and S_d, kern distance, K_u and K_d (Fig. 9(b)), and stresses, f_u and f_d (up-stream and down-stream face), are shown. In Columns (32), (35), and (39), the arch deflection, δ'_A, and the cantilever deflections, δ'_B and δ'_S, for full load (water surface at Elevation 710) are as shown in Fig. 9(a). The cantilever deflections, $\delta_C = \delta_B + \delta_S$, for partial load and the arch deflections, δ_A, for partial load are shown in Columns (50) and (55) to coincide closely enough to confirm the load distribution as shown in Fig. 9(e). A further adjustment of these deflections would change the respective loads very little. The stresses f_A, f_u, and f_d, due to partial arch and cantilever loads, respectively (Fig. 9(e)), are given in Columns (65), (59), (60), (61), and (62).

In determining the average arch thrust, the influence of elastic deformations has been included, and the result as shown in Columns (56) to (68), Table 1, indicates that, in the lower part of the dam, arch action is gradually being replaced by beam action until a condition is reached at the bottom of the dam where bending becomes negligible as compared with radial shear; that is, where the respective part of the dam acts as a wedge. Assuming the crushing strength of the concrete to be 1 500 lb. per sq. in., or 216 000 lb. per sq. ft., the area required to transmit this thrust is shown under δA_A, Column (67), and the maximum percentage of the existing area is shown in Column (68). Inasmuch as the behavior of an arch, as well as that of a beam of such dimensions as in the lower part of the dam, is of considerable uncertainty, it may be stated that the respective values for the percentage of A_A required, are meant to be indicative rather than exact.

In Columns (69) to (78), Table 1, the load limit lines are determined as shown in Fig. 9(e). They were calculated for $W = 160$ lb. per cu. ft. and $W = 143$ lb. per cu. ft., respectively. They represent the water load that may be brought against the dam so as to produce a stress, $f_u = \pm 0$, at the up-stream face.

The conditional equation, therefore, is:

$$f_u = \pm 0 = \frac{W}{A} - \frac{M_0}{S_u} \qquad (30)$$

$$M_0 = \frac{W \times S_u}{A} \qquad (31)$$

and as the sum of the moments must be equal to zero,

$$-M_{P'} + M_W + M_0 = 0$$

and,

$$-M_{P'} = -M_W - M_0$$

From Fig. 10:

$$M_{P'} = \frac{62.5\ h^2}{6} \times x$$

and,

$$x = \frac{6\ M_{P'}}{62.5\ h^2} = \frac{M_{P'}}{10.42\ h^2} \qquad (32)$$

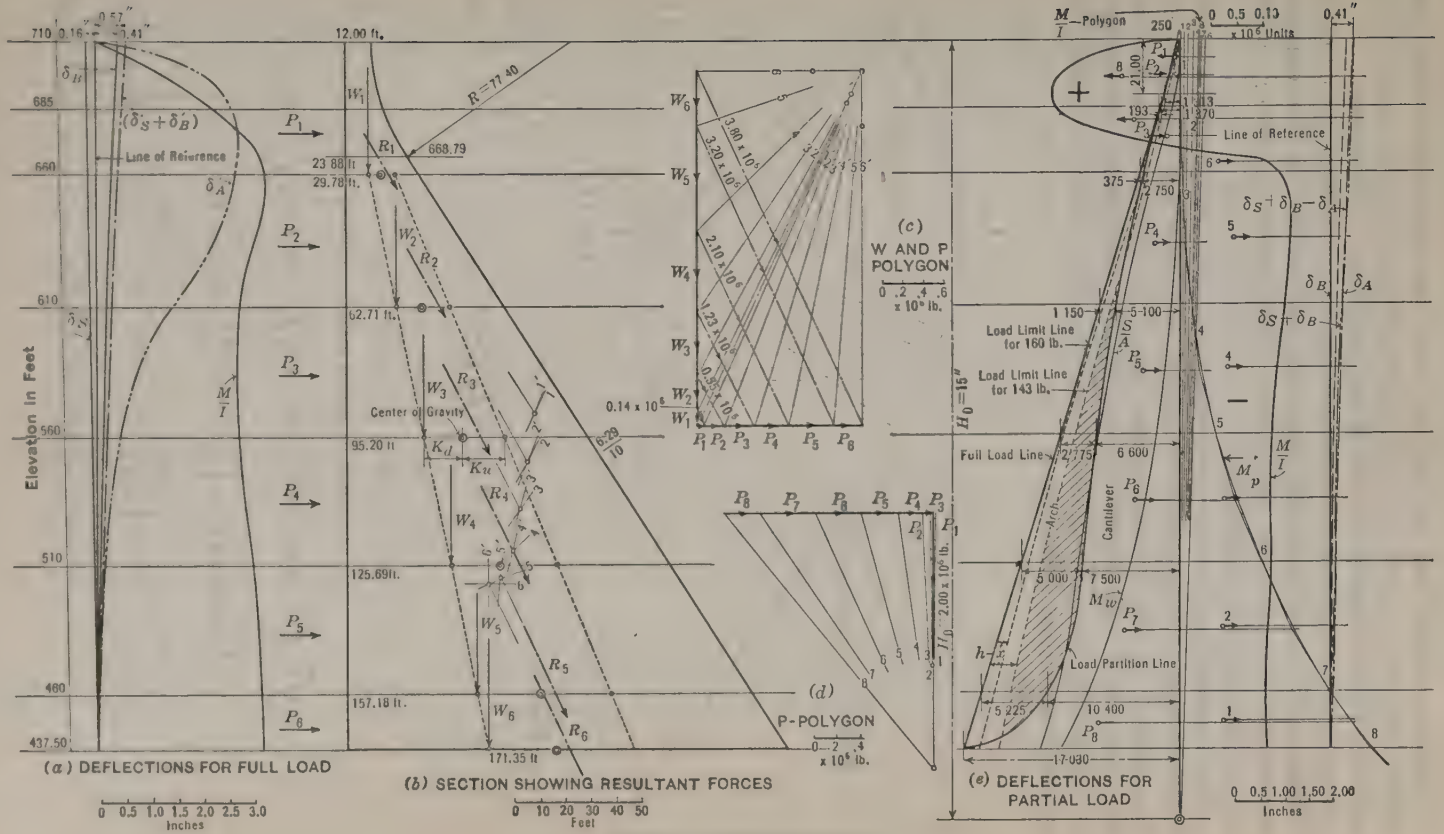

FIG. 9.—DESIGN OF EXCHEQUER DAM.

The cross-hatched area in Fig. 9(*e*) shows the margin between the load limit line for $W = 143$ lb. per cu. ft. and the load partition line, and may be considered as the "clearance of arch action" in this part of the dam.

Finally, the water loads, P, as shown in Fig. 9(*e*), have been combined with the weights, W (based on 160 lb. per cu. ft.) in Fig. 9(*c*), and the respective resultants are shown in Fig. 9(*b*) relative to the centers of gravity and the kern points of horizontal sections.

The formulas, as given by the author, hold good for any central angle except the one for the moment of inertia which holds for a hollow sector (trapezoid), 1 ft. wide at the up-stream face. In order to enable the determination of stresses of a section between any two radial planes (for instance, two contraction joints), a precise formula for the moment of inertia was derived by the writer, as follows:

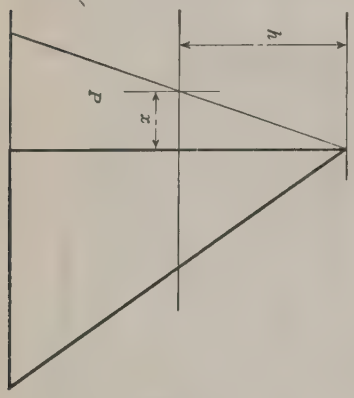

FIG. 10.

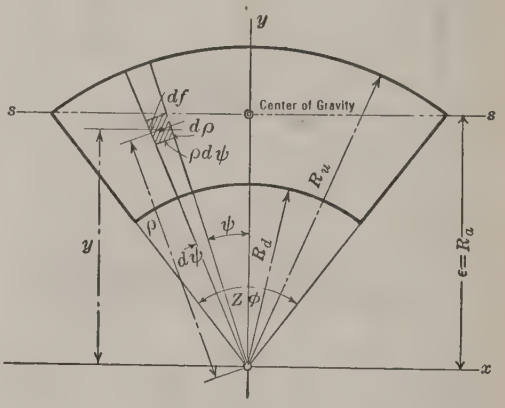

FIG. 11.

From Fig. 11:

$$I_x = 2\int_0^{\phi} y^2\, d\, f \qquad (33)$$

$$y = \rho \cos \psi$$

$$y^2 = \rho^2 \cos^2 \psi$$

$$d\, f = \rho\, d\, \rho\, d\, \psi$$

$$I_x = 2\int_0^{\phi}\int_{R_d}^{R_u} \rho^2 \cos^2 \psi\, d\, \psi\, \rho\, d\, \rho = 2\int_0^{\phi} \cos^2 \psi\, d\, \psi \int_{R_d}^{R_u} \rho^3\, d\, \rho$$

$$\int_0^{\phi} \cos^2 \psi\, d\, \psi = \left[\frac{\sin 2\phi}{4} + \frac{\phi}{2}\right] + C_1\ (= 0)$$

$$\int_{R_d}^{R_u} \rho^3\, d\, \rho = \left[\frac{\rho^4}{4}\right]_{R_d}^{R_u} + C_2\ (= 0) = \frac{R_u^4 - R_d^4}{4}$$

$$I_x = \frac{R_u^4 - R_d^4}{8}\,[\sin 2\phi + 2\,\phi] \qquad (34)$$

$$R_u^4 - R_d^4 = (R_u^2 - R_d^2)(R_u^2 + R_d^2) = (R_u - R_d)(R_u + R_d)$$
$$[(R_u + R_d)^2 - 2\,R_u\,R_d]$$
$$R_u - R_d = t$$
$$R_u + R_d = 2\,R_m$$
$$R_u^4 - R_d^4 = 2\,t\,R_m\,[4\,R_m^2 - 2\,R_u\,R_d]$$
$$I_x = \frac{t\,R_m}{4}\,[4\,R_m^2 - 2\,R_u\,R_d]\,[\sin 2\phi + 2\phi]$$
$$= t\,R_m\left[R_m^2 - \frac{R_u\,R_d}{2}\right][\sin 2\phi + 2\phi] \quad \ldots\ldots (35)$$

which is the equation for the moment of inertia about the x-axis. For the moment of inertia about the center of gravity of the section:

$$I_S = I_x - F\,\varepsilon^2 \quad \ldots\ldots (36)$$

in which,

$$F = 2\int_0^{\phi} d\,f = 2\int_0^{\phi}\int_{R_d}^{R_u} d\,\psi\,\rho\,d\,\rho = 2\,\phi\left[\frac{\rho^2}{2}\right]_{R_d}^{R_u}$$
$$= \phi\,[R_u^2 - R_d^2] = 2\,\phi\,t\,R_m \quad \ldots\ldots (37)$$
$$\varepsilon = R_d^* = \left(R_m + \frac{t^2}{12\,R_m}\right)\frac{\sin\,\phi}{\phi}$$
$$\varepsilon^2 = \left(R_m + \frac{t^2}{12\,R_m}\right)^2\frac{\sin^2\,\phi}{\phi^2}$$
$$\left(F \times \varepsilon^2\right) = 2\left(R_m + \frac{t^2}{12\,R_m}\right)^2\frac{\sin^2\,\phi}{\phi} \times t \times R_m$$
$$2\left(R_m + \frac{t^2}{12\,R_m}\right) = \frac{1}{72\,R_m^2}\left(12\,R_m^2 + t^2\right)$$
$$(12\,R_m^2 + t^2) = 3\,R_u^2 + 6\,R_u\,R_d + 3\,R_d^2 + R_u^2 - 2\,R_u\,R_d + R_d^2$$
$$= 4\,[R_u^2 + R_u\,R_d + R_d^2] = 4\,[(R_u + R_d)^2 - R_u\,R_d] = 4\,[4\,R_m^2 - R_u\,R_d]$$

Introducing this value:

$$\left(F \times \varepsilon^2\right) = \frac{16\,t}{72\,R_m}\left[4\,R_m^2 - R_u\,R_d\right]^2\frac{\sin^2\,\phi}{\phi}$$
$$= \frac{32 \times t}{9 \times R_m}\left[R_m^2 - \frac{R_u\,R_d}{4}\right]^2\frac{\sin^2\,\phi}{\phi} \quad \ldots\ldots (38)$$

Equation (36) now becomes:

$$I_S = t\,R_m\left[R_m^2 - \frac{R_u\,R_d}{2}\right]\left[\sin 2\,\phi + 2\phi\right]$$
$$- \frac{32 \times t}{9 \times R_m}\left[R_m^2 - \frac{R_u\,R_d}{4}\right]^2\frac{\sin^2\,\phi}{\phi} \quad \ldots\ldots (39)$$

WILLIAM CAIN,† M. AM. SOC. C. E. (by letter).—The writer has been much interested in this excellent paper. For the assumptions, all the derived formulas are exact. A volume 1 ft. wide at the up-stream face is considered.

* As derived by the author.

† Prof. Emeritus, Univ. of North Carolina, Chapel Hill, N. C.

If this width had been taken as $d\,s$ in place of 1, then, at once, 1 could replace $\frac{\sin\,\phi}{\phi}$, and Equation (4) could be more easily derived.

Curved gravity dams are ordinarily constructed with radial, vertical contraction joints. If these are not provided, the dam is likely to develop vertical cracks. Assuming such joints or cracks to extend from top to bottom, the author's theory applies to portions of the dam between cracks when the distance between them is not too large. If, however, by reinforcement or grouting, it is possible to realize a monolithic dam, then the theory presented does not apply and recourse must be had to the theory for the dam treated as a whole, as outlined by Fred A. Noetzli, M. Am. Soc. C. E.,* or an equivalent method may be used. However, if such dams are made by simply grouting the joints or cracks after full shrinkage has taken place, it is doubtful if the dam can be maintained as a monolith under extreme changes of temperature.

The author has treated completely the arched gravity dam of triangular cross-section with a vertical water face and has applied the results to a dam of such cross-section that, if the dam is first regarded as straight, with reservoir full, and uplift neglected, the stress at the heel is zero. Afterward, the dam of this same cross-section is considered curved with an up-stream radius of 674.7 ft.; the stress at the heel is again computed and found to be tension and, in amount, 25.9 lb. per sq. in.

The conclusion is inescapable that it is dangerous to neglect curvature in a curved gravity dam, and it is plain that the error increases as the radius diminishes. The error has been computed on the usual assumptions. There are likewise "uncertainties involved in determining the stresses near the foundation of a gravity dam", as the author notes. It would seem, then, that the base of the dam should always be thicker than the usual middle-third theorem prescribes.

The author gives a complete solution for the arched gravity dam of a triangular cross-section with the up-stream face vertical. It may be of interest to indicate the solution for the usual cross-sections, as given in Fig. 12, where the lines, $F\,G$ and $G\,B$, are tangent to the curved down-stream profile, not drawn.

The value of M_c, the moment about C of the solid the cross-section of which is $A\ O\ B$ ($A\ O$ being vertical), is given directly by the author (page 769). For the remaining sections, Equation (7),

$$M_c = 2\,w \sin\,\phi\,f\,r^2\,h\,d\,r$$

applies on substituting proper limits and values of r in terms of h.

Let the dotted lines in the sections, $E\,A\,O$, $O\,D\,F\,I$, and $I\,F\,G$, represent the variable ordinate, h, and let r be the radius, with center at C, corresponding to h, or the horizontal distance from C to the point where the dotted lines produced meet the base, $E\,B$. Also, let the horizontal radii from C to Points E, A, and the points on $E\,B$ vertically under F and G, be designated by the symbols, r_e, r_a, r_f, and r_g, respectively. Then, from similar triangles,

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 44.

Section $E\,A\,O$,

$$\frac{h}{O\,A} = \frac{r_e - r}{E\,A}$$

Section $O\,D\,F\,I$,

$$h = O\,D + (r_a - r)\tan\alpha$$

Section $I\,F\,G$,

$$\frac{h}{I\,F} = \frac{r - r_g}{r_f - r_g}$$

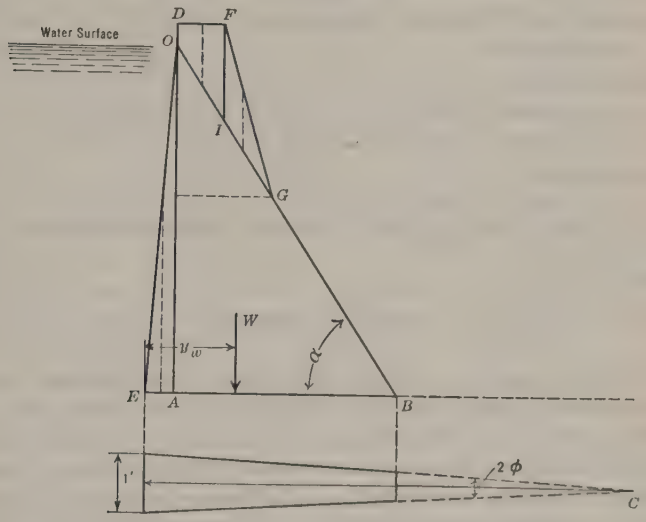

FIG. 12.

For a numerical illustration, the cross-section of the straight dam so thoroughly analyzed by the writer* will be adopted, and the dam will be regarded as curved, with an up-stream radius of 500 ft. The dimensions, in feet, will be given in reference to Fig. 12. The height to the water surface, $A\,O = 200$, $E\,A = 4$, and $A\,B = 130$, so that the base, $E\,B = 134$ ft. Also, $O\,D = 8$, $D\,F = 20$, and $I\,F = 38.8$; and, $\tan\alpha = \frac{200}{130} = \frac{100}{65}$. The radii are as follows:

$$r_e = 500;\ r_a = 496;\ r_f = 476;\ r_g = 463.5;\ r_b = 366$$

The radius to the vertical through the center of gravity of the section, $E\,O\,D\,F\,G\,B$, is 455.3 ft., and its area, 14 112 sq. ft.; so that the volume of the part of the curved dam having the central angle, $2\,\phi$, is,

$$14\,112 \times 2\,\phi \times 455.3 = 14\,112 \times \frac{1}{500} \times 455.3 = 12\,851 \text{ cu. ft.}$$

and its weight,

$$W = 12\,851\,w$$

* "Stresses in Masonry Dams," *Transactions*, Am. Soc. C. E., Vol. LXIV (1909), p. 208. This paper is likewise given in the writer's "Retaining Walls" (Van Nostrand's Science Series No. 3, 7th Edition).

Substituting the numerical values in the formulas just given, involving h and r, and solving for r:

For Section $E\ A\ O$,

$$r = 500 - 0.02\,h;\ dr = -0.02\,dh$$

For Section $O\ D\ F\ I$,

$$r = 501 - 0.65\,h;\ dr = -0.65\,dh$$

For Section $F\ I\ G$,

$$r = 463.5 + 0.322\,h;\ dr = 0.322\,dh$$

Substituting these values for the sections, $E\ A\ O$, $O\ D\ F\ I$, and $F\ I\ G$, in Equation (7), as quoted,

For Section $E\ A\ O$,

$$M_c = \frac{0.02}{500}\,w \int_{200}^{0} (500 - 0.02\,h)^2\,h\,d\,h = 197\,900\,w$$

For Section $O\ D\ F\ I$,

$$M_c = \frac{0.13}{100}\,w \int_{38.8}^{8} (501 - 0.65\,h)^2\,h\,d\,h = 218\,690\,w$$

For Section $F\ I\ G$,

$$M_c = \frac{0.0644}{100} \int_{0}^{38.8} (463.5 + 0.322\,h)^2\,h\,d\,h = 107\,820\,w$$

The M_c for the section, $A\ O\ B$, is determined directly from the formula given by the author (page 769), in which, $H = 200$, $B = 130$, and $R_d = 366$, and is found to be, $M_c = 5\,352\,000\,w$. The total M_c, or moment about C for the entire solid, is the sum of the separate values. Therefore, $M_c = 5\,876\,410\,w$.

For a high dam, the parts outside $A\ O\ B$ are relatively small and a fair approximation to M_c for either $E\ A\ O$, $O\ D\ F\ I$, or $F\ I\ G$, is found by multiplying its area by the radius to the vertical through its center of gravity. This assumes a rectangular in place of a trapezoidal base for such parts. For this dam, the approximation was sufficiently close.

Having found M_c and W for the entire solid of the angle, 2ϕ, the radius to its center of gravity is,

$$\frac{M_c}{W} = \frac{5\,876\,410}{12\,851} = 457.27 \text{ ft.}$$

whence, the horizontal distance from this center of gravity to E is,

$$y_w = 500 - 457.27 = 42.73 \text{ ft.}$$

y_a, the distance from E to the center of gravity of the trapezoidal base, is given by Equation (4). Thus, $y_a = 63.55$ ft. and $y_a - y_w = 20.82$ ft.

The remainder of the solution is effected by the author's Equations (10), (12), and (14).

$$x = 0.732;\ A = 116;\ I = 172\,400;\ M = -41\,266\,000$$

$$w \text{ (assumed)} = \frac{5}{2}\,(62.5) \therefore W = 2\,008\,000 \text{ lb.}$$

$$s_u = \frac{W}{A} + \frac{M}{I}\,y_a = 17\,300 - 15\,240 = 2\,060 \text{ lb. per sq. ft. stress at } E$$

or 14.3 lb. per sq. in. compression at the up-stream edge under full water load. For the straight dam, the unit compression at E was 32.24 lb. per sq. in. This ignores uplift. Where that is to be considered, Equation (17) directly applies.

The change in the vertical component of the stress at E from 32.24 lb. per sq. in. compression for the straight dam to 14.3 lb. per sq. in. for the curved dam, indicates that if the straight dam had been designed for such a value of w as to give zero stress at E, then the curved dam would be in tension at the heel, E. This result is exactly in line with the author's conclusion, and indicates that, for a curved gravity dam, the curvature should be considered in the analysis.

F. W. Hanna,* M. Am. Soc. C. E. (by letter).—The writer has been greatly interested in the author's discussion of arched gravity dams and believes that he has done the Engineering Profession a distinct service in presenting this subject in a comprehensive manner at this time. The author states that it is the purpose of his paper to show that it is not safe to neglect the curvature in calculating the stresses in an arched gravity dam and that this may lead to, and has led to, dams having tension in the up-stream face. He also states that the Habra Dam, in Algiers, and the Bouzey Dam, in France, failed from tension in the up-stream face several years after they were built. It appears to the writer that these claims are too broad and possibly may be misleading.

In regard to the Habra Dam, Wegmann states† that the main dam was straight in plan (not curved), that the failure of the dam cannot be attributed to any defect in design, but was caused, in all probability, by faults in the execution of the work, and that the dam failed on account of a defective foundation. It appears, moreover, from a discussion of the dam by M. Leon Ponchet that the foundation was unsatisfactory; that defective stone may have been used in the masonry; that the sand used was not good; that clayey red earth was used instead of sand for the inner part of the dam; that the hydraulic lime used was not very good; and that a combination of these circumstances caused the destruction of the dam. It appears, therefore, that this dam was not curved in plan and that its immediate failure was caused by defective foundation, possibly augmented by low-grade masonry in the body of the dam.

Wegmann also states that the Bouzey Dam was built straight in plan (not curved); that it was founded on red sandstone which was fissured and quite permeable; that considerable difficulty was experienced in the foundation trench from springs; that when the water reached a level of 33 ft. below the top of the dam springs of about 2 cu. ft. per sec. appeared on the lower side of the wall; that when the water reached a level 10.5 ft. below the top of the dam a portion of the dam, 444 ft. long, was shoved forward so as to form a curve convex down stream, causing additional fissures and increasing the flow of the springs to about 8 cu. ft. per sec.; that the failure of the dam is supposed to have been due to a greater tension at the up-stream face than

* Hydr. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

† "The Design and Construction of Dams."

the masonry could resist; and that this tension was probably increased by an upward water pressure under the dam. It appears from this statement that the initial failure of the Bouzey Dam was caused by sliding on the foundation, and that the final failure was probably caused by combined hydrostatic pressure, sliding, and shearing within the body of the dam due to poor masonry, and possibly injury to the dam through the initial failure. Here, as in the case of the Habra Dam, there was no curvature in plan, and neglect of the radial plane stress theory had nothing to do with the failure of the dam.

In order to prove the contention that it is never safe to neglect the curvature of a gravity dam in calculating the stresses, the author selects for analysis a radial-sided slice with a chord thickness of 1 ft. at the up-stream face of an arched gravity dam. The selection of this narrow slice is evidently a remnant of the custom of considering vertical slices of this thickness in calculating the stresses in straight gravity dams. The selection of a slice 1 ft. thick ignores the fact that in straight dams the analysis of a slice of this thickness will show the same stability and stress as a slice of any other thickness and that in curved dams the analysis of a radial slice of up-stream chord thickness of 1 ft. will show results materially different from those obtained by taking a radial slice of a greater thickness. Inasmuch as a 1-ft. radial slice cannot conceivably shear out from the surrounding material, an analysis for curved dams based on this assumption cannot yield reliable results. In view of this fact it would appear that stress computations in a curved gravity dam should be considered from other viewpoints.

In the usual dam site the radial plane analysis of arched gravity dams does not give consideration to the weight of all the material in the dam. In this connection, let Fig. 13 represent the plan and crown section of a symmetrical arched gravity dam placed in a box-shaped canyon. Let the dam be divided by vertical planes parallel to the axis of the canyon as shown in the diagram. The water pressure on each of these slices is made up of a transverse component equal to the water pressure times the slice thickness times the tangent of the angle of curvature of the dam from the center line of the canyon and a down-stream component equal to the slice thickness times the water pressure per unit width of the canyon. It is evident that the transverse components on the two sides of the canyon will balance one another and will have no effect on the overturning moment in a down-stream direction. It is also evident that the down-stream components are adequately resisted at the crown section and are still more adequately resisted for the oblique sections near the sides of the canyon, if the section of the dam is safe for a dam that is straight in plan. The parallel-sided sections can be made actual sections by placing all the contraction and construction joints parallel to the axis of the canyon. By referring to Fig. 13, it will be noted that the radial plane theory entirely neglects the resistance of the triangles, *abc* and *def*, and that this material may be omitted from the dam since no arching action is to be relied on in this theory.

In an arched gravity dam with properly spaced, constructed, and grouted contraction joints, the dam can generally be relied on to act as a unit. This fact is entirely ignored in the radial plane analysis theory. It brings arch

action and increased moment resistance into play. Let Fig. 14 show the plan and section of a triangular dam; and, in order to simplify the mathematical treatment, let like parabolic curves bound the up-stream and down-stream faces of the base. It will be possible to substitute such parabolic

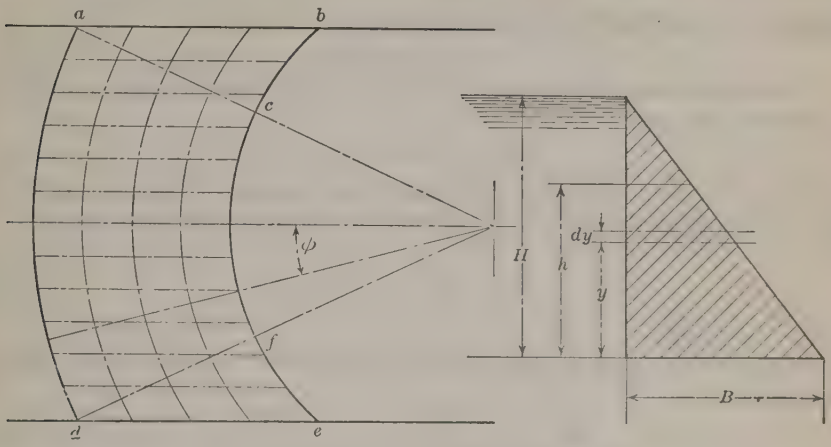

FIG. 13.—SYMMETRICAL ARCHED GRAVITY DAM.

curves for the usual arcs without material error. All vertical sections taken parallel to the crown will be equal, and the total weight of material in the dam will be the same as that in a straight dam of the same section. The basis of comparison will be very slightly unfair to the curved dam of uniform radial

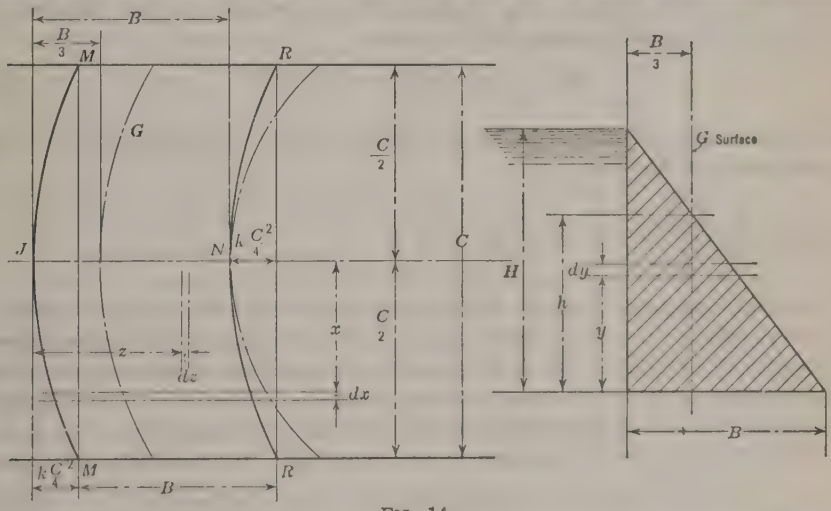

FIG. 14.

section. Let the co-ordinate axes be taken as coincident with the axis of the canyon and a line perpendicular thereto at the up-stream edge, J. Using the notation shown in Fig. 14, let the equation of the parabola representing the up-stream edge of the base be:

$$z = k x^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40)$$

that representing the line, G, at one-third the distance between the heel and toe on a line parallel to the z-axis be:

$$z - \frac{B}{3} = k\,x^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (41)$$

and that representing the down-stream edge of the base:

$$z - B = k\,x^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (42)$$

As already noted, the weight, W, of the dam will be the same as that for a straight dam, or,

$$W = \tfrac{1}{2}\,B\,H\,c\,w \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

in which, w is the weight of a cubic unit of the masonry. The moment, M, of this weight about the heel, J, is expressed by the following equation:

$$M = \int_{-\frac{c}{2}}^{\frac{c}{2}} \frac{w\,B\,H}{2}\,z'\,dx \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

in which, $z' = \frac{B}{3} + k\,x^2$, and which, on integration for the limits shown, becomes,

$$M = \frac{w\,B\,H\,c}{6}\left(B + \frac{k\,c^2}{4}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

Let the intensity of the hydrostatic uplift on the base be $62.5\,f\,H$ at the heel and zero at the toe, varying linearly between these points. The total uplift will then be $31.25\,f\,B\,H\,c$ as for a straight dam. For every slice of the dam the center of gravity of uplift may be taken vertical below the center of gravity of the weight. The moment, M_2 of the uplift about the heel, J, derived similarly to Equation (45), becomes,

$$M_2 = 10.42\,f\,B\,H\,c\left(B\,\frac{k\,c^2}{4}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

Also, as in the case of a straight dam, the horizontal water pressure, P, may be expressed as follows:

$$P = 31.25\,f\,c\,H^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47)$$

and the moment thereof about the heel, as,

$$M_3 = 10.42\,f\,c\,H^3 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

Let it be assumed that the vertical unit pressure under the base varies in a line parallel to the z-axis uniformly from D at the points, R, farthest down stream to U at the point, J, farthest up stream; and let Q represent the value of this pressure at any distance, z, from the x-axis. When $x = 0$, $z = 0$ from Equation (40) and B from Equation (42) for the up-stream edge at the point, J, and for the down-stream edge, at the point, N, respectively; and when $x = \frac{c}{2}$, $z = \frac{k\,c^2}{4}$ for the up-stream edge at the point, M, and $B + \frac{k\,c^2}{4}$ for the down-stream edge of the base at the points, R. For any intermediate point at the distance, z, from the x-axis,

$$Q = U + \left(\frac{z}{B + \frac{k\,c^2}{4}}\right)(D - U) \quad \ldots\ldots\ldots\ldots\ldots\ldots (49)$$

The total base pressure, P, is that on the area, $M\,J\,M\,R\,N\,R$, which may be expressed as follows:

$$P = 2\int_0^{\frac{c}{2}} \int_{k\,x^2}^{(B+k\,x^2)} \left[U + \left(\frac{z}{B + \frac{k\,c^2}{4}} \right) (D - U) \right] d\,z\,d\,x \ldots\ldots (50)$$

which, on integration, equals,

$$P = B\,U\,c + \frac{\left(\frac{B^2\,c}{2} + \frac{B\,k\,c^3}{12} \right) (D - U)}{\left(B + \frac{k\,c^2}{4} \right)} \ldots\ldots\ldots\ldots (51)$$

In a similar manner the moment, M_4, of the base pressure about the heel at J is,

$$M_4 = \int_0^{\frac{c}{2}} \int_{k\,x^2}^{(B+k\,x^2)} \left[U + \left(\frac{D - U}{B + \frac{k\,c^2}{4}} \right) z \right] z\,d\,z\,d\,x \ldots\ldots\ldots (52)$$

which, on integration, equals,

$$M_4 = c\,B \left[\left(\frac{B}{2} + \frac{k\,c^2}{12} \right) U + \left(\frac{D - U}{B + \frac{k\,c^2}{4}} \right) \left(\frac{B^2}{3} + \frac{B\,k\,c^2}{12} + \frac{k^2\,c^4}{80} \right) \right] \ldots (53)$$

Let consideration now be given to results obtained from applying Equations (51) and (53), involving the parabolically curved dam with stresses calculated on a parallel-sided vertical slice, 100 ft. wide, as compared to a vertical slice, 100 ft. wide, of a straight gravity dam of the same section. Take a horizontal section of the Exchequer Dam at Elevation 427.5 as cited by the author (page 772), in which, $H = 272.5$ ft. and $B = 171.4$ ft., and let $w = 160$ lb. per cu. ft. For a straight dam of this section and masonry weight, the stress at the heel is zero. For a parabolically curved dam, a solution of Equations (51) and (53) gives U equal to 2.6 lb. per sq. in. compression at the heel, which is negligibly different from the zero stress obtained for the straight dam. This shows that, if stresses in an arched gravity dam are calculated on parallel-sided sections of reasonable width, the results do not differ materially from those obtained from calculating on the basis of the usual methods for straight gravity dams.

In the matter of arch action coming into play to relieve the overturning moment from water pressure in an arched gravity dam, let the Exchequer Dam again be considered, using the triangular vertical up-stream face section assumed by the author; and let the water elevation be assumed to be at the crest of the triangle section. When any gravity dam is subjected to water pressure, as here assumed, the down-stream fibers of the dam are compressed by bending moment much more than the up-stream fibers, which causes the dam to be deflected down stream considerably. Shearing action also tends to increase this down-stream deflection. Computations of these combined deflections for the Exchequer Dam show the total deflection at 50 ft. below the crest of the dam on the axis thereof to be about 0.74 in.; at 100 ft. below the

top of the dam, 0.51 in.; and at 150 ft. below the top of the dam, 0.32 in. Assuming the water load to be carried entirely by the arch and computing the crown deflections at the same three elevations, the corresponding deflections are found to be 3.18 in., 2.28 in., and 0.81 in., respectively. These figures indicate that the cantilever deflections from the water load in the gravity section at various levels are a very considerable proportion of those of the arch sections, indicating that an appreciable proportion of the water pressure will be taken by arch action in this dam, much more, in fact, than any deficiency of computed stress resulting from applying parallel-sided instead of radial-sided slices of the dam.

The arch deflections given in the preceding paragraph are computed with Cain's formula for fixed-ended thin circular arches under normal loads. The deflections of the gravity section are computed by means of the law of displacements of the internal work theory, the fundamental formula for which is as follows:

$$\Delta_h = \int_0^h \frac{M\,m}{E\,I}\,dy + 3\int_0^h \frac{V\,v}{E\,A}\,dy \qquad (54)$$

in which, M and V are the moment and shear due to the water load acting in producing stress on the elementary strip, dy, while m and v are the respective moment and shear on dy for a unit load of 1 lb. applied at the point of deflection, h, all as shown in Fig. 13. By assigning proper values to the various quantities involved in the fundamental formula and integrating, Δ_h, for any point, h, is found to be,

$$\Delta_h = \frac{62.5\,H^3\,h^2}{E\,B^3} + \frac{46.875\,H}{E\,B}(2\,H\,h - h^2) \qquad (55)$$

There are, however, cases where it may be desirable to compute the stresses in arched gravity dams on the basis of radial-sided slices, such as in a canyon converging down stream, with abutments not suitable for taking arch thrust, and such as may give better foundation conditions for a curved structure than for a straight structure combined with earth abutments or abutments otherwise not suited to taking the arch thrust. In such cases, it is desirable to compute the stresses on the theory of radial-sided slices. Formulas for considering stresses on this theory are not at all out of place, but they should not be allowed to displace the customary and reliable method of computing stresses in arched gravity dams by the parallel-sided slice theory. In view of this statement the writer is submitting herein general formulas for this purpose, developed by means of the principles of calculus which check and supplement the formulas presented by the author.

Development of Formulas for Effect of Curvature on Stresses.—Assume a vertical slice of an arched gravity dam between radial planes thereof; let this vertical slice be divided into convenient segments by horizontal planes; and let Fig. 15 represent the plan and sectional elevation of one of these segments. Also, let the symbols shown on the diagram represent the quantities there indicated. Assume each segment to be acted upon only by water pressure and gravity, and take moments about a horizontal line perpendicular to the

radial plane bisecting the segment and passing through the center of curvature called the center axis in the plane of the base of the segment. Consider an elementary volume and an elementary surface of the segment of the dam as shown in Fig. 15, and extend these considerations to the entire segment thereof by integration of the differential quantities between proper limits. Let all units be expressed in pounds and feet.

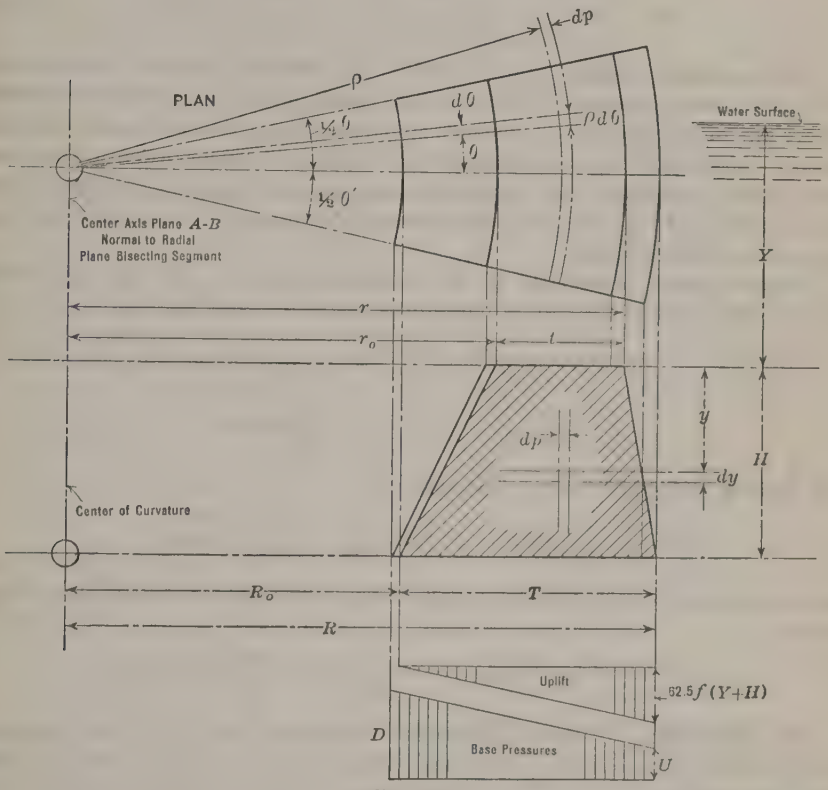

FIG. 15.

If w represents the weight per cubic foot of material in the segment, then the weight of the elementary volume, m, is $w\ dy\ d\rho\ \rho\ d\theta$, and the moment of m about the center axis, $A\ B$, is $w\ dy\ d\rho\ \rho\ d\theta\ \rho\cos\theta$. The total weight of the segment and the total moment thereof about the center axis are readily found by integrating these differential quantities between the proper limits as follows:

$$W = w \int_{y=0}^{y=H} \int_{\rho = r_0 + \frac{y}{H}(R_0 - r_0)}^{\rho = r + \frac{y}{H}(R-r)} \int_{\theta = -\frac{\theta'}{2}}^{\theta = \frac{\theta'}{2}} d\,y\,d\,\rho\,\rho\,d\,\theta \ldots\ldots (56)$$

whence,

$$W = \frac{w\ H\ \theta'}{6}\left[\left(\frac{R^3 - r^3}{R - r}\right) - \left(\frac{R_0^3 - R_0^3}{R_0 - r_0}\right)\right] \ldots\ldots\ldots\ldots (57)$$

and,

$$M = w \int_{y=0}^{y=H} \int_{\rho = r_0 + \frac{y}{H}(R_0 - r_0)}^{\rho = r + \frac{y}{H}(R-r)} \int_{\theta = -\frac{\theta'}{2}}^{\theta = \frac{\theta'}{2}} d\,y\,d\,\rho\,\rho\,d\,\theta\,\rho\cos\theta \ldots\ldots (58)$$

whence,

$$M = \frac{w\,H \sin\frac{\theta}{2}}{6}\left[\left(\frac{R^4 - r^4}{R - r}\right) - \left(\frac{R_0^4 - r_0^4}{R_0 - r_0}\right)\right] \ldots\ldots\ldots\ldots (59)$$

The up-stream surface of the segment is acted on both by vertical and horizontal water pressure. The vertical pressure acts in conjunction with the weight of the segment to increase its stability and the horizontal pressure acts in opposition thereto to produce overturning. In accordance with the principles of hydraulics, the vertical pressure acts on the horizontal projection of the surface of the segment and the horizontal pressure acts on the vertical projection of the surface.

The horizontal projection of the elementary area, *n*, of the up-stream face of the segment lies at a horizontal distance from the center axis of $r + \frac{y}{H}(R - r)$, and it has a width of $\frac{d\,y}{H}(R - r)$. Its area, therefore, is,

$$\left(\frac{R-r}{H}\right)\left[r + \frac{y}{H}(R-r)\right] d\,y\,d\,\theta$$

The vertical water pressure on this area is,

$$62.5\left(\frac{R-r}{H}\right)(Y+y)\left[r + \frac{y}{H}(R-r)\right] d\,y\,d\,\theta$$

and the moment of the vertical water pressure on this area about the center axis is,

$$62.5\left(\frac{R-r}{H}\right)(Y+y)\left[r + \frac{y}{H}(R-r)\right]^2 d\,y\cos\theta\,d\,\theta$$

The integration of these differential quantities gives the total vertical water pressure on the up-stream face of the segment and its total moment about the center axis. Let W_1 and M_1 represent the respective total pressure and moment; then,

$$W_1 = 62.5\left(\frac{R-r}{H}\right)\int_{y=0}^{y=H}\int_{\theta=-\frac{\theta'}{2}}^{\theta=\frac{\theta'}{2}}(Y+y)\left[r + \frac{y}{H}(R-r)\right] d\,y\,d\,\theta. \ldots\ldots (60)$$

whence,

$$W_1 = 10.42\,\theta'\,(R-r)\,[3\,Y\,(R+r) + H\,(2\,R + r)] \ldots\ldots\ldots (61)$$

and,

$$M_1 = 62.5\left(\frac{R-r}{H}\right)\int_{y=0}^{y=H}\int_{\theta=-\frac{\theta'}{2}}^{\theta=\frac{\theta'}{2}}(Y+y)\left[r + \frac{y}{H}(R-r)\right]^2 d\,y\cos\theta\,d\,\theta \ldots\ldots\ldots\ldots (62)$$

whence,

$$M_1 = 41.66 \sin \frac{\theta'}{2} (R - r) \left[Y \left(\frac{R^3 - r^3}{R - r} \right) + \frac{1}{4} H (3 R^2 + 2 R r + r^2) \right] \ldots (63)$$

In determining the horizontal water pressure acting on the up-stream face of the segment, the vertical projection of an elementary areal strip, q, across the up-stream face of the segment is used. The vertical projection of this area is,

$$2 \left[r + \frac{y}{H} (R - r) \right] \sin \frac{\theta'}{2} d y$$

the horizontal water pressure on it is,

$$125 \sin \frac{\theta'}{2} (Y + y) \left[r + \frac{y}{H} (R - r) \right] d y$$

and the moment of this pressure about the center axis is,

$$125 \sin \frac{\theta'}{2} (Y + y) \left[r + \frac{y}{H} (R - r) \right] (H - y) d y$$

By integrating these differential quantities and denoting W_2 and M_2, as the total pressure and moment, respectively, the following values are found:

$$W_2 = 125 \sin \frac{\theta'}{2} \int_{y=0}^{y=H} \left[r + \frac{y}{H} (R - r) \right] (Y + y) d y \ldots\ldots (64)$$

whence,

$$W_2 = 125 H \sin \frac{\theta'}{2} \left[\frac{Y}{2} (R + r) + \frac{H}{3} \left(R + \frac{1}{2} r \right) \right] \ldots\ldots (65)$$

and,

$$M_2 = 125 \sin \frac{\theta'}{2} \int_{y=0}^{y=H} \left[r + \frac{y}{H} (R - r) \right] (Y + y) (H - y) d y \ldots (66)$$

whence,

$$M_2 = 10.42 H^2 \sin \frac{\theta'}{2} \left[2 Y (R + 2 r) + H (R + r) \right] \ldots\ldots (67)$$

The uplift pressure on the base of the dam varies with the permeability of its foundation, but it is believed to be a fair assumption for the case here under consideration to assume: (1) That the intensity of pressure at the heel of the dam is equal to some specified factor times the intensity of water pressure at that point; (2) that this intensity of pressure is zero at the toe of the dam; and (3) that the intensity of pressure varies as a straight line between the heel and toe. If P designates the entire uplift on the base of the dam, f the coefficient of intensity of water pressure at the heel, and M_3 the moment of the uplift, P, on the base of the dam about the center axis, then,

$$P = \int_{\rho = R_0}^{\rho = R} \int_{\theta = -\frac{\theta'}{2}}^{\theta = \frac{\theta'}{2}} d \rho \, \rho \, d \theta \, 62.5 (Y + H) f \left(\frac{\rho - R_0}{R - R_0} \right) \ldots\ldots (68)$$

whence,

$$P = f \left(\frac{62.5 (Y + H) \theta'}{(R - R_0)} \right) \left[\frac{1}{3} (R^3 - R_0^3) - \frac{R_0}{2} (R^2 - R_0^2) \right] \ldots (69)$$

and,

$$M_3 = \int_{\rho = R_0}^{\rho = R} \int_{\theta = -\frac{\theta'}{2}}^{\theta = \frac{\theta'}{2}} d\rho\ \rho\ \rho\ d\theta\ 62.5\ (Y + H)\ f \left(\frac{\rho - R_0}{R - R_0}\right) \rho \cos\theta \quad \ldots(70)$$

whence,

$$M_3 = 125\ f \sin\frac{\theta'}{2}\ (Y + H) \left[\frac{1}{4}\left(\frac{R^4 - R_0^4}{R - R_0}\right) - \frac{R_0}{3}\left(\frac{R^3 - R_0^3}{R - R_0}\right)\right] \ldots(71)$$

The downward pressure on the foundation of the base of the dam is due to the weight of the superimposed masonry plus the vertical water pressure on the up-stream face thereof due to batter. The downward pressure at any intermediate point on an elementary area, $d\rho\ \rho d\theta$, is,

$$D - \frac{\left(\rho \cos\theta - R_0 \cos\frac{\theta'}{2}\right)}{R - R_0 \cos\frac{\theta'}{2}} (D - U)$$

in which, D is the intensity of pressure at the toe and U is the intensity of this pressure at the heel. Now, if P_1 equals the entire downward pressure on the foundation, and M_4 the moment thereof about the center axis,

$$P_1 = \int_{\rho = R_0}^{\rho = R} \int_{\theta = -\frac{\theta'}{2}}^{\theta = \frac{\theta'}{2}} d\rho\ \rho\ d\theta \left[D - \frac{\rho \cos\theta - R_0 \cos\frac{\theta'}{2}}{R - R_0 \cos\frac{\theta'}{2}} (D - U)\right] \quad \ldots(72)$$

whence,

$$P_1 = D\ \theta' \left(\frac{R^2 - R_0^2}{2}\right) - (D - U)$$
$$\left[\frac{2 \sin\frac{\theta'}{2}\left(\frac{R^3 - R_0^3}{3}\right) - \theta' R_0 \cos\frac{\theta'}{2}\left(\frac{R^2 - R_0^2}{2}\right)}{R - R_0 \cos\frac{\theta'}{2}}\right] \quad \ldots\ldots(73)$$

and,

$$M_4 = \int_{\rho = R_0}^{\rho = R} \int_{\theta = -\frac{\theta'}{2}}^{\theta = \frac{\theta'}{2}} d\rho\ \rho\ \rho\ d\theta\ \rho \cos\theta$$
$$\left[D - \left(\frac{\rho \cos\theta - R_0 \cos\frac{\theta'}{2}}{R - R_0 \cos\frac{\theta'}{2}}\right)(D - U)\right] \quad \ldots\ldots\ldots\ldots(74)$$

whence,

$$M_4 = D\ \frac{2}{3} \sin\frac{\theta}{2}\ (R^3 - R_0^3) - (D - U)$$
$$\left[\frac{\frac{1}{8}\ (\theta' + \sin\theta')\ (R^4 - R_0^4) - \frac{1}{3}\ R_0\ (\sin\theta')\ (R^3 - R_0^3)}{R - R_0 \cos\frac{\theta'}{2}}\right] \quad \ldots\ldots(75)$$

The pressure intensities, D and U, can now be found from a combination of Equations (73) and (75), the total base pressure having been previously found from Equations (57) and (65), and the moments thereof from Equations (59), (63), and (67). Where hydrostatic uplift is assumed to act on the base of the dam, Equations (69) and (71) must be used to determine the modifications of stresses resulting therefrom.

Acknowledgment is made to T. L. E. Haug, M. Am. Soc. C. E., for valuable assistance in developing and checking the methods of analysis and formulas herein presented.

E. W. KRAMER,* M. AM. SOC. C. E. (by letter).—This able paper is very timely in calling attention to the danger of allowing tension in the heel of any dam that depends entirely on gravity action for its stability, and also in emphasizing the importance of considering a slice between two vertical radial planes in analyzing the stresses in a gravity dam arched in plan. The timeliness is due to the number of gravity dams exceeding 300 ft. in height, either proposed or under construction.

Among the important questions arising in connection with the planning of these structures, on which there seems to be some difference of opinion, are the following:

1.—Should a gravity dam be arched in plan where topographical conditions permit?

2.—If arched in plan, is a smaller safety factor with respect to maximum compression at the toe, tension at the heel, and uplift assumption permissible?

3.—What is the amount of uplift for which provision should be made?

4.—Should a section between radial or parallel vertical planes be considered in determining stresses?

5.—What should the allowable working stresses be?

These problems are, of course, not new. However, knowledge on the questions involved is continually being increased by observing dams actually constructed, as these subjects of observation are continually increasing in height and varying in form. Great advancement in the mathematical treatment of stresses and strains in structures has been made in recent years as well as an increase in knowledge as to the strength of the materials of which these structures are built. Therefore, it is hoped that the following discussion, in which an attempt is made to enlarge on some of the points made by Mr. Jakobsen, will be at least of passing interest.

The answer to the first question depends to a great extent upon the answers to the other questions, and more particularly to the second question. There are, however, some points that can be considered independently.

As a general rule a larger concrete yardage will be required at a greater cost per yard for the gravity dam arched in plan than for the straight dam, regardless of the stand taken by the designer on the other questions. Therefore, the arched dam will cost more. An exception to this rule might occur in a case where the arching throws the center of the dam up stream on better and higher foundations.

* Hydr. Engr., U. S. Forest Service, San Francisco, Calif.

Having decided that the arched plan will cost more, it is then necessary to justify this extra cost. The usual answer is that an additional safety factor is provided. It is the writer's opinion, however, that the arching affords only a secondary or delayed support in the case of dams arched on a greater radius than about 800 ft. This support may not come into play under certain very reasonable assumptions until after partial failure has occurred.

For instance, observations of the temperature of large concrete dams show that in the interior it rises rapidly as high as 110° Fahr. The gradual cooling will open the contraction joints. As this cooling covers a long period, there is no assurance that these contraction joints can be grouted before the load comes on the dam. In fact, it is not a general practice to grout the contraction joints of gravity dams. Some of the engineers most prominent in the design of high dams hold that it is inadvisable to do so. Observations show that these cracks are sometimes as large as 0.1 in. For a dam of long radius, computations and observations indicate that the cantilever will not deflect sufficiently to close the cracks, which is essential to bring the arch into play.

An incipient failure caused by the dam sliding on its base a matter of some hundredths of a foot would bring the arch into play. It would also greatly increase the uplift. The support given by the arch might prevent a complete and rapid failure and a serious disaster involving loss of life and property, while it might not preserve the usefulness of the dam. This additional safety factor, no doubt, has at least psychological value.

On the other hand, the science of engineering has advanced in regard to methods of exploring foundations, grouting and draining foundations, knowledge of designing and placing concrete, designing cross-section, etc., to such a point that the question arises, "is not the additional safety provided by arching a gravity dam on a long radius in most cases superfluous?" Before the designer will answer this question, it is likely that he will first determine what the arching will cost. To do this it will be necessary for him to make decision in regard to the other questions.

Confining the answer to gravity dams with radii of more than 700 or 800 ft., the writer's answer to the second question would be that it is not advisable to use a smaller safety factor with respect to compression at the toe, tension at the heel, or uplift assumption, than is customary in a straight dam. For radii of less than, say, 700 ft., the answer is not so evident.

To support this answer take the case of the Exchequer Dam of the Merced Irrigation District, Merced, Calif., referred to by Mr. Jakobsen. The cross-section of this dam, as published,* is shown on Fig. 16. The radius of the up-stream face at the crest is 674 feet. The section is very nearly triangular. In order to simplify the deflection computations, assume the triangular cross-section that would be obtained by extending the principal batter of the down-stream face (10 on 6.29) to the crest and foundations. For a height of 320 ft. the bottom width will be 202 ft. and the top width, zero (very nearly).

The assumption is made that the cantilever carries the entire load and gives as great a deflection as can occur, unless cracks develop in the up-stream face.

* *Western Construction News*, January 25, 1926.

Therefore, for the present purpose, this assumption is allowable. The following equation* will be used for obtaining the cantilever deflection at the crest, neglecting shear and yielding of foundations, and assuming that the cantilever takes the entire load:

$$Y_c = \frac{62.5\ H^3}{E\ t_b^3} X^2$$

in which,

Y_c = deflection, neglecting shear;
H = height of dam;
t_b = thickness of base; and
X = height of point above base for which deflection is to be determined.

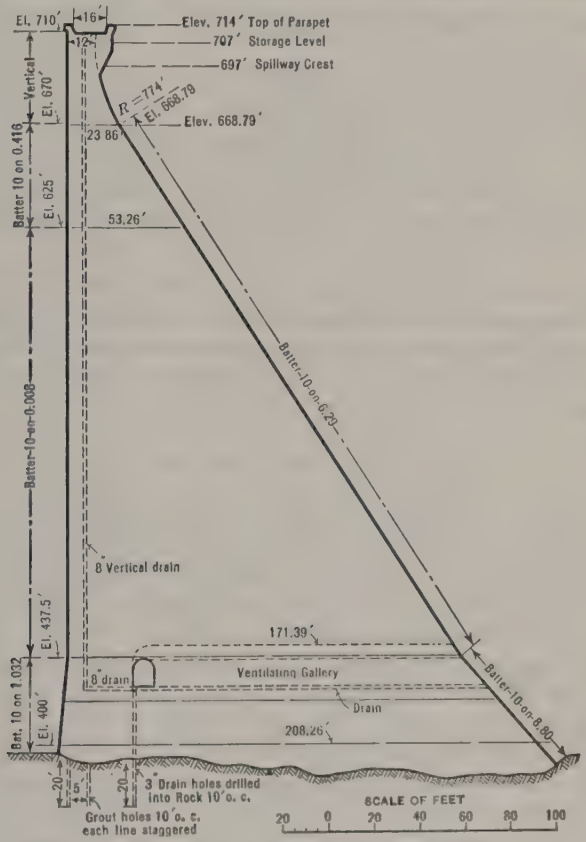

FIG. 16.—MAXIMUM CROSS-SECTION OF EXCHEQUER DAM.

For the Exchequer Dam, remembering that $t_b = 0.63\ H$,

$$Y_c = \frac{62.5\ H^3}{E\ (0.63\ H)^3} X^2 = 0.000000868\ X^2$$

Therefore, Y_c for the crest, when $X = 320$, is 0.0889 ft.

* Derived by F. A. Noetzli, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 6.

In his discussion of Mr. Noetzli's paper, to which reference has been made, Mr. Jakobsen shows that the deflection due to shear is very considerable in a case of this kind, and that it should be added to the computed cantilever deflection with shear neglected.

Mr. Jakobsen developed the equivalent of the following formula* for the determination of the cantilever deflection due to shear alone at the crest of the dam where $X = H$,

$$Y_s = \frac{1.2 \times 31.3 \times H^3}{144 \times G \times t_b}$$

Values of $E = 2\,000\,000$ and $G = \frac{2}{5} E$ are low and will give a high value for the deflections. They will be used, therefore, in order to get the largest probable deflection.

Taking $H = 320$ ft. and $t_b = 202$ ft. for the Exchequer Dam gives $Y_s = 0.0265$ ft. at the crest. Therefore, the total cantilever deflection,

$$Y_c + Y_s = 0.0889 + 0.0265 = 0.1154 \text{ ft.}$$

Consider a block of the dam between two vertical contraction joints 50 ft. apart on the up-stream face. For a fall of 20° Fahr. the contraction will be,

$$0.0000055 \times 20 \times 50 = 0.0055 \text{ ft.} = 0.076 \text{ in.}$$

This dimension is of the order of the size of the cracks in the Mulholland Dam referred to by Mr. Jakobsen. To close these cracks on the up-stream face at the crest for a radius of 674 ft., using the relation between the arc and radius of a circle, will require a shortening of the radius and hence a deflection of,

$$Y = \frac{674}{50} (0.0055) = 0.0741 \text{ ft.}$$

Since this is considerably less than the cantilever deflection, 0.1154 ft., it would seem that the cracks would be closed before full cantilever deflection took place and that arch action would be developed in the upper part of the dam. This would materially lessen the cantilever stresses. Hence, the doubtful exception made by the writer for dams with radii less than 700 or 800 ft. The foregoing statement is based on the assumption that the maximum fall in temperature of the concrete below the temperature at which it took its permanent form will not greatly exceed 20° Fahr.

Suppose, however, that the radius of the up-stream face at the crest was 1 200 ft. To close the cracks at the up-stream face would require a shortening of the radius at the crest or, in other words, of the deflection at the crest of,

$$Y = \frac{1\,200}{50} (0.0055) = 0.132 \text{ ft.}$$

which is considerably greater than the cantilever deflection at the top of the dam where it would be greatest until the arch action came into play. Remember, also, that a most liberal estimate was made of the cantilever deflection

* *Transactions*, Am. Soc. C. E., Vol LXXXIV (1921), p. 100.

and that shrinkage of the concrete, due to setting, was neglected in computing the width of the contraction crack.

The selection of a fall in temperature of 20° Fahr. may be open to criticism as being too small when compared with the high temperature that the concrete may reach while it is setting. On the other hand these high temperatures are not all closing temperatures. The practice of pouring the dam in alternate blocks allows some time factor between the peaks in the block temperatures. One alternate set of blocks may have passed their maximum temperature before the intermediate blocks were poured.

It is admitted that a greater drop of mean temperature below that at which the concrete took its permanent form in the case of the Exchequer Dam might be justified. On the other hand, it is believed that a drop of at least 20° occurred.

If any unreasonable assumptions appear in this argument, they were adverse to the argument in so far as the dam with a 1 200-ft. radius is concerned (with the one exception of making no allowance for yielding foundations). It is believed, therefore, that the statement that no reduction in the usual safety requirements should be made on account of a gravity dam being arched in plan on a radius greater than, say, about 800 ft., has been substantiated.

Some further reference to the Mulholland Dam will be made to prove that the contraction of concrete in a dam is real and not theoretical.

The writer saw the dam on March 10, 1926. It was completed in 1925. The maximum height is 200 ft. It is a concrete gravity dam arched in plan on a radius of 542 ft. The elevation of the crest is 750 ft. and that of the spillway, 746 ft. The water stood at Elevation 716 ft. or within 36 ft. of the spillway crest. No contraction joints were placed in the structure.

Numerous cracks extending from the foundations to the crest and from the front to the back face, in so far as the front face could be observed, had opened up and were still open, although the dam was under about four-fifths of its full head. While these cracks did not interfere with the usefulness of the structure, it was evident that no benefit was being derived from the arch at that time.

This condition might not be true of a higher dam arched on the same radius since the cantilever deflection at the top, say, for a 300-ft. dam, would have been sufficient to have closed the cracks theoretically at least, thereby developing arch action. Arch action in the upper part of the structure would greatly relieve cantilever stresses in the lower part.

To illustrate the probability of this latter point, some preliminary data in regard to the deflection of the Don Pedro Dam of the Turlock and Modesto Irrigation Districts of California, will be given (see Table 2). This experiment is not as yet complete, but in so far as it goes, it is believed to be accurate. It was made under the direction of R. V. Meikle, Chief Engineer of the Turlock Irrigation District.

The dam is a concrete gravity dam arched in plan on a 676-ft. radius. The maximum height is 284 ft. The section and plan are very similar to that of the Exchequer Dam, of which it appears to have been the model.

The deflections were measured on July 24, and August 1, 1923 (Table 2). Most of the concrete had been placed prior to October 1, 1922, although a gap had been left at the crest, about 90 ft. high and 32.5 ft. wide, which was closed prior to March, 1923.

TABLE 2.—Deflection Measurements, Don Pedro Dam.

Date.	Elevation of water, in feet.	Temperature.		Deflections.		
		Air.	Water.	Point No. 1, Elevation 1172.	Point No. 2, Elevation 1099.	Point No. 3, Elevation 1049.
July 24, 1923	1 158.45	.....	.....	0.022 ft.	0.029 ft.	0.0075 ft.
August 1, 1923	1 157.95	70° Fahr.	16° cent.	0.019 ft.	0.028 ft.	0.018 ft.

Three plumb-bobs were embedded in the down-stream face with their points projecting vertically at Elevations 1172, 1099, and 1049, respectively (assumed datum). The first elevation, 1 172 ft., is on top of the concrete wall on the lower side of the roadway crossing on top of the dam, the roadway and top of the dam being at an elevation of 1 168 ft.

Three points were located in the rock on the opposite side of the stream from the transit point, one in each vertical plane passing through the transit point and the plumb-bob points. This was done as carefully as possible while the reservoir was empty.

It will be noted from Table 2 that the deflection at the top under approximately full load is less (by 0.009 ft., or 0.108 in.) than the deflection at a point 73 ft. lower in this dam in the second case and almost this in the first case. This is a material difference well above the limits of error of the observation. Since the dam under cantilever stresses alone could not deflect less at the end of the cantilever than at some point below the end, this is conclusive proof that arch action was being developed at that time.

The question might well be raised in this case as to whether or not the dam had cooled off in the interior. It is planned to make further observations with empty and full reservoir, which will be of great value in settling this phase of the question.

In regard to the third question, it is believed that an allowance should be made for uplift; but that, with grouting the foundations and with proper drainage in the dam and foundations, it is hard to understand how this uplift can exceed the equivalent of 25% of the full hydrostatic pressure at the heel, diminishing uniformly to zero at the toe, except in cases where the foundations are unusually poor.

Modern concrete dams of considerable height are now provided with a drainage channel extending under the full length of the dam immediately down stream from the cut-off wall. An inspection gallery extending the length of the dam, usually at a distance of about 30 ft. from the up-stream face and above tail-water elevation, provides a free outlet for water collected from vertical drain pipes. The pipes should be about 12 ft. apart and should

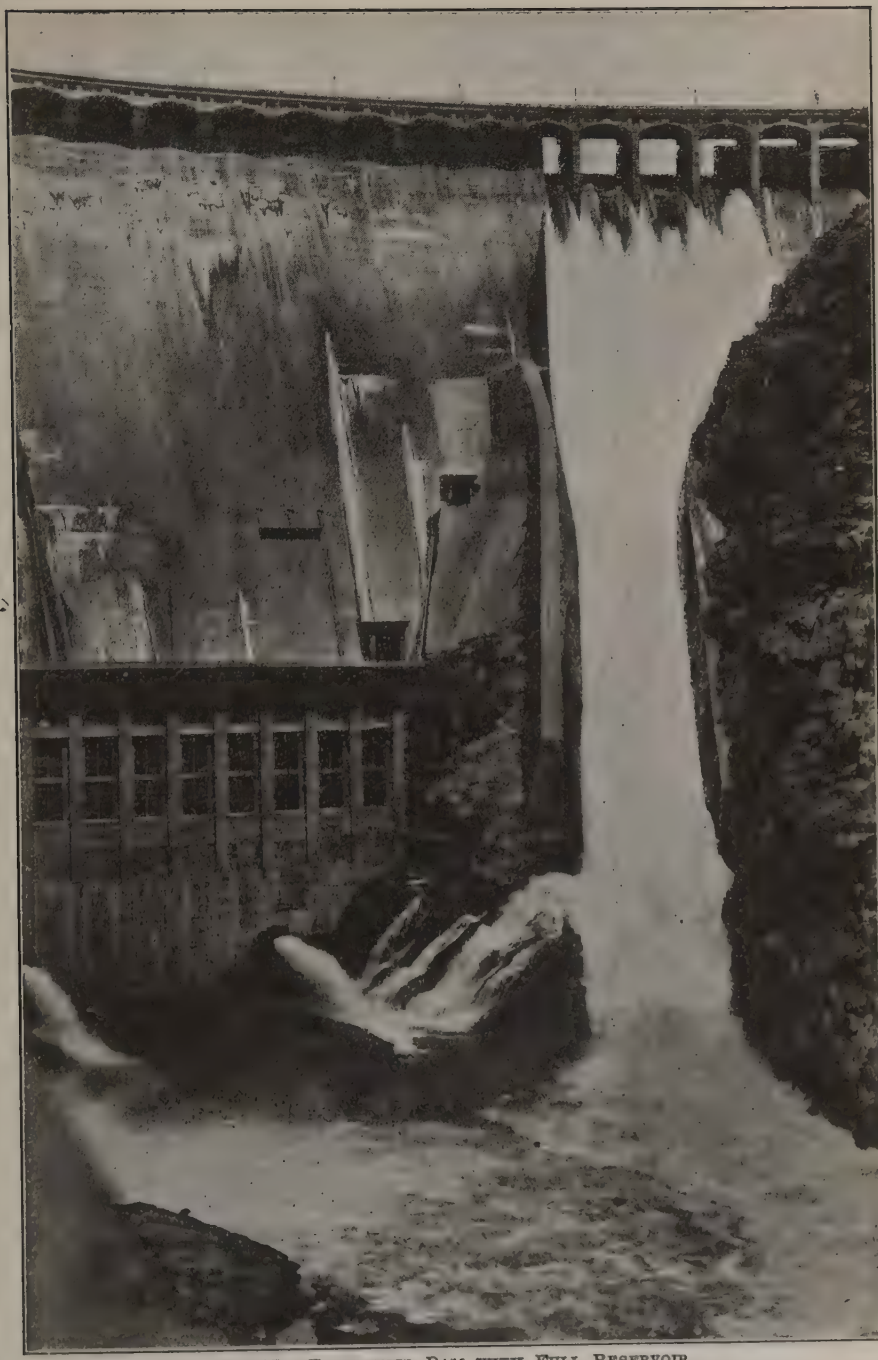

FIG. 17.—EXCHEQUER DAM WITH FULL RESERVOIR.

extend from 12 to 20 ft. into the foundations. Also, good practice requires vertical drain holes on about 12-ft. centers, extending upward from the inspection gallery to the top of the dam. Since water seeks the path of least resistance, these drains collect a very large percentage of the water getting through on construction joints or reaching the bottom of the dam under the cut-off wall.

They do not get all the water, however, as is shown by the leaks appearing on the down-stream face of the horizontal construction joints. An example of this leakage is shown (Fig. 17) of the down-stream face of Exchequer Dam after first filling. The usual care was exercised in cleaning the construction joints and flushing them with mortar before pouring new concrete. This leakage decreased very materially after the reservoir had been filled only a short time. The writer has seen similar leakage in other high dams.

An allowance for uplift, varying from at least 10% to at most 25%, should be made except for foundations of a very unreliable nature. The higher figure has the writer's recommendation, even in cases of the best foundations.

As stated by Mr. Jakobsen, it is impossible for full uplift to occur under the entire dam since the concrete is heavier than the water. If sufficient allowance is made in the design to take care of the initial uplift without tension developing at the heel, there will not be, in any horizontal plane in a block of the dam between any two vertical contraction joints, more than 30 or 40% of the area which does not have contact even with careless handling of construction joints. The drainage system should safely reduce this to the equivalent of less than 25% uplift at the heel, diminishing to zero at the toe, except, possibly, in cases of very porous foundations.

On the other hand, if sufficient allowance was not made in the original design to care for the initial uplift, and tension sufficient to open cracks does develop at the heel, the uplift will increase to full hydrostatic pressure over the surface of the crack, and cause the depth of the crack to increase. Hence, it is important to provide for the initial uplift in the design.

In regard to the section that should be considered in making an analysis of the stresses in a gravity dam arched in plan, Mr. Jakobsen has shown that the method of selecting a section between radial planes will give results much more closely approaching the actual condition than those obtained by means of the parallel-plane method.

The radial-plane method was used by the engineers of the Los Angeles County Flood Control District in the design of the San Gabriel Dam to be constructed at the Fork's site. Very good reasons for its use are given in a paper by S. M. Fisher, M. Am. Soc. C. E., Chief Designing Engineer of the District.* The action in this case is very important, since this is the highest gravity dam now planned for early construction, and a very material addition to the concrete yardage was involved in adopting this method.

Taking a section between parallel planes does not account for water pressure on the up-stream face on the sections immediately adjoining the one selected. This pressure will have a component that would have to be partly absorbed or resisted by it. In other words, the down-stream end of a section

* *Western Construction News*, July 10, 1927.

between parallel planes 1 ft. apart would be subjected to the pressure from a section of the up-stream face greater in width than 1 ft.

The writer believes that considering sections between radial planes is the most correct method that has been advanced. It does not, however, in itself, provide any additional factor of safety. If it shows tension at the heel, good engineering practice requires that a change in the design be made to overcome this fault.

On the other hand, as confidence increases in the mathematical analysis applied to structures due to study, discussion, and experiment, it is the writer's opinion that higher unit stresses can be allowed, for instance, in compression in the concrete at the toe.

Concrete developing a strength in compression in laboratory tests on 6-in. or 8-in. cylinders of 1 500 lb. per sq. in. at the end of 28 days, should allow working stresses in a gravity dam of 700 lb. per sq. in., or its equivalent of 50 tons per sq. ft., since at 6 months the strength will be greatly increased. While as strong a concrete is not likely to be obtained in the dam from the same mix as in the laboratory, this is more than offset by the fact that it seems safe to assume that a large mass of concrete will safely stand a much greater unit stress than a small cylinder.

The controlling specification for gravity dams up to about 400 ft. in height is the uplift assumption and its effect on the tension at the heel and not the strength of the concrete. Mr. Jakobsen shows the maximum stress in the Exchequer Dam at Elevation 437.5 (which is 272.5 ft. below the crest) to be 504 lb. per sq. in., which the writer believes to be a very moderate stress. He finds the objectionable condition in this case to be tension at the heel even with zero uplift, unless, of course, some of the load is taken by the arch before the cantilever deflects sufficiently to allow the tension to develop. That the uplift assumption governs, is true of all gravity designs of about this height. Any reasonable section that provides for some uplift without tension at the heel will not show compressive stresses of more than 600 lb. per sq. in.

For dams of much greater height, the stress at the toe becomes one of the governing factors. For sections much more than 400 ft. in height it is necessary to place more material in the upper part of the dam than is required to keep the resultant within the middle third in the upper section, in order to steepen the batter of the down-stream face near the bottom. This is due to the Cain theory, now rather generally accepted, which states that the maximum stress at the toe is a function of the angle that the down-stream face makes with the vertical. The well-known formula being:

$$\text{Maximum stress} = \text{maximum stress in horizontal plane} \times \sec^2 \theta$$

in which, θ is the angle that the down-stream face makes with the vertical. The steeper the batter the less the secant will be, and, therefore, the less the maximum stress, other things being equal.

To show the great increase in cost due to curving a high gravity dam, two gravity designs, made by the writer, are submitted (Fig. 18). They were made for a project requiring a dam 595 ft. high above the foundations and 495 ft. high above the stream bed.

The designs were intended for the purpose of a preliminary consideration of the possibilities of constructing a high dam at the Granite Dike site on the San Gabriel River, California. Exploration of one abutment by tunneling and other factors at a later date caused the elimination of the site from further consideration. The estimated stresses are listed in Table 3. The specifications governing the design were not fixed by the writer. They were, as follows: Maximum allowable compression, 40 tons per sq. ft.; uplift assumption, 50% of the hydrostatic pressure at the heel decreasing uniformly to zero at the toe; maximum sliding factor, 0.75; maximum stresses in the down-stream face to be calculated by the Cain formula; and stresses in the curved dam to be calculated by the radial slice method.

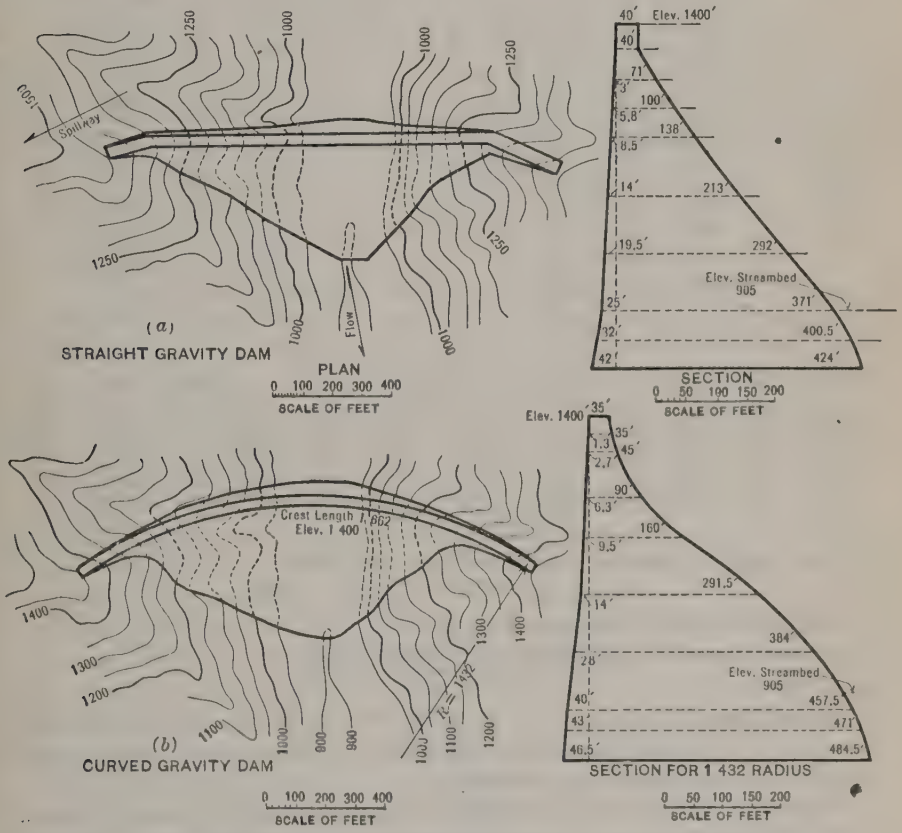

FIG. 18.—GRANITE DIKE SITE, SAN GABRIEL RIVER, CALIFORNIA.

The writer approves of all these specifications except those for maximum stresses and for uplift assumption. In the case of the uplift, it is thought that 25% instead of 50% would have been sufficient. It is believed that 50 tons per sq. ft. would not be too high for maximum stresses.

Fig. 18 (*a*) is a straight dam and Fig. 18 (*b*) is a dam arched with a radius of 1 432 ft. for the up-stream face at the crest. Unless some reliance is placed

on the arch, the stresses, uplift provision, and sliding factor are about the same for both structures. The concrete yardage for the straight dam is estimated as 2 720 000 and for the curved dam 3 100 000, an increase of 380 000, or approximately 14 per cent. The yardage estimate is based on the assumption of excavating 50 ft. into the right bank, 20 ft. into the left bank, and 100 ft. below the stream bed in both cases.

* The formula for maximum pressure at the down-stream face, is,

$$F \text{ maximum} = \frac{\text{maximum horizontal pressure}}{\cos^2 \theta}$$

θ = angle between vertical and down-stream face.

† The sliding factor $= \frac{\text{Total horizontal pressure above the joint}}{\text{Total vertical pressure above the joint}}$.

This increase in cost is due entirely to arching the dam in plan, provided no departure is made from the specifications. In the writer's opinion, the arching cannot be justified in this case.

The designs shown could, no doubt, be improved and still comply with the specifications. A design showing zero stress at the heel and exactly 40 tons per sq. ft. compression at the toe would reduce the yardage slightly in both cases.

Some reduction could have been made by changing the entire section for about every 50 ft. difference in height since, for heights of more than about 400 ft., material has to be added to the upper part of the section to reduce the stresses at the base. However, this method might have introduced very great

arch stresses near the abutments in the curved dam for an increase in temperature much above the closing temperature. It was therefore rejected.

The writer's conclusion is that, what additional safety may be obtained in arching a gravity dam on a radius greater than about 800 ft., is, in most cases, superfluous and not worth the additional cost, except where the foundation is questionable.

All dams curved in plan should be calculated as such and no reduction should be made in the usual safety factor, unless curved on radii so short that it can be shown that arch action will be developed under any reasonable assumption, the burden of the proof being on the designer.

Maximum stresses as high as 700 lb. per sq. in. should be allowed in gravity dams for the usual concrete placed in such structures.

A. J. WILEY,* M. AM. SOC. C. E. (by letter).—So far as the writer knows, none of the arched gravity dams built to date has had its section increased over a straight gravity section and it has been considered that such dams were much safer than if they had been given the same section and had been made straight in plan. Mr. Jakobsen's paper is very well timed because at least two important arched gravity dams, recently designed, have had their sections increased beyond that required under the same assumptions for a straight gravity dam.

Of course, it has always been known and admitted that the section of an arched gravity dam between converging radii would not be free from tension in the up-stream face unless there was arch action in the dam transmitting some load horizontally to the abutments. In fact, it has been assumed that there could not be a down-stream deflection of the vertical cantilever without a corresponding deflection of the horizontal arches and a division of the load between the cantilever and the arches.

The author claims that "as gravity dams are usually constructed, however, the arch cannot act until the cantilever has been broken. * * *" This condition, he claims, is due to the shortening of the arches by setting shrinkage and temperature contractions.

The writer thinks it can be shown that an arched gravity dam is made stronger and not weaker by reason of the arch. To show this, it must be proved that the deflection of the vertical cantilevers with no tension in their up-stream face is more than the deflection of the arch when carrying enough of the water load to avoid tension in the vertical cantilever.

After developing equations for the stresses at the up-stream and the down-stream faces of a section of a dam, between converging radii, in terms of the moment of the water pressure, the weight of the section, and the area and the moment of inertia of a horizontal section, the author applies the equations to a horizontal section at Elevation 437.5 of the Exchequer Dam, where the thickness is stated to be 171.4 ft. In this discussion the writer is using the author's figures, except that he is assuming the height of the arch ring above the base as 52.5 ft. and is using 158 lb. per cu. ft. for concrete because this

* Cons. Hydr. Engr., Boise, Idaho.

was the weight of the concrete used in the designs and is also the weight given by the author's Equation (1) when correctly computed.

It is assumed that the interior of the dam, beyond approximately 20 ft. inside the faces, is practically unaffected either by seasonal temperature changes or by setting shrinkage. Proof of the first assumption is found in the paper by Charles H. Paul, M. Am. Soc. C. E., and the late A. B. Mayhew, Assoc. M. Am. Soc. C. E., entitled "Temperature Changes in Mass Concrete",* in which it is shown that beyond about 20 ft., the temperature of the concrete is not sensibly affected by seasonal changes, but gradually approaches the mean annual temperature.

The action of the concrete in the arch due to expansion by the setting heat is somewhat obscure, but it seems reasonable to assume that it is divided between the elastic compression of the concrete and of the abutments and results in up-stream deflection of the arch ring. As the concrete cools, this compression and deflection are relieved, but there seems to be no reason for assuming that it results in tension or in contraction cracks, as would be the case if the concrete could be assumed not to act elastically until it had reached a higher temperature than that of the initial set. In this, reference is made to the concrete in the interior of a large mass and not to the part near the surface where it is affected both by drying and by seasonal temperature changes.

In his discussion of the paper by Fred A. Noetzli, M. Am. Soc. C. E., entitled, "Gravity and Arch Action in Curved Dams", Mr. Jakobsen states† that,

"* * * in the lower part of high curved dams, the temperature variation is small, especially at the up-stream face, and the effect of lateral deformation due to the weight of the overlying concrete will, in most cases, more than balance any temperature shrinkage likely to take place."

The vertical compression due to cantilever action on the horizontal arch at Elevation 437.5 varies from zero at the heel to 362 lb. per sq. in. at the toe. With a lateral deformation coefficient of one-fifth the resulting compression in the arch is 72 lb. at the toe and zero at the heel, which is equivalent to a temperature change of zero at the heel and 6.5° at the toe. This seems to provide for a much greater range of temperature than exists in the body of the dam.

In the up-stream and down-stream faces of the arch, within a distance of about 20 ft. of the faces, the concrete is affected both by temperature and by setting shrinkage. In the case of two 4 by 5 by 48-in. bars, quoted by Mr. Jakobsen in his discussion‡ of the paper by Mr. Noetzli previously referred to, one beam, which was exposed to air, shrank 0.0005 in. per in. and swelled 0.00028 in. per in. on being placed in water. The other beam, which set in water, did not shrink at all.

The concrete in the face of a large dam has one face exposed to the air and the other is a part of the interior of the dam. The excess water of the

‡ *Loc. cit.*, p. 103.

interior forms a source of moisture for the outside part, the rate of setting shrinkage for which should, therefore, be much less than that of small laboratory specimens.

The movements at the contraction joints of the Arrowrock Dam, given in the paper by Messrs. Paul and Mayhew previously referred to, show a combined average setting and temperature contraction of 0.0708 in. in 50 ft., at the face, 0.044 in. at 16 ft., and 0.0324 in. at 22 ft. from the face. This corresponds to a unit shrinkage of 0.00012 at the surface, 0.00007 at 16 ft., and 0.000054 at 22 ft. from the surface; but the last two measurements were taken on exposed surfaces of concrete, subject to local shrinkage and temperature changes in excess of the true shrinkage and temperature variations in the concrete at their respective depths from the surface. It should be noted, however, that when these measurements were made, there was still some setting temperature in the dam.

As the unit of expansion of the arch ring, due to lateral deformation from vertical compression at 20 ft. in from the down-stream face, is $\frac{151.4 \times 72}{171.4 \times E}$ = 0.000032 ft., it is thought that by neglecting 21.4 ft. of the down-stream part of the arch, the effects of temperature and setting shrinkage will be eliminated and that the intrados of the remaining part of the arch will be under compression from the lateral component of the vertical pressure.

At the up-stream face of the arch ring there is no compression from lateral expansion, but the setting shrinkage and temperature contraction are partly offset by the swelling from wetting.

The shrinkage at Arrowrock was, at a unit rate of 0.00012, and a unit rate of 0.0002 should be an ample allowance for setting shrinkage at the up-stream face.

For the swelling due to wetting, the same unit rate will be used for the up-stream face so that these two will cancel. The temperature drop in the concrete at the up-stream face may vary from the temperature of the concrete at the time of placing to the minimum temperature of water, or perhaps through a range of 50° at the surface, corresponding to a unit contraction of 0.000275. From the Arrowrock tests the temperature drop, 10 ft. from the surface, would be 8° and at 20 ft. it would be negligible.

Contraction joints at 50-ft. intervals might open 0.165 in. at the surface and 0.026 in. at 10 ft. from the surface, which, it may be noted, is more than twice that observed at Arrowrock. These contractions are confined to the outside 20 ft. of the concrete and do not affect the body of the arch ring.

There is a depth of 272.5 ft. at the arch ring so that the water pressure in the contraction joints, or in any intermediate vertical cracks, would be 118 lb. per sq. in. and the unit pressure in the arch ring would be the same. As this pressure on the arch ring would be confined to the up-stream 20 ft., considered as affected by temperature, it would not cause an up-stream deflection of the arch and can only be considered as effective in converting the up-stream part of the arch (which is affected by temperature), from a state of tension to one of compression while being deflected by water pressure.

Using the author's equations and dimensions, but with a unit weight of 158 lb. for concrete and with no arch action, there would be a tension of 29 lb. per sq. in. in the vertical cantilever at the arch ring.

If it is assumed that the unit weight of water carried by gravity action is reduced to an amount that would give zero tension on the vertical face at the arch ring 272.5 ft. below the surface, this unit weight on the cantilever will be 56.95 lb. per cu. ft. If it is assumed that the remaining weight will be carried by arch action, the unit pressure will be $5.55 \times 272.5 = 1\,512$ lb. per sq. ft.

Using the ordinary formula for cantilever deflection, $y = \frac{p\,H^3\,x^2}{E\,t^3}$, the deflection at the arch ring is 0.0022 ft.

The author has also called attention to the increase in cantilever deflection due to foundation deformation, and to a further increase due to the fact that the plane of the horizontal section assumed in the usual cantilever deflection formula is not normal to the neutral axis and that the resulting deflection is too small.

There seems to be no doubt that the cantilever deflection would be increased by both these conditions, but the arch deflection would also be increased by foundation deformation, although probably in a less degree, and consideration has been given only to the cantilever deflection.

Using Cain's equations with shear included, and $t = 150$, $r = 600$, $Z = 14°$, and $E = 288\,000\,000$ lb. per sq. ft., the deflection at the crown of the arch ring is found to be 0.000318 ft. as compared with the cantilever deflection of 0.0022 ft. for the same conditions.

The stresses in the arch ring are as follows: At the extrados, 3.6 lb. per sq. in. compression at the crown and 4.5 lb. per sq. in. tension at the abutments; and at the intrados, 2.0 lb. per sq. in. tension at the crown and 6.7 lb. per sq. in. compression at the abutments.

For equal deflections in cantilever and arch ring the unit weight of water carried by the cantilever would be 37.5 lb. per cu. ft. and by the arch 25 lb. per cu. ft. The deflection of the cantilever from bending alone would be 0.00143 ft. and the arch deflection at the crown with shear included would be the same.

The stresses in the arch ring are as follows: At the extrados, 14.5 lb. per sq. in. compression at the crown and 17.5 lb. per sq. in. tension at the abutments; and at the intrados, 8.0 lb. per sq. in. tension at the crown and 27.5 lb. per sq. in. compression at the abutments.

The stress on the vertical face of the cantilever at the arch ring with the load divided between the cantilever and the arch to give equal deflections in each would be 14 688 lb. per sq. ft., or 102 lb. per sq. in.

The author claims that open shrinkage cracks at the down-stream face of an arched gravity dam prove that it is not acting as an arch. The writer thinks that this discussion has shown that the shrinkage or contraction cracks in an arched gravity dam extend only about 20 ft. beyond the surface. As further evidence of this it is very seldom that seepage is visible in the open contraction cracks at the down-stream face from full reservoir pressure. Even

if they should show seepage, however, this is no evidence that they are not under heavy pressure. There may be uplift under the undrained base of a dam in spite of the fact that it is exerting a greater unit pressure on the foundation than is required in the arches of an arched gravity dam.

It may be claimed that there is temperature shrinkage in the whole body of a dam due to the difference in temperature between that of the concrete at the time of initial set and that of the mean annual temperature of the locality, which the interior temperature of the dam gradually approaches. Considering the quantity of water used in the concrete and its high specific heat compared with that of the other constituents, and considering the constant use of water on the concrete after placing, it does not seem probable that the average temperature at the time of initial set is above the mean annual temperature.

The temperature of the rings, or layers, placed in winter, however, will be considerably less than that of rings placed in summer, while there will be alternate rings placed in the spring and fall that will be of about mean annual temperature. The tendency, therefore, will be to have constant initial tension in some horizontal zones of the dam and constant initial compression in others, alternating with zones of no initial stress.

These stresses are independent of seasonal changes and after the setting temperatures have been dissipated, they will be constant at all times. The zones of initial compression will tend, when the dam is loaded, to carry more than their proportional share of the arch load; but there will be a tendency to equalize the load by shear between the arch rings.

This unequal initial stress condition might be equalized by pressure grouting, but it would be useless to attempt this until after the setting temperature had been dissipated. As it may require about five years to effect this, the dam will be exposed during this period to these possible concentrated arch stresses. As the arch stresses in an arched gravity dam are very low, the concentrated stresses can be safely carried permanently if desired.

The writer has not analyzed the arch stresses near the top of the dam, but thinks it would improve the design in a gravity type, whether arched or straight, to make the top thicker than customary practice and to compare the cantilever and arch ring deflections and stresses at all heights, using the author's method of computing the cantilever stresses.

W. P. Creager,* M. Am. Soc. C. E. (by letter).—The writer has checked carefully the equations and calculations contained in the author's interesting paper and can find no chance for disagreement except, perhaps, in regard to his conclusions. In order to determine whether or not a gravity dam actually has been made weaker by curving it in plan, it is necessary to investigate the fundamental reasons for providing a factor of safety against failure.

The necessary factor of safety against failure has no fixed value, but, within certain limits, usually is based on the designer's judgment guided by the probable seriousness of the calamity resulting from failure. The cost of a

* Vice-Pres. and Chf. Engr., Northern New York Utilities, Inc., and The Power Corporation of New York, Watertown, N. Y.

structure increases with the factor of safety adopted. It seems quite evident that a designer would not be warranted in requiring as great an expenditure to insure against unsightly cracks or small leakage as he would to insure against complete failure with resulting enormous financial loss and sacrifice of life.

The author states that "an arched gravity dam will receive some support from the arch and, in most cases, probably sufficient support to prevent actual failure." It is the writer's opinion, based on considerable study, that any properly designed gravity dam having a curvature sufficient to affect its strength as a gravity section materially, would undoubtedly hold as an arch dam in conjunction with its remaining strength as a gravity section, particularly if the joints were properly grouted under pressure.

Calculations by the writer indicate that the Exchequer Dam would probably hold as an arched structure irrespective of its strength as a gravity dam; although even if it were pressure-grouted, unsightly cracks and some leakage might occur before it deflected sufficiently to act as an arch.

Is it logical to assume that the Exchequer Dam, even with its slightly reduced strength caused by the curvature, still has an ample factor of safety against cracking and leakage, in consideration of the fact that the element of curvature has provided an increased factor of safety against complete failure? The writer is inclined to believe that it has.

The author states that "the smaller the radius, the larger is the error". However, the smaller the radius, the greater the ability to act as an arch, and the latter has the greater influence as affecting complete failure.

Edward Godfrey,* M. Am. Soc. C. E. (by letter).—It is encouraging to note that the author frankly recognizes under pressure as a factor in the design of a dam. His statement that even drainage is sure to be at least a partial failure should give pause to designers who recommend that under pressure be ignored or even to those who would guard against it by installing a system of drainage.

The author deduces the fact that a triangular-section gravity dam will be completely stable against up-stream pressure only if the base is about 0.65 of the height; and against both up-stream pressure and full under pressure if the base is about 0.85 of the height. It is significant to apply a triangle on the comparison of the large dams in existence (Fig. 5). The ratio, 0.85, will be found to fit all but those that are marked curved in plan. The significant thing is that the straight gravity dams that have withstood water pressure are wide enough at the base for complete stability against both up-stream pressure and full under pressure. The New Croton Dam is included among these, and this dam has several times been publicly held up as an example of a dam the designer of which did not consider under pressure.†

In Fig. 5 the dams that are curved in plan do not all come in the 0.85 class. They are nearer the 0.65 class. The author maintains that a dam convex toward the water has less stability than a straight dam of the same

* Structural Engr., Pittsburgh, Pa.

† Wegmann in *Engineering and Contracting*, December, 1922, p. 126, and *Waterworks*, June, 1923, p. 1302

cross-section. However, in his theoretical demonstration he neglects significant forces which, in fact, should reverse the conclusion.

By analogous processes it can be apparently shown that a dam curved away from the water has greater stability than a straight dam and (as the author has done) that one curved toward the water has less stability. The actual relative stabilities, however, are just the reverse. This is because both these apparent demonstrations neglect forces of vital importance, acting on the element of the dams considered. In the case of the dam that is curved away from the water, there is a circular tension that in any ordinary dam would rupture the concrete and lift it from its abutments. In the dam curved toward the water, the author finds reduced stability. However, he neglects the forces tangent to the curve of the dam. In other words, there is arch action which aids very materially in supplying stability. This aid may, in fact, mean the difference between stability and failure.

In the writer's judgment it is the curved plan of some dams, which do not show full stability on the basis of straight gravity dams, that is responsible for their continued existence as dams. Not that this is a proper method of design, but it is the accident of design that has saved some structures. Reliance on it has wrecked more than one.

It cannot be denied that a trapezoidal element of a curved dam must exert pressure on the adjacent trapezoidal elements. The several elements are not free to rotate, and an arc of the dam tends to rotate on the ends of that arc, thus with an increased lever arm. This, however, means increased and unusual pressure against the soil at the ends of the arc which is one of the reasons to be urged against reliance on a mere curved plan.

Any dam must diminish in height toward the ends. If it is founded on rock near the ends, this rock may be utilized as abutment, and then the curved plan (convex toward the water) has undoubted and very real advantages. Arch action can be utilized under such conditions.

However, if the foundation is not rock, attempts to make long thin arch dams may result in disaster. Two dams of this type recently failed.* One of these two similar dams was 236 ft. long and 62 ft. high at the highest point. The whole dam weighed about 6 000 000 lb. while the thrust of the arch at the mid-section was 18 000 000 lb. Much of this would travel to the ends and to the small abutments. The estimated pressure on this dam in the direction of the axis of the stream was 9 000 000 lb. It is not to be expected that a dam of these proportions would stand; but if it had been built of a cross-section approaching that required for a gravity dam, the curved section might have been the salvation of it.

Real stability in a gravity dam is attained when the width of the base is made about 0.85 of the height. Failure and freezing of drainage systems can then be forgotten. No dam of these proportions has ever failed.

C. A. P. Turner,† M. Am. Soc. C. E. (by letter).—Published measurements on the experimental arch dam at Stevenson Creek, California, having

* *Engineering News-Record*, October 14, 1926, p. 616.

† Cons. Engr., Minneapolis, Minn.

a vertical up-stream face, should furnish an opportunity for testing Mr. Jakobsen's formulas and the accuracy of the assumptions involved.

The tensile fiber stress on the up-stream face when the dam was full, may be roughly computed according to his formulas at from 6 000 to 10 000 lb. per sq. in. Yet the concrete held together and the dam carried the pressure without injury and was later over-topped in a flood. The computed down-stream deflection under this stress in the central part of the dam is from fifteen to fifty times greater than that measured when the dam was full. The quarter-point presented no down-stream deflection whatever, while between the quarter-point and the end of the dam the crest deflection was up stream against pressure, instead of down stream as computed by Mr. Jakobsen's notes.

This divergence of computed and measured results indicates that the predominant resistance of an arched dam, having the relative height and length of the test dam, is wholly different from that of the straight one, as assumed in the derivation of the formulas under discussion.

Consider, for example, a dam, straight in outline, that is, two or three times as long as it is high, placed in a rectangular opening in rock. Under the water pressure, the center of the dam will deflect down stream. The base, being held rigidly by the rock bottom, will not move and the ends of the dam, likewise being held rigidly by the rock sides, do not deflect. Consequently, the dam is both bent and warped or twisted. In such warping and twisting horizontal shears in vertical planes are developed, transferring a portion of the applied pressure toward the ends instead of vertically downward to the base.

In an arched dam, down-stream deflection of the crown or center of the arch cannot take place without twisting the structure. Such twisting shears transfer the reaction of the horizontal forces away from the center toward the ends of the dam and the reaction of the vertical forces shifts in like manner. The down-stream deflection of the top at the center of the dam would tend to twist the crest between the quarter-point and the end of the dam in the opposite direction. Torsion becomes the predominant resistance as opposed to the cantilever gravity action of a straight dam and the middle-third rule cannot be applied rationally to such a structure. Moreover, the curvature of the arch tends to reduce the over-turning moment on each individual element, because the axis of the moment of pressure on the individual elements makes an angle with its neighbor and with adjacent elements so that interference of moments is developed, which accentuate twist and reduce the effectiveness of the applied moment. A component of the pressure on the up-stream face produces a small amount of axial compression, or arch thrust.

If the opening is a V-formation the shift of the reaction laterally places it at a higher elevation than the base at the center or deepest part, thereby reducing the lever arm of the over-turning forces. Thus, an arched dam presents elements of resistance that the straight dam lacks. It permits an economy of material that cannot be secured when constructing a straight dam.

Rankine, in his "Applied Mechanics", states the premise on which the commonly accepted theory of flexure is founded; to wit, that the beam be subjected

to transverse forces only and that the length be fifteen or more times greater than the depth. Then, shear strain may be disregarded as negligible from the practical standpoint only in determining the elastic deflection and maximum tensile and compressive fiber stresses.

In a triangular gravity section, such as that considered by Mr. Jakobsen, the ratio of base to height of strip exceeds the limits under which shear strain may be ignored. Again, because the weight of the strip constitutes a longitudinal force greater than the transverse force, the condition of transverse force normal to the axis only, under which Rankine demonstrates the ordinary theory to be approximate, is lacking.

The assumption on which the ordinary theory of flexure is based, differs widely from the elastic theory. The shearing modulus of the material, F, is assumed to be infinite, an imaginary value, in place of its true value of approximately three-eighths of the modulus of tension or compression. The utility of the ordinary theory is confined to the determination of the maximum fiber bending stress, at a section where rhombic shear strain passes through zero. It is not adapted to the determination of the elastic behavior or elastic stress in a beam subjected to longitudinal thrust.

For example, a wood strut, supporting concrete work, is more rigid laterally when loaded reasonably than when it is carrying little or no weight. If its deflection is to be computed correctly the moment of inertia to be applied differs from that permissible under the condition of transverse force only without axial strain, and the idea* that the center of gravity of the section constitutes the axis of internal rotational resistance must be discarded. Every attempt to solve the problem of elastic resistance by assuming perfect elasticity of material under tension and compression and no elasticity at all under shear stress invariably leads to inconsistency and error.

Arch action in an arched dam is computed by some on the assumption that no shear may be transmitted by the concrete longitudinally along horizontal planes; but if the concrete can transmit no shear longitudinally (since the material has the same resistance to shear transversely in the same plane), cantilever resistance would be an anomaly unrelieved by an additional assumption that the concrete cannot resist horizontal shear in vertical planes on which, in turn, twisting resistance depends. Thus, all assumptions, differing unreasonably from a complete acceptance of the natural characteristics of the material dealt with, lead to theoretical uncertainty and confusion.

To determine the predominant resistance of an arched dam it is necessary to consider the fact that the base of the dam on a rock formation is fixed. It does not slide down stream and it cannot be deformed† lengthwise along the rock bottom. This eliminates the idea of the predominant action as an arch, provided the height is a fraction of the length. Any strip above the base which is shortened by down-stream deflection would involve, of necessity, longitudinal horizontal shears in horizontal planes represented by twisting couples about horizontal axis normal to the face of the dam. The shift of the

* This erroneous idea apparently constitutes a premise in the derivation of Mr. Jakobsen's formulas.

† The section of the rock base being far greater than the dam, its elastic compression becomes relatively negligible.

reaction along the arch results in twisting couples on a normal section about the longitudinal axis of the structure and, in turn, horizontal shears in vertical planes involve a twisting couple about a vertical axis. A three-dimensional twisting strain is the result.

Computing torsional resistance involves the polar moment of inertia of the cross-section. In the case of the Stevenson Creek Dam, the polar moment of inertia resisting torsion is enormously greater than the transverse moment of inertia resisting cantilever action. Torsion accounts for the precise kind and character of deflections measured, which may not be accounted for by either arch action or cantilever strip action.

As previously noted, the stress approximately computed on the cantilever principle for the test dam would be thirty to fifty times as great as the ultimate resistance of the material; and yet it does not appear from the reports to have been cracked where the greatest tensions from torsional stress would naturally occur; that is, nearest the axis of rotation. It is to be borne in mind that the shearing resistance of concrete is far greater than the tensile resistance and one does not have to assume an imaginary tensile resistance to accompany an imaginary infinite value of the shearing modulus in order to make the computed and experimental results reasonably consistent. The fact that the experimental dam was relatively thinner than many existing arched dams would in no wise alter the character of resistance involved, because the increase in polar moment of inertia increases with the transverse moment of inertia.

Relative thinness accentuates the deflections and permits a rational deduction therefrom, which would be more difficult to make were the experimental dam thicker and the deflections too small for accurate measurement and relative comparison. In considering the torsional resistance of an arched dam structure, the engineer may well investigate the form of cross-section which will produce the minimum stress in the material. He will avoid the expensive warped surfaces embodied in certain types of design and revert to a cross-section more readily built and more nearly approaching the rectangular or trapezoidal section.

The reverse curvature of the crest deflection of the experimental dam has been attributed by some to a buckling tendency due to axial compression, but it is impossible to harmonize such a tendency with the condition of uniform hydrostatic pressure normal to the arch. Again, the exact theory of elasticity negatives such an explanation because where shear strain exists, as it must in a section of this kind fixed at the end, there is a definite limit to the number of changes of curvature and points of inflection which approximate theory fails to indicate and which are exceeded in the reported results.

A thin steel spring under compression fixed at its ends will buckle with two points of contraflexure only. To deflect, as the crown of the experimental dam was observed to deflect, would require four points of inflection because the end of the arch where the height is small was fixed in position.

Toward the conclusion of his paper, uncertainty regarding the distribution of shear at the base of the dam is noted by Mr. Jakobsen and he explains that he has purposely excluded this from his discussion, desiring only to

show the influence of curvature when his assumptions were maintained. This is unfortunate because the magnitude of the resisting moment and the overturning moment depends on the relative location, position, and elevation of the reaction which determines the lever arm of the external forces.

The principle that an applied force is transferred to its support in a linear direction by the internal stresses of shear, twisting, and bending, and by the shortest path that the cross-section and rigidity of the material permit, may perhaps be utilized in mathematical form to locate the distribution of the reaction with reasonable precision, as has already been accomplished in the exact theory of plate action.
